Recognizing the potential of an e-intervention to impact psychological skills sustainably among talented young athletes, we designed two studies aimed at (1) evaluating the effectiveness of an e-intervention to support athletes in developing these skills and (2) assessing the usability of the intervention, thus providing insights into the user experience. To do so, we employed mixed methods by combining the results of qualitative and quantitative investigations. In Study 1, we conducted quantitative analyses to examine both short- and long-term impacts, offering insights into the interventions effectiveness. Study 2 subsequently focused on quantitative and qualitative data, ensuring the programs design met the practical needs of young athletes while fostering sustainable engagement.

The study sample consisted of 105 athletes (73 males, 32 females), comprising 61 skiers (33 males, 28 females), 29 male footballers, and 15 track and field athletes (11 males, 4 females), recruited from four sports clubs in Switzerland and France. Participants aged 13 to 18 ($M = 14.67$, $SD = 1.13$) trained an average of 4.10 times per week ($SD = 1.01$) and had been practicing their sport for an average of 8.65 years ($SD = 2.46$). All athletes were enrolled in training centers recognized by their regional committees and were potential candidates for national youth teams. They were randomly assigned to either an Intervention group or a Control group.

The e-intervention, structured as a four-week program, was developed using a psychotherapy process-outcome research framework (Allemand & Flückiger, 2017) and integrated the principle of implementation intention (Achtziger et al., 2008). To measure the impact on psychological skills, the French version of the Psychological Characteristics of Developing Excellence Questionnaire-Short (PCDEQ-S) by Hauw et al. (2023) was administered pre-and post-intervention. The System Usability Scale (SUS) assessed the intervention's usability.

The intervention group demonstrated a significant improvement in self-analysis skills over time [$b = 0.49$, 95% CI (0.18, 0.80), $SE = 0.16$, $p < 0.05$]. The e-intervention earned a high usability score, exceeding 80 points on the SUS, placing it in the top 10% of usability rankings. Feedback from participant interviews highlighted areas for potential improvement.

EVALUATING COGNITIVE ABILITIES AND MENTAL HEALTH IN YOUTH NATIONAL FOOTBALL PLAYERS: A FOUNDATION FOR TARGETED INTERVENTIONS

VINCZE, A.

ROMANIAN FOOTBALL FEDERATION, ELITE MIND

Introduction

Psychological interventions within youth national football teams are markedly constrained due to the restricted duration of time these teams spend in a coordinated manner. The periods for national team selection are governed by the Union of European Football Associations (UEFA). As a result, each football player may be selected for the national team during a maximum of six separate periods annually. Taking into account their commitments to their respective clubs, the impact of injuries, and the tactical decisions made by the coaches, their participation in the youth national team may be further diminished. Nevertheless, in order to identify junior football players who will eventually contribute to the senior national team, it is imperative to consider the psychological development of these athletes. The initial and crucial step in implementing an effective psychological intervention is to conduct a comprehensive psychological assessment.

METHODS: Over three successive UEFA periods (September- December 2024), we evaluated 150 male football players (mean age = 16.20, $SD = 1.41$) who are members of the national youth team (U15- U19). We assessed three primary components: ten cognitive abilities empirically associated with football performance (e.g., focused attention, visual memory), mental health status (e.g., symptoms of anxiety and depression), and subjective recovery states (e.g., football-related stress and recovery). The comprehensive evaluation for an individual player required 2 to 3 hours.

RESULTS: Individual scores for cognitive abilities, along with team-level scores, were calculated. No overall differences have been identified at the team level; however, distinct cognitive ability profiles have emerged. In the overall sample, visual perception, visual memory, and movement anticipation exhibited lower scores, while mental reaction speed and motor reaction speed demonstrated higher scores.

In terms of mental health status, 70% of the sample indicated the absence of mental health symptoms, which exceeds the incidence reported in existing literature. Sleep disorder symptoms and eating disorder symptoms were most frequently reported among the remaining 30% of players. No problematic scores were identified concerning the subjective recovery states. All athletes indicated moderate to optimal subjective recovery states.

Discussion

Subsequent to the psychological evaluation, a range of interventions aimed at enhancing psychological functioning has been proposed for the upcoming year: (1) a group of coaches tasked with creating training exercises to enhance cognitive abilities that had lower scores, (2) psychological group workshops aimed at individuals exhibiting mental health symptoms, (3) personalised therapy for athletes experiencing significant mental health challenges. Furthermore, we will address different initiatives aimed at enhancing the psychological development of youth football players.

EFFECTS OF ACUTE DIFFERENT INTENSITY CYCLING EXERCISES FOR LOWER LIMBS ON SEGMENTAL ARTERIAL STIFFNESS

NISHIWAKI, M., KUME, D., OI, N., YASUI, T., ISHIDA, T., KIKUCHI, K.

OSAKA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Many previous studies indicate that acute or regular exercises reduce Pulse Wave Velocity (PWV) as an index of arterial stiffness. The increased arterial stiffness is an independent risk factor for future cardiovascular diseases, so preventing an increase in arterial stiffness by exercise is of paramount importance. One-legged physical exercises (aerobic, resistance, and stretching) acutely reduce arterial stiffness in the exercise limb, but not in the none-exercise limb. Blood flow in brachial artery as inactive limbs generally increases in moderate-(MOD) and severe-(SEV) intensity cycling exercises for lower limbs, but not in low-intensity cycling exercise (LOW). These data thus suggest that arterial stiffness responses to exercise are mainly affected by the difference in arterial segment and blood flow associated with exercise intensity. However, the influences of different intensity cycling exercises on segmental arterial stiffness are now well unknown. Therefore, this study aimed to examine the effects of acute different intensity cycling exercises on segmental arterial stiffness.

METHODS: Nineteen young males and females (21 ± 2 years) participated in four separate trials of 40 min in random order and on different days: (1) resting and sitting on a comfortable chair, as a control (CON); (2) LOW; (3) MOD; and (4) SEV. Each exercise intensity was determined by heart rate levels; 100, 125, and 150 beats/min, respectively. Before (Pre) and immediately (Post 1) and 30 min (Post 2) after the exercises, heart-brachial PWV (hbPWV), which reflects arterial stiffness of the upper limbs from the aorta to the brachium; brachial-ankle PWV (baPWV), which reflects arterial stiffness of central (large arteries in the cardiothoracic region) and leg from the femoral to the ankle; and heart-ankle PWV (haPWV), which reflects systemic arterial stiffness, were measured as an index of segmental arterial stiffness.

RESULTS: No significant differences in baseline parameters were observed among trials. After the exercise, the reductions in hbPWV were significantly higher in both MOD ($6.1 \pm 4.5\%$) and SEV ($14.4 \pm 11.6\%$) trials than in CON ($-1.4 \pm 6.0\%$) trials, but not in LOW ($2.3 \pm 6.0\%$) trials. On the other hand, interestingly, a significantly higher reduction in baPWV in both MOD ($4.1 \pm 5.2\%$) and SEV ($4.2 \pm 4.6\%$) trials and a tendency towards higher reduction in LOW ($2.6 \pm 4.0\%$) trials as compared to CON ($-6.4 \pm 18.9\%$) trials. Finally, the reductions in haPWV were significantly higher in all LOW ($2.6 \pm 3.6\%$), MOD ($5.3 \pm 3.9\%$), and SEV ($9.1 \pm 5.5\%$) trials than in CON ($-3.7 \pm 9.8\%$) trials, but not in trials.

CONCLUSION: Our data indicate that cycling exercise of higher intensity induce reductions in relatively systemic arterial stiffness (i.e., blood flow increases in both active and inactive limbs), but lower intensity induce reductions only in the relatively limited and local arterial stiffness (i.e., blood flow increases only in active limbs).

EFFECTS OF CUSTOM-FIT COMPRESSION GARMENTS ON STROKE VOLUME AND BLOOD FLOW REGULATION

LEWIS, S., KELLY, V., PEAKE, J.

QUEENSLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Athletes commonly wear compression garments during and after exercise, in the belief that compression garments improve blood flow. However, relatively little is known about how compression garments influence central haemodynamics. This ongoing study investigates differences in resting stroke volume while wearing custom-fit compression garments (which are designed to apply more consistent pressure and gradient) compared with commercial off-the-shelf compression garments.

METHODS: Using thoracic electrical bioimpedance, stroke volume in two body orientations—standing and supine—while wearing custom-fit tights, custom-fit calf sleeves, off-the-shelf tights, off-the-shelf calf sleeves, and no compression gar-

ment was measured. Testing has been completed on eight physically active participants (5F, 3M), with an average height, weight, and age of 166.5cm, 71.6kg, 33.6 years of age for females and 171.8cm, 92.8kg, and 30.3 years of age for males respectively. 13 more participants will be tested. To explore the physiological mechanisms underlying these observations, a secondary analysis of differences in pressure exerted by custom-fit and off-the-shelf compression garments is also being conducted. A pressure sensor is placed under the compression garments at the medial and posterior aspect of the greatest circumference of the lower leg and on the midpoint between the inguinal crease and the superior-posterior border of the patella.

RESULTS: The preliminary findings indicate a notable increase in stroke volume while wearing custom-fit tights in the standing orientation compared with the other conditions. This improvement suggests enhanced cardiac efficiency via the Frank-Starling mechanism, whereby the heart achieves greater output per beat due to an increased venous return. Data also reveals that off-the-shelf calf sleeves exert the highest pressure but yield minimal stroke volume improvements. By contrast, despite covering less than half the surface area of off-the-shelf tights, custom-fit calf sleeves demonstrate a comparable stroke volume increase in the standing position.

CONCLUSION: This work will provide important new insights into how compression garments influence central haemodynamics, and the variability between custom-fit and off-the-shelf compression garments. These data will improve understanding of how compression garments work physiologically and will inform decision-making about the most effective type of compression garment for athletes.

POSTEXERCISE HYPOTENSION FOLLOWING EXHAUSTIVE AND SUBMAXIMAL EXERCISE AND ITS ASSOCIATION WITH LONG-TERM BLOOD PRESSURE REDUCTION THROUGH EXERCISE TRAINING

MAZZOLARI, R., HECKSTEDEN, A.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Hypertension is a major global health concern and a leading risk factor for cardiovascular diseases and premature mortality. While regular physical activity is an effective strategy for managing blood pressure (BP), individual responses to exercise vary, highlighting the need for reliable predictors of long-term BP adaptation. The magnitude of postexercise hypotension (PEH), the acute BP reduction following a workout, has emerged as a potential indicator of chronic BP improvements [1,2,3]. However, most studies have focused on acute BP changes in response to exhaustive exercise, and little is known about the relationship between acute BP responses to guideline-conforming training intensities and long-term benefits [2,3]. Therefore, this study aimed to investigate whether PEH following continuous submaximal exercise and maximal exercise are correlated, and whether they are associated with long-term BP reductions.

METHODS: Thirty-three untrained, healthy adults (18–45 years) participated in an 8-week aerobic training program, completing three 30-minute sessions per week at a vigorous intensity set midway between two lactate thresholds. BP was measured at rest and 10 minutes after a graded exercise test during baseline testing (MAX), following a training bout at the start of the intervention period (SUBMAX), and at rest after the 8-week training period. Changes in BP were analyzed using paired t-tests. The relationships between PEH following SUBMAX and MAX, as well as between acute and long-term BP changes, were assessed using Pearson correlation. To minimize the impact of math coupling on the strength of associations between PEH and long-term BP changes, the average of the two respective resting BP measurements was used.

RESULTS: A significant acute decrease in BP was observed following SUBMAX (systolic: -4.6 [95% CI: -6.9, -2.3] mmHg, $p < .001$; diastolic: -3.1 [-5.4, -0.8] mmHg, $p = .011$) and in systolic BP following MAX (-3.0 [-5.3, -0.7] mmHg, $p = .013$). A significant reduction in resting diastolic BP was observed after the 8-week training intervention (-2.3 [-4.9, -0.6] mmHg, $p = .015$). PEH after SUBMAX and MAX was significantly correlated (systolic: $r = 0.68$ [0.44, 0.83], $p < .001$; diastolic: $r = 0.54$ [0.24, 0.75], $p = .001$). Correlations between PEH and long-term systolic BP reduction were statistically significant for both SUBMAX (systolic: $r = 0.58$ [0.30, 0.77], $p < .001$; diastolic: $r = 0.56$ [0.27, 0.76], $p < .001$) and MAX (systolic: $r = 0.60$ [0.32, 0.78], $p < .001$; diastolic: $r = 0.45$ [0.13, 0.69], $p = .009$).

CONCLUSION: The observed correlations between PEH following SUBMAX and MAX, along with their associations with long-term BP reductions, suggest that acute BP changes may partly reflect an individuals responsiveness of resting BP to exercise.

A MODIFIED STRINGER FORMULA ENHANCES POPULATION-LEVEL CARDIAC OUTPUT ESTIMATION BUT LACKS INDIVIDUAL CLINICAL ACCURACY

TREFF, G., WUSCHEK, N., ZANARDO, E., STEINACKER, J.M., SAREBAN, M.

PARACELUS MEDICAL UNIVERSITY

INTRODUCTION: The Stringer method enables non-invasive cardiac output (Q) estimation during cardiopulmonary exercise testing. The method is based on the observation that the arteriovenous oxygen difference (avDO₂) increases as a linear function of the percentage $\dot{V}O_{2\max}$ and was described with the regression equation $\text{avDO}_2 = 0.1047 * \% \dot{V}O_{2\max} + 5.721$. Therefore, applying the Fick principle, Q can be calculated when the actual $\dot{V}O_2$ and $\% \dot{V}O_{2\max}$ are known as $Q = \dot{V}O_2 / [0.1047 * \% \dot{V}O_{2\max} + 5.721]$.

Since the Stringer method was calculated in 5 men only, we aimed to validate the Stringer formula in a larger population with a wider range of $\dot{V}O_{2\max}$. We also aimed to optimise it by including the magnitude of $\dot{V}O_{2\max}/\text{kg}$ as a variable potentially influencing the avDO_2 regression proposed by Stringer et al. (1997).

METHODS: Sixteen healthy male participants (age 26 ± 4 yr, body mass 78.1 ± 6.8 kg, $\dot{V}O_{2\max}$ 56 ± 9.8 mL/min/kg) performed an incremental CPET, during which $\dot{Q}$ was measured using the Innocor inert gas rebreathing technique (QRB) at seven exercise intensities ranging 40-100% of $\dot{V}O_{2\max}$. At the same time, $\dot{Q}$ was estimated using the Stringer formula (QST). To modify the Stringer formula, we then calculated (i) avDO_2 from $\dot{V}O_2$ and QRB measured at each intensity, (ii) used these results to calculate individual linear regression equations ($\text{avDO}_2 = a \cdot \dot{V}O_{2\max} + b$), (iii) then calculated the regressions of these individual results for a and b , respectively, vs. $\dot{V}O_{2\max}/\text{kg}$, and (iv) finally used these to calculate $\dot{Q}$ based on the thereby modified Stringer formula (QSTmod). Intermethod agreement was assessed by Bland-Altman analyses.

RESULTS: The measured data were highly plausible with QRB = $4.8 \cdot \dot{V}O_2 + 5.6$ L/min. For QRB vs. QST, Bland-Altman analysis indicated a mean difference of -2.9 ± 3.2 L/min with limits of agreement ranging -9.1 to 3.4 L/min.

The modified Stringer formula was calculated as follows:

$$\text{QSTmod} = \dot{V}O_2 / [(-0.0019 * (\dot{V}O_{2\max}/\text{kg}) + 0.1966) * \% \dot{V}O_{2\max} + (0.1387 * (\dot{V}O_{2\max}/\text{kg}) + 1.068)].$$

Here, the mean difference to QRB was 0.3 ± 3.0 L/min with limits of agreement ranging -5.5 to 6.2 L/min.

CONCLUSION: When considering the entire intensity range investigated in this study, which included men with varying fitness levels, the original Stringer formula does not provide a consistently accurate estimate of $\dot{Q}$. Our modified formula considerably improves accuracy at the population level, however, its wide limits of agreement indicate that it lacks the necessary precision for individual clinical application.

SEVERELY REDUCED PEAK $\dot{V}O_2$ IN YOUNG MALE SURVIVORS OF PROLONGED VENO-VENOUS ECMO AFTER BLAST INJURY MAY BE RELATED TO ABNORMAL MUSCLE OXYGEN EXTRACTION

REUVENY, R., SHAFRAN, I., EPSTEIN, Y., LEVY, L., SEGEL, M.J.
UNIVERSITY OF HAIFA

INTRODUCTION: Veno-venous (V-V) Extra-Corporeal Membrane Oxygenation (ECMO) is used as rescue therapy for severe respiratory failure. Little is known about exercise physiology of ECMO survivors. This study assesses the physiological response during cardio-pulmonary exercise tests (CPET), including muscle oxygenation pattern, in young previously healthy men who had survived prolonged ECMO treatment following blast injury.

METHODS: Three male patients (age 21-25 years old) with refractory respiratory failure after blast injury were treated with veno-venous (V-V) ECMO for 6-12 weeks; two eventually received bilateral lung transplant. All had normal echocardiograms (Left ventricular ejection fraction = 60%). At 6-10 months post-ECMO they performed lung function tests (spirometry, volumes by plethysmography and diffusion capacity for carbon monoxide (DLCO)) and graded symptom-limited cardio-pulmonary exercise tests (CPET) on a cycle ergometer. Near-infrared spectroscopy (NIRS) was used to measure the change in tissue hemoglobin saturation index (TSI) of the vastus lateralis muscle from rest to peak exercise.

RESULTS: Spirometry and lung volumes were within normal limits. DLCO was ranged from normal to mildly reduced (64-103% predicted). Peak Respiratory exchange ratios (1.2-1.5) indicate minimal cardiovascular reserve. Peak oxygen consumption ($\dot{V}O_2$) was severely reduced (38-52% predicted). $\dot{V}O_2$ at the gas exchange threshold (GET) was low (25-31% predicted peak $\dot{V}O_2$), as was peak $\dot{V}O_2$:heart-rate (HR) (41-60% predicted) and $\Delta(\dot{V}O_2):\Delta(\text{work})$ (6.1-6.8 mL/min/W). $\dot{V}O_2$:HR plateaued above the GET in all patients may suggest impaired muscle oxygen utilization. Exercise gas exchange was normal and there was no evidence of ventilatory limitation at peak exercise. All patients exhibited an attenuated decline of TSI from rest to peak exercise (8-12% decrease) suggesting impaired muscle oxygen extraction during exercise.

CONCLUSION: This case series study of three young male survivors of prolonged ECMO treatment for severe respiratory failure demonstrates a markedly reduced aerobic exercise capacity 6-10 months post-ECMO, potentially due to impaired muscle oxygenation extraction.

THE INFLUENCE OF AN EXPERIMENTALLY INCREASED ARTERIAL BLOOD PRESSURE ON LEFT VENTRICULAR FUNCTION DURING EXERCISE

PERKINS, D., SIMPSON, L., MUGELE, H., CORNWELL, W., LAWLEY, J.
UNIVERSITY OF INNSBRUCK

INTRODUCTION: Dynamic exercise elevates arterial blood pressure, increasing cardiac load and enhancing global left ventricular (LV) function to maintain cardiac output. Previous research shows that inducing hypertension via forearm post-exercise circulatory occlusion (PECO) reduces LV mechanics at rest. However, how the healthy human heart adapts to elevated blood pressure during dynamic exercise remains unknown.

Purpose: To determine the effect of an acute increase in blood pressure on LV function during dynamic exercise.

METHODS: Blood pressure was elevated (without a concomitant increase in heart rate) by inflating a cuff around the forearm after 2-minutes of 30% maximal isometric handgrip (i.e. PECO). Dynamic exercise (DEX) was performed on a semi-recumbent (30°) stepping device at 30% peak power output. Blood pressure and LV function were assessed using a fi-

nometer and transthoracic echocardiography, respectively, at rest and following a randomised exposure to PECO only, DEX only and DEX with PECO (DEX+PECO).

RESULTS: Systolic blood pressure increased from rest during all three conditions ($p < 0.001$), while HR only increased during DEX ($p < 0.001$) and DEX+PECO ($p < 0.001$), but not PECO ($p = 0.946$). Compared with DEX, DEX+PECO resulted in a statistical increase in systolic blood pressure ($\Delta: 15 \pm 8$ mmHg, $p = 0.039$), with no difference in heart rate ($p = 0.509$).

Cardiac output increased from rest during DEX ($p < 0.001$) and DEX+PECO ($p < 0.001$), with no difference between the two conditions ($p = 0.776$). Increases in cardiac output were primarily due to the aforementioned increases in heart rate, as stroke volume did not differ between conditions (Rest vs. PECO: $p = 0.812$; Rest vs. DEX: $p = 0.573$; Rest vs. DEX+PECO: $p = 0.930$; DEX vs. DEX+PECO: $p = 0.488$). Ejection fraction was also similar across conditions (Rest vs. PECO: $p = 0.333$; Rest vs. DEX: $p = 0.964$; Rest vs. DEX+PECO: $p = 0.911$; DEX vs. DEX+PECO: $p = 0.894$).

Despite no differences in global LV function between conditions, apical rotation was reduced during DEX+PECO compared with DEX ($\Delta: -3.25 \pm 3.86$ degrees, $p = 0.032$), alongside a reduction in apical systolic rotational velocity ($p = 0.043$). Coinciding with these reductions in LV mechanics at the apex, a significant elevation in basal radial strain rate was observed in DEX+PECO compared with DEX ($\Delta: 0.25 \pm 0.39$ 1/s, $p = 0.048$).

CONCLUSION: Whilst an elevated blood pressure during dynamic exercise does not influence global LV function, decreased rotational mechanics at the apex were observed. The basal region of the LV appears to compensate for these mechanical reductions in the healthy heart, to preserve stroke volume during an elevation in left ventricular afterload.

THE MECHANISM OF INDIVIDUAL VARIATIONS IN BLOOD PRESSURE RESPONSE TO HANDGRIP EXERCISE

OGOH, S., TAKEDA, R., KUNIMATSU, N., TSUKAMOTO, H., FEELEY, M., WATANABE, K., MIYAMOTO, T.

TOYO UNIVERSITY

INTRODUCTION: Even among healthy individuals, arterial blood pressure (ABP) responses to exercise vary significantly. Notably, normotensive individuals who exhibit exaggerated ABP responses during exercise may have an increased risk of developing hypertension later in life. However, the mechanisms underlying this variability in blood pressure responses among healthy young individuals remain unclear.

METHODS: Even among healthy individuals, arterial blood pressure (ABP) responses to exercise vary significantly. Notably, normotensive individuals who exhibit exaggerated ABP responses during exercise may have an increased risk of developing hypertension later in life. However, the mechanisms underlying this variability in blood pressure responses among healthy young individuals remain unclear.

METHODS: To investigate these mechanisms, 29 participants performed isometric handgrip exercises at 30% of their maximum voluntary contraction, followed by post-exercise muscle ischemia (PEMI) to evaluate metaboreflex activity. ABP responses were assessed, along with peripheral cardiovascular parameters associated with hypertension, including muscle oxidative capacity (mVO_2) and arterial stiffness (carotid-femoral pulse-wave velocity, cfPWV).

RESULTS: Variability in systolic blood pressure (SBP) responses to exercise was not significantly associated with cfPWV ($P = 0.745$, $r = -0.063$) or mVO_2 ($P = 0.093$, $r = 0.317$).

CONCLUSION: Previous studies have indicated that exaggerated ABP responses during exercise are associated with higher arterial stiffness and lower muscle oxidative capacity in older adults and patients with hypertension. In contrast, the findings of the present study suggest that the mechanisms underlying individual differences in ABP responses to exercise in healthy young individuals differ from those driving exaggerated ABP responses in older adults and patients with cardiovascular diseases, such as hypertension.

COMPARING MARKERS OF LEFT ATRIAL REMODELLING IN MALE AND FEMALE ELITE ENDURANCE AND SPRINT CYCLISTS

GALLOWAY, C., ROBINSON, S., FEKADU, J., HOWELL, L., MAXWELL, J., SHAVE, R., OXBOROUGH, D.

UNIVERSITY OF BRITISH COLUMBIA OKANAGAN

INTRODUCTION: The hearts of elite cyclists undergo regular hemodynamic loading which may result in structural, functional and electrical remodelling¹. Divergent patterns of remodelling have been proposed to occur in the left ventricle in response to different types of exercise stimulus², yet the left atrium (LA), a far thinner walled chamber, has received little scientific attention especially in non-male, non-endurance athletes. Accordingly, the purpose of this study was to compare LA structural, functional and electrical parameters in endurance and sprint cyclists and examine potential sex differences. We hypothesized that 1) endurance cyclists would exhibit the greatest degree of LA remodelling 2) endurance females would have greater LA functional remodelling, and 3) male endurance cyclists would have greater LA electrical remodelling.

METHODS: Using a cross-sectional design we compared electrocardiographic (p wave duration) and absolute and scaled echocardiographic measures (LA volumes, strain and electromechanical delay) between elite endurance and sprint cyclists from the Great Britain cycling team. Using independent t-tests (with Bonferroni correction), we first compared female sprint ($n=18$, mean $\pm$ SD: 21 ± 3 yrs) and female endurance ($n=41$, 22 ± 5 yrs) cyclists, and then male sprint ($n=33$, 22 ± 5 yrs) with male endurance ($n=45$, 21 ± 6 yrs) cyclists. We then tested for sex-based differences in both sprint and endurance disciplines.

RESULTS: Both male and female endurance cyclists had larger absolute (mean difference: 11.43, $P=0.001$; 9.73, $P=0.008$) and indexed (mean difference: 7.47, $P<0.001$; 6.92, $P=0.001$) LA size vs. their sex-matched sprint counterparts. Male endurance cyclists also had larger reservoir volumes (mean difference: 6.24, $P=0.011$), slower LA systolic and late diastolic strain rates (mean difference: -0.24 & 0.33; both $P<0.001$) than male sprint cyclists. After performing a sex-based comparison, we found that male endurance cyclists had greater absolute LA size (mean difference: 9.99, $P=0.002$) and lower LA peak strain (mean difference -3.26, $P=0.012$) than female endurance cyclists. Lastly, male sprinters had longer atrial activation times than female sprinters (mean difference: 16.6, $P=0.005$).

CONCLUSION: These data suggest greater LA remodelling in endurance vs. sprint cyclists. Male and female endurance cyclists experience similar structural remodelling when indexed to body size with differing functional adaptations. Further work is needed to understand the mechanisms responsible for the differential adaptation observed, and to explore the physiologic and pathologic significance.

SEX DIFFERENCES IN THE MAGNITUDE OF THE HEMODYNAMIC RESPONSES DURING MAXIMAL STATIC APNEA WITH FACE IMMERSION IN NON-DIVERS

MAKRIS, A., CHEROUVEIM, E., GELADAS, N., KOSKOLOU, M.

NATIONAL AND KAPODESTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: The simple act of breath holding induces vagally-mediated bradycardia and sympathetically-mediated peripheral vasoconstriction (the so-called dive response) which serve as a protective mechanism against asphyxia. Surprisingly, studies investigating sex differences on the dive response have shown inconsistent findings (1). The purpose of the present study was to examine sex differences in the dive response during maximal static apnea with cold-water face immersion.

METHODS: Ten females (aged 24.8 ± 3.2 yrs) and 10 males (aged 25 ± 5.5 yrs) unaccustomed to apnea and matched for breath hold time ($P=0.96$) participated in this study. After obtaining body measurements the participants performed five repeated maximal apneas (at 80% of vital capacity) with the face immersed in cold water, separated by two minutes of normal breathing. Apnea duration and the hemodynamic (HD) parameters: heart rate (HR), stroke volume (SV), cardiac output (Q), systolic pressure (SP), diastolic pressure (DP), and mean arterial pressure (MAP) were measured throughout the experimental protocol. Mean HD values in the 90-30s period prior to the first apneic bout was considered as baseline. The mean HD values during the longest apneic bout, excluding the first 30s, was considered as the HD response values to apnea. T-tests for independent samples were performed to detect differences in means with α set at 0.05.

RESULTS: Males showed higher baseline values compared to females in SP, MAP, DP, SV and Q ($P<0.05$), whereas baseline HR did not differ between sexes. During maximal apnea, males exhibited higher SP, MAP and DP values compared to females ($P<0.05$). However, apneic HR, SV and Q did not differ between sexes. When comparing the magnitude of change (Δ) in the HD parameters between sexes, larger decreases in SV and Q from baseline were observed in males compared to females ($P<0.05$), whereas the magnitude of change in SP, MAP, DP and HR did not differ between sexes.

CONCLUSION: The present study showed that, in an untrained state, males exhibited higher blood pressure and larger decrease in SV and Q than females during maximal apnea of the same duration. These differences could be attributed to the lower vasoconstriction capacity of females (2).

FEEDBACK FROM GROUP III AND IV SKELETAL MUSCLE AFFERENTS SLOWS HEART RATE ACCELERATION DURING THE TRANSITION FROM REST TO LOW-INTENSITY EXERCISE

BUCKLEY, J., BURGESS, S., SIDHU, S.K., CHALMERS, S., AMANN, M.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: The maximal rate of heart rate (HR) increase (rHRI), a marker of HR acceleration during the transition from rest to standardised light exercise is linearly related to changes in exercise performance during differing states of training and fatigue (1,2,3,4). It has been hypothesised that rHRI might be linearly related to changes in exercise performance due to feedback from group III/IV skeletal muscle afferents (1). This study evaluated whether feedback from group III/IV skeletal muscle afferents modulates rHRI.

METHODS: Using a randomised, counter-balanced, cross-over design HR data from eight male recreationally active participants (24 ± 1 years) were collected as R-R intervals during the transition from rest to three minutes of leg cycling at 100

W. Data were collected under control (CON) conditions and following lumbar intrathecal fentanyl (FENT) to impair feedback from group III/IV skeletal muscle afferents of the leg. rHRI was determined as the first-derivative maximum of a logistic curve fit of the HR data.

RESULTS: Pre-exercise HR was not different between CON and FENT (CON 91.7 ± 16.7 bpm, FENT 99.8 ± 15.5 bpm, $p=0.25$). HR increased more with exercise during CON compared with FENT ($B = 12.2$, 95%CI 6.5 to 17.9, $p<0.001$) but rHRI was faster during FENT compared with CON ($B = 1.52$, 95% CI = 0.24 to 2.80, $p=0.02$).

CONCLUSION: Feedback from group III/IV skeletal muscle afferents increase HR during standardised light exercise but inhibit rHRI at the onset of exercise.

ACE2 EXPRESSION AND RENIN-ANGIOTENSIN SYSTEM ADAPTATIONS IN SKELETAL MUSCLE FOLLOWING SPRINT INTERVAL TRAINING WITH AND WITHOUT POST-SPRINT ISCHAEMIA

GARCIA, G., GARCIA-GONZALEZ, E.1, GALLEGO-SELLES, A.1, GALVAN-ALVAREZ, V.1, MARTINEZ-CANTON, M.1, DE NIGRIS, E.1, GIL-RODRIGUEZ, S.1, SANTANA, A.2, MORALES-ALAMO, D.1, FERNANDEZ-GARCÍA, B.3, BOUSHEL, R.4, HALLEN, J.5, MARTIN-RINCON, M.1, CALBET, J.A.L.1,4,5

1 IUIBS AND ULPGC, SPAIN; 2 CLIN. GENETICS UNIT CHUIMI, LPA, SPAIN; 3 UNIV. OVIEDO, SPAIN; 4 SCHOOL OF KINESIOLOGY, UBC, CANADA; 5 NIH, NORWAY

INTRODUCTION: Angiotensin-converting enzyme 2 (ACE2) regulates the renin-angiotensin system (RAS) by converting angiotensin II into angiotensin (1-7), with vasodilatory, antioxidative, and anti-inflammatory effects. In skeletal muscle, ACE2 is necessary for adaptation to exercise. TMPRSS2 cleaves ACE2, affecting shedding, and viral entry in SARS-CoV-2 infection, being involved in muscle post-viral disorders, oxidative stress (OS), and inflammation. Animal models suggest exercise benefits RAS balance, but human data are lacking. Given the role of OS in ACE2 and TMPRSS2 regulation, we investigated whether Sprint Interval Training (SIT) either alone or combined with post-exercise ischaemia—an intervention transiently elevating OS upon reperfusion—drives molecular adaptations in RAS components in human skeletal muscle. We hypothesised that brief ischaemia during SIT recovery would boost ACE2 and TMPRSS2 expression levels through OS-related mechanisms.

METHODS: Ten volunteers (7M/3W) completed a SIT program (4-6 × 30s sprints, 4min rest) in six sessions over two weeks. After each sprint, occlusion (300mmHg, 30-50s) was applied to one leg, followed by rest. PRE and POST training, participants did an incremental exercise to exhaustion (IE), a 90min rest, and six supramaximal exercise bouts (SPE, 120%VO₂max) with 20s bilateral ischaemia applied between bouts. V. lateralis biopsies were taken at baseline (BS), 90min post-IE, and immediately post-SPE unilaterally at PRE and bilaterally at POST (SIT-IS vs. SIT-CT leg) for WB analysis. Stats: ANOVA, t-test, Pearson's correlation.

RESULTS: Basal ACE2 and TMPRSS2 increased by ~145% with SIT-IS but did not change with SIT-CT ($p<0.05$). Basal ACE1 rose by 66% with SIT-IS and dropped 24% with SIT-CT ($p<0.001$). AT2R levels decreased by 19% with SIT-IS (all timepoints). Acute high-intensity exercise increased ACE2 (61%) and TMPRSS2 (88%) after IE, but not further with SPE ($p>0.05$ vs. BS). SIT-IS blunted these effects, unlike SIT-CT ($p<0.05$). ACE1 increased acutely only after SIT-CT (53%) and similarly after IE and SPE ($p<0.05$), with no AT2R changes. ACE2 and TMPRSS2 correlated across conditions ($R=.74$) and with pS359 p47 NOX2 ($R=.59/.72$), Nrf2/Keap1 ($R=.74/.73$), and Catalase ($R=.73/.57$), all $p<0.001$. ACE1 correlated with ACE2 ($R=.39$, $p<0.001$) and TMPRSS2 ($R=.21$, $p=.04$). AT2R negatively correlated with ACE2 ($R=-.28$, $p=.008$).

CONCLUSION: While SIT alone did not upregulate ACE2 or TMPRSS2 in skeletal muscle, SIT combined with post-exercise ischaemia-reperfusion potentiated their expression, likely via an OS-related mechanism, as indicated by Nrf2/Keap1 activation. The blunted post-exercise increases in ACE2 and TMPRSS2 after training with post-exercise ischaemia suggest increased antioxidant capacity after training with ischaemia. The associations between ACE2, TMPRSS2, and OS signalling support this interpretation.

INFLUENCE OF ACTN-3 C.1729C>T (RS1815739) POLYMORPHISM ON MATCH-PLAY MAXIMAL RUNNING SPEED IN ELITE FOOTBALL PLAYERS: A PRELIMINARY REPORT.

MASSIDDA, M., FLORE, L., ALLEGRA, G., BALDUS, M., SECCI, J., CUGIA, P., PIRAS, F., SCORCU, M., KIKUCHI, N., CIESZCZYK, P., CALÒ, C.M., TOCCO, F.

UNIVERSITY OF CAGLIARI

INTRODUCTION: A frequent genetic variant in the alpha actinin-3 gene (ACTN-3, c.1729C>T (rs1815739)) has been linked to the progression of soccer career [2], the prevalence and severity of muscle injuries [3], and elite athletic performance [1]. While the TT genotype appears to have a detrimental impact on football career advancement and the likelihood of developing muscle injuries, the C allele and the CC genotype of the ACTN-3 polymorphism appear to favour the capacity to produce strong and forceful muscle contractions, which are necessary during sprinting performance. A crucial component of contemporary football is high-intensity running, which can distinguish between players at the highest level of competition and those at a lower level [4]. We hypothesized that football players harbouring the C allele would have a higher maximal running speed (MRS) during matches than those footballers with the TT genotype.

METHODS: MRS was collected, using a Global Position System (GPS) at high sampling frequencies (50 Hz), from 45 elite football players of a same professional football team during 26 official matches for a total of 707 matches observations. Genomic DNA was extracted using a buccal swab, and the ACTN-3 genotype was performed using a RFLP PCR method.

RESULTS: The main finding was that CC players showed significantly higher MRS than TT players (CC=33.1±1.3 km•h⁻¹ vs TT=31.5±1.9 km•h⁻¹, p=0.041). Moreover, the players harbouring a copy of the C allele showed a trend toward higher MRS than players carriers of the TT genotype (CC+CT= 32.9±1.5 km•h⁻¹ vs TT=31.5±1.9 km•h⁻¹, p=0.06). The MRS (36.4 km•h⁻¹) was registered for a player carrier of CC genotype, while the lower running speed (29.8 km•h⁻¹) was reordered for a player carrier of TT genotype.

CONCLUSION: For the first time, we discovered an association between elite football players match-play maximal sprinting speed and the ACTN-3 polymorphism. If our findings will be confirmed in more extensive studies, they may be applied in the future to modify training regimens in order to improve football performance.

THE AGTR2 RS11091046 (A>C) POLYMORPHISM AND CLIMBING LEVEL IN POLISH SPORT CLIMBERS.

GINSZT, A., STYK, W., GINSZT, M., JARZYNSKI, A., ZIELINSKI, G., ZMORZYNSKI, S.

MEDICAL UNIVERSITY OF LUBLIN

INTRODUCTION: The associations between the AGTR2 genotypes and athletic performance have been proven in various sports disciplines. However, there is a lack of studies investigating the AGTR2 rs11091046 polymorphism in sport climbers. This study aimed to examine whether the rs11091046 polymorphism in the AGTR2 gene is associated with athletic climbing status in sport climbers from Poland.

METHODS: AGTR2 genotypes of 142 sport climbers (55 female, 87 male athletes) were compared with 89 sedentary controls. Genotyping was performed using TaqMan SNP genotyping assays on Thermo Fisher Scientific (Waltham, MA, USA). Deviation of genotype frequencies in sport climbers and controls from Hardy-Weinberg equilibrium (HWE) was assessed using a Chi-squared test with Yates's correction. For a 95% confidence interval (CI), we assumed p=0.05 and $\chi^2=3.84$; therefore, if the $\chi^2 \leq 3.84$ and the corresponding p≥0.05, the population is in HWE. Both male and female athletes were classified into four groups: "Higher elite", "Elite", "Advanced", and "Intermediate" based on the self-reported most difficult route ever climbed converted to the International Rock Climbing Research Association (IRCRA) Reporting Scale (IRS) based on IRCRA standards for the International Rock Climbing Association.

RESULTS: Mean IRCRA scores were 19.48 (SD = 3.92) for individuals with the AA genotype, 19.66 (SD = 3.58) for AC, and 17.07 (SD = 3.41) for CC. The chi-square test showed a significant relationship between the AGTR2 genotype and the IRCRA level in the group of male sport climbers ($\chi^2 = 14.85$, df = 6, p = 0.02) in comparison to female climbers (p=0.96). Most male climbers with AA and AC genotypes were in the "Advanced" category, while in the CC group, most athletes were in the "Intermediate" category. Notably, no results were recorded among athletes with the CC genotype in the "Elite" and "Higher Elite" categories.

CONCLUSION: The results suggest that the impact of the AGTR2 (rs11091046) polymorphism on IRCRA results may be gender dependent. The male sport climbers with the CC genotype obtain lower IRCRA scores than athletes with the AC genotype, which may indicate the potential impact of this polymorphism on the climbing status. The AGTR2 gene is located on the X chromosome, which may explain the difference in results - in men, the effect of a single allele may be more pronounced than in women, in whom a second copy of the gene may compensate for the possible negative impact of the risk allele. Future studies should include a larger sample size of women to determine further whether the effect of this polymorphism on the IRCRA score is indeed specific to men.

TRANSCRIPTOMIC ANALYSIS OF RAT SKELETAL MUSCLE AFTER ELECTRICAL STIMULATION WITH DIFFERENT FREQUENCIES

HOSHINO, D., SATO, S., KUSANO, T., SOTANI, Y., KANO, R., KANO, Y.

THE UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: Comprehensive RNA expression levels (transcriptome) can be measured using RNA sequencing (RNA-seq). It is reported that skeletal muscle transcriptome using RNA-seq after exercise differed between resistance and endurance exercises. However, the effects of differences in frequency, which determines the muscle tension of electrical stimulation (ES)-induced contraction, on transcriptome have not been elucidated. Therefore, this study aimed to examine transcriptome after different muscle contractions with 1, 10, 20, 60, and 100 Hz ES.

METHODS: Under isoflurane anesthesia, ES-induced muscle contractions as a resistance exercise model (5 sets $\times$ 10 times of 3 s of 0, 1, 10, 20, 60, 100 Hz ES) were applied to the right tibialis anterior (TA) muscle of Wistar male rats ($n=3$) using surface electrodes. At 3 hours after the muscle contractions, TA muscle was harvested and total RNA was extracted for RNA-seq. Differentially expressed genes (DEGs) were identified with a fold-change (FC) >2 or <0.5 to 0Hz-muscle contraction samples and false discovery rate <0.05 (one-way analysis of variance). Gene ontology analysis and transcription factor estimation were performed for distinctive gene groups using Metascape and Landscape In Silico deletion Analysis (LISA), respectively.

RESULTS: Maximum muscle tensions (relative to 100Hz) with 1, 10, 20, and 60 Hz ES were $29.7 \pm 0.91\%$, $29.1 \pm 1.44\%$, $68.6 \pm 6.91\%$ and $89.3 \pm 2.95\%$, respectively. There were 229 and 43 upregulated DEGs (UP_DEGs) and downregulated DEGs (DOWN_DEGs), respectively. In UP_DEGs, we identified Hz-specific upregulated genes whose expression increased in a low-frequency (1 and 10 Hz) specific manner and Hz-dependent upregulated genes whose expression increased in a Hz-dependent manner. Genes related to "skeletal muscle cell differentiation" and "response to mechanical stimulus" were significantly enriched only for Hz-dependent genes. We calculated peak50, which was the Hz to reach 50% of the peak of FC, as an index of the Hz sensitivity. According to the distribution of Peak50, we classified the Hz-dependent genes into two groups (high-sensitivity group: Peak50 < 35 Hz, low-sensitivity group: Peak50 ≥ 35 Hz). For only the low-sensitive genes that need higher Hz ES to increase their expression level, genes related to "skeletal muscle cell differentiation" were enriched. Estimated transcription factors were different between low- and high-sensitive gene groups.

CONCLUSION: Low Hz-specific genes and Hz-dependent genes were identified in UP_DEGs. Also, low- and high-sensitive genes existed in the Hz-dependent gene group. Genes related to resistance training adaptation were especially enriched for low-sensitive genes, which need higher Hz ES to increase their expression levels. Estimated transcription factors were also different between low- and high-sensitive gene groups. These results suggest that different muscle contraction-induced selective muscle adaptation is mediated by genes and transcription factors in response to different frequencies.

CHARACTERISING MARATHON-INDUCED METABOLIC PERTURBATIONS AND SUBSEQUENT RECOVERY THEREOF USING UNTARGETED ¹H-NMR METABOLOMICS

LOOTS, D., STANDER, Z., MASON, S., KEANE, K., HOWATSON, G., CLIFFORD, T., STEVENSON, E., BESTER, R.

NORTH-WEST UNIVERSITY

INTRODUCTION: Although physical activity is a health-promoting, popular global pastime, regular participation in extreme endurance events results in numerous adverse metabolic, immunologic and physiological perturbations, that may diminish athletic performance and adversely affect the overall health status of an athlete, especially in the absence of sufficient recovery. A comprehensive understanding of the metabolic changes occurring during and following extreme endurance events can inform the development of improved training and recovery strategies.

METHODS: This investigation employed an untargeted proton nuclear magnetic resonance (¹H-NMR) metabolomics approach to characterise the changing serum metabolite profiles of 15 athletes at 4 time points (pre-, immediately post-, 24 h post-, and 48 h post-marathon), to better understand the impact of a marathon on the metabolome and the physiology of an athlete.

RESULTS: The results show 26 metabolites to significantly fluctuate, indicating dramatic changes to ATP and glycogen use and synthesis, fat catabolism, aerobic and anaerobic glycolysis, ketogenesis, amino acid catabolism (in particular the BCAAs) and the TCA cycle, in response to the high energy demands of a marathon. Metabolites associated with muscle and kidney damage, changes to the gut microbiota and the impact of energy drink consumption were also observed, in addition to metabolite markers associated with delayed-onset muscle soreness during the recovery period. Although a complete recovery of those metabolites associated with the energy-producing pathways and fuel substrate stores occurred within a 48-hour recovery period, several other metabolites remained perturbed beyond this period (phenylalanine, tyrosine, BCAAs and proline), indicating incomplete recovery of other physiological processes.

CONCLUSION: This study provides a comprehensive description of the marathon-induced metabolic changes and post marathon recovery and additionally suggests pre- and post-marathon nutrition and supplementation strategies (involving fats/ketones, the type of carbohydrate, phenylalanine, tyrosine, BCAAs and proline) for improving the health and performance of athletes who participate in such extreme endurance events. Furthermore, the "late-stage recovery" metabolite markers identified may also later be investigated for personalized monitoring of athletic health/recovery/performance.

ASSOCIATION OF METABOLOMIC PROFILES AND MIR-126 IN RESPONSE TO ENDURANCE TRAINING IN HYPERTENSIVE POSTMENOPAUSAL WOMEN

CHACON-MIKAHIL, M., FERREIRA, M.L.V., AMARAL, M.A.B., FIORINDO, G.M., PANZARIN, C., VASCONCELOS, L., TORSONI, A., CAVAGLIERI, C.R., CASTRO, A.

UNICAMP - UNIVERSIDADE ESTADUAL DE CAMPINAS AND CNPEM-BRAZIL

INTRODUCTION: Endurance training (ET) effectively promotes reductions in blood pressure (BP) levels. However, the factors and molecular mechanisms of reduced BP remain unknown, and investigating them can help design more efficient training strategies. We investigated the association of baseline circulating miRNAs, serum metabolomic profiles, and metabolic pathways with BP changes after 12 weeks of ET.

METHODS: Thirty-six hypertensive postmenopausal women (57.7 ± 6.4 years old) were randomly allocated into the ET ($n=16$, cycling at moderate intensity 3 times a week) and control - CO ($n=6$, non-exercise) groups. BP and blood samples were collected at baseline and 12 weeks post-intervention. Samples were analysed: by Proton Nuclear Magnetic Resonance spectroscopy-based metabolomics and, miRNA was analysed by RT-qPCR. We checked the normality and homoscedasticity of the data. T-test was performed on the samples characteristic variables and a Pearson correlation test was carried out between the metabolites, the Mir-126 and the Δ Systolic BP (Δ SBP) and Δ Diastolic BP (Δ DBP). Finally, a pathway enrichment analysis along with the variables correlated with Δ SBP and Δ DBP was realized.

RESULTS: No significant differences were found in the variables characterising the sample. Of the 58 metabolites acquired, 5 were associated with Δ SBP: acetate, glycolate, proline, threonine and xanthine ($0.43 < r < 0.64$; $p < 0.02$). And 8 metabolites were associated with Δ SBP: 2-hydroxyisovalerate, ascorbate, citrate, histidine, inosine, lysine, methanol, myo-inositol ($-0.45 > r > -0.67$; $p < 0.03$). The most enriched pathways for Δ SPB were: glyoxylate and dicarboxylate metabolism, glycolysis and gluconeogenesis and pyruvate metabolism, and for Δ DBP was: methylhistidine and biotin metabolism. The mir-126 was not correlated with Δ SBP and Δ DBP.

CONCLUSION: These results suggest the changes in DBP were associated with pathways and metabolites related to nitric oxide, while the changes in SBP were associated with the regulation of oxidative metabolism. Investigation that targets these metabolic pathways, may improve the specific exercise load control (intensity, duration, and frequency) to reduce blood pressure.

TRANSCRIPTOMIC RESPONSES TO NINE DAYS OF HEAT ACCLIMATION IN EQUINE SKELETAL MUSCLE

KITAOKA, Y., EBISUDA, Y., SUGIYAMA, F., TAKAHASHI, Y., YOSHIDA, T., MUKAI, K.

KANAGAWA UNIVERSITY

INTRODUCTION: Due to their size, horses have a relatively low body surface area to weight ratio and lose heat generated during exercise more slowly than other mammals, resulting in a marked increase in body temperature and a reduction in exercise performance in the heat. Daily heat exposure induces beneficial physiological adaptations, but the effects of heat acclimation on the skeletal muscle transcriptome remain unclear. Therefore, the aim of this study was to investigate the time course of transcriptomic responses in equine skeletal muscle following repeated exercise sessions in a hot environment.

METHODS: Three trained Thoroughbred horses were assigned to 9 consecutive days of heat acclimation involving daily interval exercise in hot conditions (Wet Bulb Globe Temperature [WBGT] 29.5°C). The training protocol consisted of alternating high- (100% VO_2max) or moderate- (70% VO_2max) intensity interval training (3 x 1 min, 2 min recovery) each day. Muscle samples were obtained from the middle gluteal muscle before and 4 hours after the 1st and 9th exercise bout. Differential gene expression was identified using DESeq2 (false discovery rate cutoff: 0.05, minimal fold change: 1.5).

RESULTS: The peak plasma lactate concentration during exercise was lower in the 9th exercise bout compared with the 1st exercise bout. RNA-seq identified 365 and 60 genes that were differentially expressed in response to the exercise in the 1st and 9th bouts, respectively. Of these genes, 49 genes, including well-known exercise responsive genes such as PPARGC1A and NR4A3, were altered in both the 1st and 9th exercise bouts. Gene set enrichment analyses, based on Gene Ontology biological process terms, showed that genes associated with the response to extracellular stimulus and nutrient levels were upregulated after both exercise bouts; genes related to protein folding were upregulated following the 1st exercise bout, whereas genes associated with gluconeogenesis were highly expressed following the 9th exercise bout.

CONCLUSION: Our results suggest that nine days of heat acclimation attenuated exercise-induced transient transcriptomic responses in equine skeletal muscle. This attenuation may be due to the changes of gene expressions at the basal level. These findings uncover the temporal sequence of molecular mechanisms underlying heat acclimation.

FUNCTIONAL FITNESS, COGNITION, URINARY METABOLOME, AND GUT MICROBIOTA IN COMMUNITY-DWELLING ELDERLY WITH CHRONIC DISEASES IN TAIWAN

CHIU, Y., LIAO, J.C., HUANG, K.C.

SOOCHOW UNIVERSITY

INTRODUCTION: Taiwan's aging population faces a high socioeconomic burden due to chronic diseases like hypertension and dementia, which impact body composition, cognition, life satisfaction, metabolism, and gut microbiota. This study explores strategies to improve health outcomes for older adults with different chronic conditions.

METHODS: A total of 129 elderly participants were included: 16 with dementia, 27 with early cognitive impairment, 28 with hypertension, and 58 healthy controls. Participants provided medical history, demographics, and anthropometric data and completed fitness, cognitive, depression, and quality-of-life assessments. Cognitive function was evaluated using the 10-item Short Portable Mental Status Questionnaire (SPMSQ), depression with the 15-item Geriatric Depression Scale (GDS-15), and quality of life with a QoL questionnaire. Urinary metabolomics and oxidative stress markers (8-OHdG, 8-isoprostanes, and AD7c-NTP) were analyzed to identify dementia biomarkers. Stool samples were collected for DNA extraction and gut microbiota analysis via next-generation sequencing (NGS).

RESULTS: Dementia patients had significantly lower physical fitness than other groups ($p < .05$), except in aerobic endurance ($p > .05$). Hypertensive individuals had weaker lower extremity strength than healthy controls ($p < .05$). Dementia patients scored lower on SPMSQ and higher on depression scales ($p < .05$). Although QoL scores did not differ significantly ($p > .05$), healthier individuals had higher scores. Dementia patients showed significantly elevated urinary 8-OHdG and AD7c-NTP, while 8-isoprostanes increased in all chronic disease groups. Five urinary metabolites increased, while 14 decreased in dementia patients. Gut microbiota analysis showed distinct differences, with healthy individuals exhibiting higher abundances of *Prevotella*, *Odoribacter*, and *Muribaculaceae*, while early cognitive impairment patients had increased *Alistipes*, *Akkermansia*, and *Escherichia-Shigella*. α - and β -diversity analyses confirmed gut microbiota alterations in early dementia.

CONCLUSION: Dementia patients exhibited the most severe declines in physical fitness and depression. The study identified dementia-related metabolic changes, oxidative stress, and gut microbiota dysbiosis, suggesting these factors as potential biomarkers for early dementia assessment.

TITIN'S ROLE IN RESIDUAL FORCE ENHANCEMENT: STRUCTURAL INSIGHTS FROM SMALL-ANGLE X-RAY DIFFRACTION

KUEHN, M., HESSEL, A., PALMER, B., NISSEN, D., MISHRA, D., JOUMAA, V., FREUNDT, J., MA, W., NISHIKAWA, K., IRVING, T., LINKE, W.

UNIVERSITY OF MUENSTER

INTRODUCTION: Titin connects the myofilaments in skeletal muscle and plays a pivotal role in modulating passive and active muscle tension. Residual force enhancement (RFE) describes the phenomenon where force remains elevated following an active stretch compared to a purely isometric contraction at the same final length. Despite its relevance to near-instantaneous muscle force control, the structural underpinnings of RFE remain elusive. This study investigates the contribution of titin to RFE by using 2 genetically modified mouse models: the titin cleavage (TC) and the muscular dystrophy with myositis (mdm) mouse lines. Small-angle X-ray diffraction was used to elucidate structural changes underlying titin's mechanical role during muscle contractions.

METHODS: Fast-twitch, skinned skeletal muscle fibers were isolated from TC (heterozygous) and mdm (wild type and homozygous) mice. In TC mice, a splice site was engineered into the I-band region of titin, enabling rapid and specific cleavage, thereby reducing titin-based force and stiffness. In mdm mice, a small deletion in the I-band of titin nearly ablates RFE. Mechanical properties and sarcomeric structures were assessed during: (1) isometric contractions at short sarcomere lengths (IsoShort), (2) isometric contractions at long sarcomere lengths (IsoLong), and (3) after active lengthen-hold from IsoShort to IsoLong (IsoRFE). X-ray diffraction captured the sarcomeric structural signature in each condition. Stats - full-factorial ANOVA design with individual random effect. Box-Cox transformation ensured normality and variance homogeneity.

RESULTS: Cleaving 50% of I-band titin in TC fibers significantly reduced RFE from $30.69 \pm 3.35\%$ to $17.44 \pm 2.24\%$ of the reference force (IsoLong; $P < 0.01$). Structural analyses revealed that IsoRFE contractions exhibited increased thick filament strain and reduced lattice spacing compared to IsoLong ($P < 0.01$). Notably, these RFE-specific structural changes were absent in mdm fibers but were prominent in wild-type controls ($P < 0.01$). We estimate that titin-mediated reductions in lattice spacing and thick filament elongation account for approximately 40-70% of RFE. The remaining 30-60% is likely attributable to an activation-dependent, 2-3-fold increase in titin stiffness preceding eccentric stretch, which relatively increases titin-based forces during and after the stretch, compared to a passive stretch-hold.

CONCLUSION: These results underscore titin's integral role in modulating sarcomeric tension and its essential contribution to RFE. The structural signatures associated with RFE—decreased lattice spacing and increased thick filament strain—are directly influenced by titin-based forces. The absence of the mechanical and structural signatures of RFE in mdm mutants highlights the necessity of I-band titin for proper RFE. Our data suggest that RFE involves both structural adjustments and an activation-dependent modulation of titin stiffness, though the precise molecular mechanisms remain to be elucidated.

MYOFIBRILLAR ATPASE EFFICIENCY OF SKELETAL MUSCLE FIBERS FROM YOUNG AND OLDER ADULTS

TEIGEN, L., FITTS, R.H., HUNTER, S.K., SUNDBERG, C.W.

MARQUETTE UNIVERSITY

INTRODUCTION: Age-related declines in skeletal muscle mass and function lead to impairments in mobility and decreased quality of life in older adults. At the single muscle fiber level, many studies show preserved function of slow myosin heavy chain (MyHC) I fibers but decrements in size and contractile function of fast MyHC II fibers(1). Studies of fast fibers from old rats suggest impairments in myofibrillar ATPase efficiency with age(2,3), however it is unknown if these impairments also occur in aging human skeletal muscle.

METHODS: Muscle biopsies were obtained from the vastus lateralis of 6 young (4F; 26.5±4.8 yrs) and 5 older (3F; 71.1±6.1 yrs) adults to assess single fiber myofibrillar ATPase activity via a micro epifluorescence system that measures NADH fluorescence during ATP hydrolysis. Activity was measured in relaxing conditions (basal ATPase) and in saturating Ca²⁺ activating conditions (pCa 4.5) during isometric contractions of chemically permeabilized single muscle fibers. Simultaneous measures of force and NADH fluorescence were made at 20°C, and the MyHC isoform for each fiber determined by 5% SDS-PAGE.

RESULTS: A total of 63 (33 old) MyHC I and 82 (44 old) MyHC II fibers were tested. Basal ATPase activity in relaxing solution was higher in young compared with older adults in both MyHC I (754±115 vs 583±87nM NADH/s; p=0.004) and MyHC II fibers (733±129 vs 606±131nM NADH/s; p=0.005); however, there were no differences when the basal ATPase activity was normalized to fiber size for either the MyHC I (0.15±0.07 vs 0.12±0.04nM NADH/s/μm²; p=0.638) or MyHC II fibers (0.13±0.08 vs 0.18±0.14nM NADH/s/μm²; p=0.852). Maximal Ca²⁺ ATPase activity was greater in young compared with older adults in both MyHC I (1,320±410 vs 910±227nM NADH/s; p=0.010) and MyHC II (3,628±1,022 vs 2,408±923nM NADH/s; p=0.031) fibers. When normalized to absolute and size-specific force, ATPase activity of MyHC I fibers was higher in young compared to older adults (2,173±824 vs 1,631±510nM NADH/s/mN; p=0.035 and 11.4±3.9 vs 8.2±2.6nM NADH/s/kN/m²; p=0.044), suggesting a greater myofibrillar ATPase efficiency with aging. In contrast, there were no differences in the MyHC II fibers when normalized to absolute (4,322±2,516 vs 3,919±1,431nM NADH/s/mN; p=0.428) or size-specific force (23.9±7.3 vs 16.8±7.2nM NADH/s/kN/m²; p=0.254).

CONCLUSION: These preliminary results suggest that during isometric contractions, older adults have more efficient MyHC I skeletal muscle fibers but that contractile efficiency of MyHC II fibers is unaltered by aging. The more efficient MyHC I fibers may explain, in part, the fatigue resistance and improved metabolic economy found in older adults during voluntary isometric contractions(4).

SPONTANEOUS LOCOMOTIVE ACTIVITY INDUCES SOLEUS MUSCLE HYPERTROPHY AND REDUCES ANXIETY-LIKE BEHAVIOR IN AN ENVIRONMENTAL ENRICHMENT

SUDO, M., KANO, Y., ANDO, S.

PHYSICAL FITNESS RESEARCH

INTRODUCTION: Environmental enrichment (EE) enhances brain function through neuroprotection and neuroplasticity. Our previous study demonstrated that EE induces soleus muscle hypertrophy and increases spontaneous physical activity (Sudo et al., 2023). However, the relationship between soleus muscle hypertrophy, locomotive behavior, and anxiety-like behavior under EE conditions remains unclear. This study aimed to clarify the relationship between soleus muscle hypertrophy and EE exposure under multiple conditions.

METHODS: Wistar rats were divided into four groups: EE (wheel + objects), EE-R (wheel only), EE-O (objects only), and CONT (standard environment) (N=6 per group). Physical activity (PA) was continuously recorded via a three-axis accelerometer. Wheel running duration was measured during the 12-hour dark phase in the final week. After four weeks, spatial memory was assessed using the Morris Water Maze (MWM) test, and anxiety-like behavior was evaluated using the Elevated Plus Maze (EPM) test. Soleus and plantaris muscle cross-sectional area (CSA) was measured from hematoxylin-eosin (HE) stained sections to assess muscle hypertrophy.

RESULTS: Total PA was higher in EE and EE-R than in CONT (P<0.001), with no difference between EE and EE-R (P=0.63). Wheel running duration was longer in EE (56.3 ± 14.7 min) than in EE-R (37.2 ± 9.4 min, P=0.03). The EPM test showed a higher open-to-closed arm time ratio (O/C ratio) in EE (203.5 ± 27.2), EE-R (98.1 ± 25.7), and EE-O (78.8 ± 33.7) than in CONT (11.4 ± 7.6, P<0.01). Soleus muscle CSA increased in all EE groups (EE: 2889 ± 162, EE-R: 2575 ± 81, EE-O: 2572 ± 132 μm², P<0.01 vs. CONT: 2184 ± 203 μm²). Soleus muscle CSA was also greater in EE than in EE-R (P=0.01). In contrast, plantaris muscle CSA did not differ among groups (EE: 2973 ± 297, EE-R: 2898 ± 514, EE-O: 2695 ± 397, CONT: 2590 ± 399 μm²). Furthermore, soleus muscle CSA correlated positively with PA (r²=0.38, P=0.002) and the O/C ratio in EPM (r²=0.65, P<0.001). In EE and EE-R, soleus muscle CSA also correlated positively with wheel running duration (r²=0.48, P=0.01), whereas plantaris muscle CSA showed no correlations.

CONCLUSION: This study revealed that soleus muscle hypertrophy and reduction in anxiety-like behavior are associated with environmental enrichment. Soleus hypertrophy was observed in EE, EE-R, and EE-O groups, with the greatest increase in EE. Since wheel running duration was lower in EE-R than in EE, soleus muscle hypertrophy may be associated with both locomotive activity involving object interaction and spontaneous wheel running in an enriched environment. Furthermore, soleus muscle hypertrophy, in concert with spontaneous intermittent physical activity, may contribute to reductions in anxiety-like behavior.

MONITORING THE MUSCLE OXYGENATION PROFILES DURING A FOREARM CRITICAL FORCE TEST: A TIME-DOMAIN NEAR-INFRARED SPECTROSCOPY PILOT STUDY

PERREY, S., LACERENZA, M., VERGOTTE, G., PLA, S., BESSON, P.
UNIV MONTPELLIER

INTRODUCTION: A key feature of the critical force (CF) concept is its ability to integrate both mechanical and metabolic response profiles (3). However, the determination of whether CF from one all-out test (1) represents a boundary between localized steady and non-steady metabolic conditions remains to be elucidated. It is hypothesised that the muscle O₂ delivery-to-O₂ utilisation ratio may drive CF, and that critical muscle oxygenation (SmO₂ steady-state) may be a relevant physiological measure (2). The present study seeks to explore whether critical oxygenation aligns with CF during a 4-minute all-out forearm handgrip exercise. It is acknowledged that physiological alterations can influence the accuracy of near infrared spectroscopy (NIRS) data (differential pathlength factor, superficial and deep layers) during high-intensity muscle contractions. To mitigate these limitations and provide more accurate assessment of muscle oxygenation, we employed a time-domain (TD) NIRS oximeter, which minimizes confounding signals from superficial tissues and provides absolute oximetry and DPF measurements.

METHODS: A total of 17 young healthy adults (13 males and 4 females, with a mean age of 28.3 ± 9.6 years, a height of 179.0 ± 11.5 cm, and a mass of 72.8 ± 11.1 kg) participated in the study. A 4-min all-out handgrip test in a seated position was conducted at a work:relief ratio of 7:3 s with the dominant hand and upper limbs flexed at 90° elbow flexion (1). During the work phase, participants were instructed to produce as much force as possible. Muscle-O₂ dynamics during all tests were assessed using a TD NIRS device (NIRSBOX, PIONIRS SRL, Italy) equipped with two picosecond laser diodes (686 nm and 830 nm), and a single-photon detector to record the distribution of the time-on-flight for the photons re-emitted from the tissue. The sensor was placed over the belly of the flexor digitorum profundus of the dominant hand. NIRS (2 Hz), force (500 Hz) signals, and automated audio instructions were synchronized using a dedicated software platform. CF and critical oxygenation were analysed as proposed (1,2).

RESULTS: Data from 16 participants were usable. CF, determined from the mean force of the last three contractions, was measured to be 73.4 ± 14.0 kg. The results show a significant correlation between CF and HHb ($r = 0.55$, $t(14) = 2.48$, $p = 0.026$, slope of 0.80), but not with SmO₂ ($r = 0.34$, $t(14) = -1.35$; $p = 0.200$, slope - 0.12).

CONCLUSION: CF is considered to be the highest metabolic rate that can be achieved by oxidative means. When assessing critical oxygenation, the steady-state level of SmO₂ may not be the most appropriate variable to consider. HHb can be a good candidate in tracking CF among the various physiological metrics available from TD NIRS.

MINIMAL NUMBER OF MAXIMAL ECCENTRIC CONTRACTIONS TO INCREASE MUSCLE STRENGTH AND THICKNESS IN TWO SESSIONS PER WEEK FOR 4 WEEKS

NOSAKA, K., YOSHIDA, R., MURAKAMI, Y., KASAHARA, K., SATO, S., NAKAMURA, M.
EDITH COWAN UNIVERSITY

INTRODUCTION: Intensity, volume, frequency and muscle contraction type are important variables in resistance exercise training. We showed that one 3-s maximal eccentric contraction performed 5 days a week (Monday–Friday) for 4 weeks (total exercise time: 60 s) increased maximal voluntary eccentric (MVC-ECC), isometric (MVC-ISO), and concentric contraction (MVC-CON) torque of the elbow flexors by more than 10%, but this was not induced by maximal isometric or concentric contraction in the same format [1]. We also reported that six 3-s maximal eccentric contractions a session performed 5 days a week for 4 weeks increased muscle strength in the same magnitude to that of the one contraction, but no significant increase in the strength was induced when 30 3-s maximal eccentric contractions were performed once a week [2]. Furthermore, when comparing the one 3-s eccentric contraction training between two and three days a week for 4 weeks, no significant increase in muscle strength were evident for the two days per week condition, but small (3%) increases were found for the three days per week condition [3]. The present study investigated whether muscle strength would be increased greater when the number of the eccentric contractions per session was increased to five or 15 than one in the twice-weekly training format.

METHODS: Healthy young adults were placed to two groups ($n=12/\text{group}$) based on the number of 3-s maximal eccentric contractions of the elbow flexors in a session performed two sessions a week for 4 weeks; 5×2 (1 set of 5 contractions, $\times 2$ indicates 2 sessions/week) or 15×2 (3 sets of 5 contractions). Changes in MVC-ECC, MVC-ISO and MVC-CON torque of the elbow flexors, and biceps brachii and brachialis muscle thickness (MT) before and after the 4-week training were compared between groups. The changes were also compared to the 1×2 (one contraction/session, 2 sessions/week) and 1×5 (one contraction/session, 5 sessions/week) groups in the previous studies [1, 3].

RESULTS: MVC-ECC ($8.6\pm 9.2\%$, $8.3\pm 5.7\%$), MVC-ISO ($7.5\pm 10.4\%$, $7.0\pm 5.8\%$), and MVC-CON ($5.0\pm 5.9\%$, $9.6\pm 6.6\%$) torque increased ($p\leq 0.05$) similarly for the 5×2 and 15×2 groups. However, these changes were smaller ($p\leq 0.05$) than those of the 1×5 group ($>10\%$). MT also increased ($p\leq 0.05$) similarly for the 5×2 ($5.4\pm 4.4\%$) and 15×2 ($8.1\pm 6.2\%$) groups. No significant changes in MVC torque and MT were evident for the 1×2 group.

CONCLUSION: These results suggest that muscle strength and size increased when the volume was increased to 5 contractions, but increasing the volume to 15 did not further increase them. It appears that the number of maximal eccentric contractions and volume are less important than the frequency for maximal eccentric contraction training, but it becomes effective by increasing the number of contractions from one to 5.

NEW PERSPECTIVES ON SKELETAL NERVE INFLUENCE IN BONE METABOLISM: INVESTIGATING THE RESTORATIVE EFFECTS OF COMBINED AEROBIC AND RESISTANCE EXERCISE IN OVARECTOMY-INDUCED OSTEOPOROTIC RATS

LEE, S., KIM, J., KIM, C.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Postmenopausal osteoporosis is characterized by significant bone loss and an increased risk of fractures. Multimodal exercise training is often recommended to mitigate the effects of menopause-related bone deterioration. While exercise has well-documented benefits on skeletal health, recent research highlights its influence on skeletal nerves, with aerobic training shown to enhance periosteal nerve fiber density. However, the effects of combined exercise on skeletal nerves and subsequent bone volume changes remain unexplored. This study aimed to evaluate whether an eight-week combined exercise regimen could restore trabecular bone metabolism and skeletal nerve density in the tibia following ovariectomy (OVX) in rats.

METHODS: Twenty-eight female Fisher-344 rats were randomly assigned to one of four groups ($n=7$ per group): (a) Sham non-exercise (SN), (b) Sham combined exercise (SE), (c) Ovariectomy non-exercise (ON), or (d) Ovariectomy combined exercise (OE). The combined exercise protocol included resistance training (tower climbing) and aerobic training (treadmill running) for eight weeks. Micro-computed tomography was used to assess changes in trabecular bone microarchitecture, while immunofluorescent imaging quantified bone-associated skeletal nerve density.

RESULTS: Ovariectomy significantly reduced serum estrogen levels ($P<0.01$) compared to the Sham group. Estrogen deficiency resulted in increased body weight and decreased bone volume. However, combined exercise significantly improved trabecular bone volume (BV, mm^3) and fractional bone volume (BV/TV, %) in both sham and OVX groups compared to non-exercise controls ($P<0.05$). Additionally, trabecular number (Tb.N, $1/\text{mm}$) was significantly increased in SE and showed a tendency to increase in OE ($P<0.10$), while trabecular separation (Tb.Sp, μm) was reduced in SE compared to SN. Interestingly, OVX led to a marked reduction in bone-associated skeletal nerve fibers (SN: 859.4 ± 310.2 in Sham vs. 195.7 ± 43.1 in ON, $P<0.01$). However, combined exercise partially restored nerve fiber density by approximately 135% (ON vs. OE, $P<0.01$). Notably, combined exercise alone had a positive impact on skeletal nerve fibers, as SE exhibited significantly greater nerve density than SN (1407.8 ± 396.9 vs. 859.4 ± 310.2 , $P<0.01$). Correlation analysis demonstrated a significant relationship between BV/TV and skeletal nerve fibers in all groups except SE (SN: $R^2=0.81$, $P<0.01$; ON: $R^2=0.45$, $P<0.05$; SE: $R^2=0.31$, $P=0.09$; OE: $R^2=0.78$, $P<0.01$). However, bone mineral density (BMD) remained unchanged between exercise and non-exercise groups.

CONCLUSION: An eight-week combined exercise regimen positively influenced tibial trabecular bone microarchitecture and stimulated bone-associated skeletal nerve fibers. These findings suggest that combined exercise training may serve as a dual mechanism for promoting bone remodeling and skeletal nerve regeneration in response to estrogen deficiency.

SENESCENCE AS A CELL REGULATORY MECHANISM DURING SKELETAL MUSCLE REGENERATION

JOHNSON, A., PARISE, G.

MCMMASTER UNIVERSITY

INTRODUCTION: Senescence is a stress response that is characterized by a permanent cell cycle arrest while remaining metabolically active and is most often considered an age-related phenomenon. Senescent cells secrete a variety of cytokines, chemokines and growth factors known as the senescence associated secretory phenotype (SASP). SASP influences the surrounding microenvironment, which can promote growth in development and contribute to the inflammatory process. Skeletal muscle regeneration is a complex process that requires the coordination of several different cell populations. Therefore, this study examines the impact of senescence on skeletal muscle during regeneration. We hypothesize that senescence serves as a control mechanism throughout the regenerative process in skeletal muscle.

METHODS: Briefly, young mice ($n=8/\text{time point}$) were treated with the senolytic drugs (Dasatinib+Quercetin, D+Q) which selectively eliminate senescent cells. Muscle damage was induced by cardiotoxin (CTX) in one hindlimb. Briefly, mice were exposed to either (a) vehicle (VEH), receiving only a CTX injection or (b) 7 days of senolytic treatment pre-CTX and 3x/week for 4 weeks post-CTX (SEN). Mice underwent grip strength measures throughout the study with CTX injured tibialis anterior

collected for biochemical analysis. Statistical significance was determined by a two-way ANOVA with a Tukey's multiple comparisons post-hoc test.

RESULTS: There were no significant differences in hindlimb grip strength between groups. Cross sectional area decreased at D7 and returned to normal in both groups. Centrally located nuclei significantly increased in both groups following CTx, however eMHC+ remained elevated at D28 in the SEN group ($p < 0.005$). Macrophage (F4/80+) infiltration was significantly increased in the SEN group compared to the VEH at D7 ($p < 0.001$). Satellite cell number ($p < 0.01$) and fibrosis area ($p < 0.05$) was significantly increased at D14 in the SEN group compared to the VEH.

CONCLUSION: The removal of senescent cells during muscle regeneration in young mice, significantly alters the kinetics of muscle regeneration. Senescent cells may act as a regulatory mechanism in skeletal muscle, likely through the secretion of SASP, to orchestrate the activity of different cell populations such as the recruitment of immune cells, satellite cells, and fibroblasts or fibro-adipogenic progenitors (FAPs) during muscle regeneration. Therefore, senescent cells may play an important role in skeletal muscle health and repair.

RESTORATIVE BENEFITS OF EXERCISE ON BONE INTEGRITY AND PERIPHERAL NEUROPATHY IN A HIGH-FAT DIET TYPE II DIABETES MODEL

AN, M., LEE, S.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Peripheral neuropathy is one of the most common complications of diabetes. This condition can lead to dysregulation of bone homeostasis, resulting in decreased bone density and increased risk of fractures. A high-fat diets (HFD) has been shown to decrease skeletal nerve fibers, potentially leading to reduced bone mass and quality. Specifically, the periosteum, recognized as a niche for bone progenitor cells sensitive to neural ligands, may experience reduced innervation due to diabetic neuropathy. This loss of innervation could disrupt the periosteal cellular niche, potentially promoting bone loss. This study investigated the impact of obesity-related type II diabetes and associated peripheral neuropathy on bone health.

METHODS: Young (4wks old) C57BL/6 mice were fed normal diet (ND) or HFD containing 60% of calories from fat for 12 wks. DEXA analysis and Thermal Sensation Test were analyzed every other 4 wks. Fasting glucose were measured at 16 wks of age to confirm the development of diabetic condition. The diabetic neuropathy was validated by a thermal withdrawal latency test. Micro-computed tomography (μ CT) was used to assess trabecular bone microarchitecture and cortical bone parameters of femur. Immunofluorescence imaging was used to characterize nerve fiber density and localization. Finally, a combination of transcriptomics and in vitro assays was performed to create a communication map between DRGs and periosteum niche bioinformatically.

RESULTS: HFD-fed mice had significantly increased total body and fat mass, along with marked hyperglycemia characteristics indicative of type II diabetes. Additionally, the mice showed sensory polyneuropathy, with significant reductions in intraepidermal nerve fiber density and diminished thermal sensitivity. Bone analysis revealed declines in cortical and trabecular bone indices in long bones, with these structural changes corresponding to a reduction in peptidergic and sympathetic nerve fibers within periosteal regions. Further, single-cell RNA sequencing analysis identified major stromal and immune compartments, as well as 16 dorsal root ganglia clusters within the periosteum niche and HFD suppresses osteoblastogenesis and MAPK signaling pathways, suggesting complex cellular interactions affecting diabetic bone health. In vitro assays demonstrated that HFD reduced osteogenic differentiation and MAPK pathway activation while adding DRG-conditioned media enhanced both in a normal diet and HFD-fed mouse periosteal cells.

CONCLUSION: In HFD-induced type 2 diabetes, we confirmed peripheral nerve reduction and bone loss. In addition, it was confirmed that the nerves in the periosteum were also reduced. We found in in vitro assay that re-exposure to physiological neuronal inputs may restore obesity-related bone health. Future research should explore whether exercise can improve skeletal nerve fiber density and positively influence bone health under HFD conditions, potentially mitigating the damaging effects of diabetic neuropathy on bone.

EFFECTS OF DAILY JUMP TRAINING DIVIDED INTO MULTIPLE BOUTS ON BONE STRENGTH, CORTICAL MORPHOLOGY, AND TRABECULAR MICRO-ARCHITECTURE

KUROKAWA, R., JU, Y.I.2, UMEMURA, Y.1

1 CHUKYO UNIVERSITY, 2 KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Physical exercise is known to increase bone mass and strengthen the bones mainly by mechanical loading. Jump training is an effective exercise model providing high-impact load to the bones. Furthermore, it is observed that jump training enlarges the diaphysis of bones cross-sectionally and not along the long-axis. Jump training also increases the trabecular thickness at the metaphysis of the bones. A previous study reported that mechanical loading was more effective in enhancing bone strength and morphological properties when load was applied for short bouts with recovery periods in between than when applied all at once. However, there is still lack of evidence whether jump training divided into multiple sets can efficiently improve bone mass, strength, morphology, and microarchitecture. Therefore, this study aimed to investigate the effects of the training divided into multiple bouts per day on bone adaptation.

METHODS: Nine-week-old male Wistar rats ($n = 32$) were randomly assigned to three body weight-matched groups: performing five 10-jumps with 2 h recovery periods (J10 $\times$ 5) group ($n = 12$), a 50-jump (J50 $\times$ 1) group ($n = 12$), and a control group without jump training ($n = 8$). The jump training consisted of 50 jumps/day, 3 days/week, with a jump height of

40 cm. After 8 weeks of training, both sides of the tibia and femur were removed. The maximum loads at the center of the tibial and femoral diaphyses were measured using a three-point bending test. Micro-computed tomography was used to analyze the three-dimensional cortical bone morphology at the tibial and femoral diaphyses and the trabecular bone microarchitecture at the proximal tibial and distal femoral metaphyses.

RESULTS: The tibial diaphysis in the J10 × 5 and J50 × 1 groups showed significantly improved maximum loading ($p < 0.001$, $p < 0.001$, respectively), cross-sectional area (CSA) ($p < 0.001$, $p < 0.001$, respectively), cortical thickness ($p < 0.01$, $p < 0.001$, respectively), and periosteal perimeter ($p < 0.001$, $p < 0.001$, respectively) compared with the control group. In addition, the J10 × 5 and J50 × 1 groups showed increased trabecular thickness ($p < 0.001$, $p < 0.001$, respectively) and number ($p < 0.01$, $p < 0.05$, respectively) by jump training compared with those in the control group. Although the CSA and cortical thickness of the femoral diaphysis increased in the J10 × 5 and J50 × 1 groups, the maximum loading did not. Only trabecular thickness of the distal femoral metaphysis was increased by jump training. There was no significant difference in the data collected between the J10 × 5 and J50 × 1 groups.

CONCLUSION: Jump training may have provided higher impact loads on bones than the artificial loads used in previous studies. Therefore, dividing training into multiple bouts per day may not have been as effective in increasing bone mass and strength, because the heavy load delayed the recovery of the mechanical sensor.

PALMITATE EXPOSURE IMPAIRS AUTOPHAGIC FLUX AND ASSOCIATED SIGNALLING PATHWAYS IN IMMORTALISED HUMAN PRIMARY MYOTUBES

HODSON, N., ACHESON, J., LIGHTFOOT, A.
MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: Lipid infiltration into skeletal muscle in conditions such as obesity and type II diabetes is hypothesized to interfere with proteostatic signalling leading to increased proteolysis and atrophy(1). Evidence from other cell types/tissues suggests lipid infiltration can inhibit autophagy(2), a cellular recycling process essential for the maintenance of skeletal muscle mass and quality(3), although this is yet to be investigated in human skeletal muscle. Therefore, the aim of this study was to investigate the effect of high-fat exposure on autophagic flux and associated cellular signalling in immortalised human primary myotubes.

METHODS: Immortalised human primary myotubes (C25/KM155 cell line) were exposed to palmitate (PAL, 500μM), or control media (CTRL), for 24h. Myotubes were then either immediately collected (BASAL, n=7 per condition) or media changed to EBSS for 5h to deprive cells of nutrients (STARVE, n=5 per condition), a process which typically activates autophagy. A set of experiments was also conducted in the presence of Bafilomycin A1 (100nM) for 2h before collection to assess pre-lysosomal autophagic flux. Immunoblotting was then completed for LC3 (autophagic flux) and a range of associated signalling targets. Two-factor independent measures ANOVAs were used to assess differences between conditions, with significance threshold set at $p < 0.05$. Data is presented as Mean ± SD.

RESULTS: Main effects of condition and nutrient deprivation (both $p < 0.001$) were observed for pre-lysosomal autophagic flux whereby STARVE elevated flux in both CTRL and PAL (2.2-fold & 3-fold) but overall was lower in PAL. This was not mirrored by more commonly used LC3II/I ratio, where no differences were observed, suggesting this 'static' measure of autophagy does not reflect flux. Further main effects of condition showed AMPK-mediated ULK1 Ser555 phosphorylation and Beclin1 protein content to be greater in CTRL irrespective of nutrient availability ($p \leq 0.036$), indicating a potential impairment of autophagy induction in PAL. Markers of mTORC1 activity (p-ULK1 Ser757, p-RPS6 Ser240/244 & Ser235/236) displayed main effects of nutrient deprivation whereby STARVE was lower than BASAL irrespective of condition ($p \leq 0.026$). However, when expressed relative to basal mean values, the reduction in p-RPS6 Ser240/244 & 235/236 following STARVE was less pronounced with PAL ($72 \pm 2\%$ vs. $83 \pm 6\%$, $p = 0.009$ & $66 \pm 4\%$ vs. $74 \pm 3\%$, $p = 0.005$ respectively).

CONCLUSION: We show that palmitate exposure impairs pre-lysosomal autophagic flux but not its responsiveness to nutrient withdrawal. This impairment may be due to reduced autophagy induction displayed by lower Beclin1 content and AMPK-mediated ULK1 Ser555 phosphorylation. These data provide initial evidence of a potential detrimental effect of high-fat/lipid exposure on autophagy in human skeletal muscle which warrants further research in vivo.

CP-PN17 Thermoregulation Training and Performance

EFFECTS OF HEAT ACCLIMATIZATION AND HYPOXIA TRAINING ON THE FAT OXIDATION CAPACITY OF COMPETITIVE ATHLETES

QIU, J., ZHIZHONG, G., JINHAO, W., CHENHAO, T., GUOHUAN, C.

SHANGHAI INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Heat acclimatization and hypoxic training have improved aerobic capacity and endurance performance, potentially linked to enhanced fat oxidation capacity. Evidence from diseased or obese populations suggests that environmental adaptations can increase fat oxidation as an energy source. However, there is limited research on the metabolic responses of elite athletes. This study aimed to assess the impact of heat acclimatization and hypoxic training on fat oxidation capacity in competitive athletes, exploring potential factors that contribute to improvements in aerobic capacity.

METHODS: Eight elite male modern pentathletes participated in a four-week aerobic endurance training program under three different environmental conditions: control (CON group; 23°C, RH45%, FiO₂=20.9%), hot (HOT group; 35°C, RH70%, FiO₂=20.9%), and hypoxia (HYP group; 23°C, RH45%, FiO₂=15.6%). Incremental exercise tests were performed before and after the training in both the control and respective specialized environments. Gas exchange data were collected to assess aerobic capacity, while indirect calorimetry was used to determine fat oxidation rates, which were plotted as a function of exercise intensity. A SIN model was employed to determine the intensity (Fatmax) causing maximal fat oxidation (MFO), and the models three independent variables, dilation (d), symmetry (s), and translation (t), were used to characterize the dynamics of fat oxidation. A two-way repeated measures ANOVA was used to assess the effects of environmental conditions and training factors, with statistical significance set at $\alpha = 0.05$. Data are presented as mean $\pm$ SD.

RESULTS: In the control environment, after the training, the HOT group exhibited a significant increase in absolute VO₂ (4322.6 ± 651.64 vs. 4560.75 ± 722.64 ml/min, $p=0.003$). Both the HOT (626.44 ± 75.58 vs. 722.50 ± 49.79 s, $p=0.006$) and HYP (573.83 ± 51.77 vs. 683.75 ± 76.15 s, $p=0.002$) groups showed significant increases in VT_{2@Time} after training. Additionally, both HOT (0.65 ± 0.14 vs. 0.78 ± 0.13 g/min, $p=0.015$) and HYP (0.63 ± 0.17 vs. 0.79 ± 0.18 g/min, $p=0.004$) groups demonstrated increased MFO after training. The HOT group also exhibited an increase in Fatmax (30.46 ± 3.61 vs. 35.76 ± 5.12 ml/min·kg, $p=0.005$). Both HOT (-0.74 ± 0.28 vs. -0.45 ± 0.16 , $p=0.003$) and HYP groups (-0.79 ± 0.27 vs. -0.51 ± 0.12 , $p=0.003$) showed significant increases in d under the control environment, with the HOT group also showing an increase in d under hot environment (-0.74 ± 0.28 vs. -0.45 ± 0.16 , $p=0.013$) after training.

CONCLUSION: Four weeks of hypoxic and heat acclimatization training can enhance aerobic metabolic capacity in competitive athletes under normal conditions, accompanied by improvements in fat oxidation curve dilation and increased fat oxidation capacity. Additionally, heat acclimatization training has similar beneficial effects on fat oxidation capacity during exercise in hot environments.

OUT WITH THE ICE AND IN WITH THE HEAT: HEAT OUTPERFORMS COLD WATER IMMERSION FOR RECOVERY OF STRENGTH AFTER EXERCISE-INDUCED DOMS IN HEALTHY ADULTS

BAYNE, F., NAGYOVA, M., STOLK, N., PLACIDO, M.A., HAMDI, M., FALZON, A., PEREZEN, R., NETO MENEZES, S., HALITI, S., ATKINSON, C., RACINAIS, S., GAOUA, N.

LONDON SOUTH BANK UNIVERSITY

INTRODUCTION: The aim of this study was to investigate the effectiveness of thermal strategies on recovery rate after exercise induced delayed onset of muscle soreness.

METHODS: The study used a randomized, parallel group design (N=40 with 10 in each group) over four consecutive test days. Participants performed a single bout of eccentric knee extensions, with baseline and post maximal voluntary contraction (MVC) measurements on a isokinetic dynamometer (HUMAC NORM), followed by a thermal recovery strategy: hot water immersion (HWI; 30 min at 42 °C), cold water immersion (CWI; 15 min at 9 °C), hot air immersion (HAI; 30 min at 30°C, 30% RH) or control (CON: 30 min at 18 °C, 30% RH). Recovery rate of strength (via MVC), and pain and muscle soreness (via visual analogue scales) was monitored over 72hr (pre exercise, post exercise, post therapy, 24hrs, 48hrs, and 72hrs after therapy). Venous blood samples were collected each session to analyse inflammatory marker Interleukin 6 (IL-6), heat shock proteins (HSP72), and Creatine Kinase Muscle-Muscle isoenzyme (CKMM).

RESULTS: HWI returned 85 and 89% of strength back to baseline MVC values at 48hr (284.30 ± 22.04 N vs 243.70 ± 25.33 ; $p=0.356$) and 72hrs (284.30 ± 22.04 N vs 256.00 ± 26.12 ; $p=0.801$) respectively. CON and HAI returned 88% and 89% of strength back to baseline MVC values at 72hrs (303.70 ± 22.04 N vs 268.50 ± 26.12 N; $p=0.314$, and 299.70 ± 22.04 N vs 268.70 ± 26.12 N; $p=0.563$ respectively). Whereas, CWI MVC values were still 25% higher than baseline at 72hrs (279.10 ± 22.04 N vs 218.80 ± 26.12 N; $p=0.005$). There was no significant difference in the recovery of pain or muscle soreness between groups over time ($P > 0.05$). CKMM increased from baseline to post-exercise in all groups ($p < 0.05$). However, HWI caused a significant decrease in CKMM in comparison to other groups over time ($p < 0.05$). HSP72 increased significantly after HWI and HAI (1.36 ± 0.11 vs 1.81 ± 0.14 mg/ml and 1.36 ± 0.11 to 1.6 ± 0.14 mg/ml; $p=0.001$), while CWI caused a significant decrease (1.36 ± 0.11 vs 0.87 ± 0.10 mg/ml; $p=0.001$), with no change in CON (1.21 ± 0.01 ; $p=0.671$). Quadriceps muscle temperature increased with HWI (36.57 ± 1.2 °C vs 38.83 ± 1.3 °C; $p=0.005$) and decreased with HAI

(37.05±0.5 °C vs 34±1.7 °C; $p=0.05$) and CON (36.61±0.9 °C vs 34.78±2.2 °C; $p=0.012$). There was no significant difference in HAI (36.05±0.9 °C vs 36.27±0.5 °C; $p=0.444$). HWI reduced IL6 after 48 hours (0.54±0.02 vs 0.56±0.02 pg/ml; $p=0.096$), whereas CWI reduced after 72 hours (0.61±0.04 vs 0.61±0.03 pg/ml; $p=0.953$).

CONCLUSION: Hot water immersion was the most effective thermal therapy for returning baseline strength. This was related to the physiological stimulus that hot water immersion caused on the body (elevation in muscle temperature and heat shock protein 70) and associated upregulation of inflammation (IL6) and low circulating markers of muscle damage (CK-MM) compared to other therapies. Therefore, hot water immersion should be favored for recovery of strength.

THE EFFECTS OF SODIUM CITRATE SUPPLEMENTATION WITH ICE SLURRY ON THERMOREGULATORY MECHANISMS DURING HEAT EXPOSURE IN INDIVIDUALS WEARING MOTORSPORT PERSONAL PROTECTIVE EQUIPMENT

PAGE, J., MALVERN, J., PEYTON-JONES, T., JAMES, C., DOUGLAS-BOISSON, Z., HEFFERNAN, S., KILDUFF, L., PEEL, J., VASSALLO, C., WALDRON, M.

SWANSEA UNIVERSITY

INTRODUCTION: Ice slurry ingestion prior to exercise can expand the heat storage window whilst improving tolerance to rising core temperature (T_{core}) [1] and blunting the sweating response [2]. Alternatively, sodium citrate (SC) supplementation has been shown to promote water retention and subsequently induce hyperhydration [3]. Both offer potential value as pre-race strategies to mitigate thermal strain experienced by motorsport driver-athletes who race in thermally resistant clothing that renders evaporative heat loss largely ineffective, thus exacerbating thermal strain in high temperature cockpit conditions [4]. The current study aimed to determine the effects of ice slurry ingestion and SC supplementation alone or in combination on thermoregulatory mechanisms during exposure to a hot environment in a motorsport-simulated environment.

METHODS: Four healthy, non-heat acclimated participants (24±2 years, 71.8±13.9 kg) completed four trials in a double-blind randomised cross-over design. Participants ingested 300mg/kg BM of SC or placebo with 25 mL/kg BM of room temperature water 150 min before a driving simulation, both with and without 10g/kg BM ice slurry consumed in the final 30 min. Simulated driving was conducted in an environmental chamber at 35 °C and 30 % humidity whilst wearing a full-body fire-retardant suit, racing overalls, gloves, boots, balaclava and helmet. Changes in T_{core} (ΔT_{core}) and plasma volume (ΔPV) were assessed pre- and post-30 min ice slurry stage. Whole-body sweat rate (WBSR), back local sweat rate area under the curve (LSR AUC), ΔT_{core} and ΔPV were measured across 60 min of simulated driving conditions.

RESULTS: There was a significant condition effect for change in T_{core} (ΔT_{core}) during the 30 min slurry ingestion period ($F(3,8) = 9.023, P<0.05$). Ice slurry ingestion significantly reduced T_{core} in both conditions compared with the no slurry + placebo condition ($P<0.05$) but not compared to no slurry + SC ($P=0.06$). There were condition effects for ΔT_{core} during the 60 min simulated driving ($P=0.05$) but no interaction effects were observed ($P>0.05$). There were no condition effects for WBSR ($P=0.90$), back LSR AUC ($P=0.11$) and thermosensitivity derived from LSR AUC relative to ΔT_{core} ($P=0.09$) during the simulated driving. There was also no significant condition effect for ΔPV between baseline and post-hyperhydration ($P=0.44$), pre- and post-chamber ($P=0.69$) and baseline to post-chamber ($P=0.14$).

CONCLUSION: Ice slurry ingestion reduced T_{core} prior to simulated driving in the heat. These preliminary data demonstrate potential uses for motor racing athletes.

CONTROLLED HEART RATE STRATEGY TO DETERMINE THE INTENSITY OF A PRACTICAL HEAT ACCLIMATION PROTOCOL UNDER PERSONAL PROTECTIVE EQUIPMENT

DEROUCK, T., DESHAYES, T., GAGNON, D., MARCEL-MILLET, P., GENDRON, P.

UNIVERSITÉ DU QUÉBEC À TROIS-RIVIÈRES

INTRODUCTION: Heat acclimation (HA) improves heat loss capacity, reduces health risks at work, and enhances performance in hot environments. However, existing HA are impractical for most occupational and sports contexts due to their reliance on specialized infrastructure and expensive measurement tools. Therefore, it is relevant to develop a HA protocol based on accessible and applicable methods for these contexts. A pragmatic approach would be to (1) induce thermal stress through exercise while wearing a personal protective equipment (PPE) in a temperate environment and (2) assess physiological strain using a percentage of maximal heart rate (%HR_{max}).

Objective: To quantify thermal stress and physiological strain during exercise performed at fixed %HR_{max} in PPE in a temperate environment, and to determine the intensity that maximizes time within a target core temperature range of 38.5–39.5°C, proposed to result in optimal HA.

METHODS: Eleven participants (5 women, 23 ± 3 years old) had their maximal heart rate measured during a first visit using a VO₂peak test (194 ± 5 bpm, 46.4 ± 6.4 ml·kg⁻¹·min⁻¹), before performing treadmill exercise (60 min at 4.5 km, with an incline modulated as a function of exercise intensity) in a temperate environment (22.7 ± 0.6°C, 27.2 ± 7.9% humidity) at four intensities (70, 75, 80, and 85%HR_{max}) while wearing a PPE (firefighter jacket, pants, hood and gloves). Thermal stress was assessed through intra-clothing temperature and humidity, while physiological strain was quantified using rectal temperature (T_{rec}), skin temperature, and heart rate.

RESULTS: Thermal stress, assessed via intra-clothing temperature ($33.7 \pm 0.5^{\circ}\text{C}$) and relative humidity ($70.7 \pm 10.0\%$), did not differ between conditions ($p=0.22$). Final Trec values differed between the four intensity conditions ($p<0.01$), with higher values during 80% and 85%HRmax ($p<0.05$) compared to 70% and 75%HRmax. Mean Trec values were $38.3 \pm 0.3^{\circ}\text{C}$, $38.6 \pm 0.4^{\circ}\text{C}$, $38.9 \pm 0.3^{\circ}\text{C}$, and $39.0 \pm 0.4^{\circ}\text{C}$ for the 70, 75, 80, and 85%HRmax conditions, respectively. During 85%HRmax, two participants stopped exercising after exceeding the pre-determined safety threshold of 39.5°C , and one additional participant abandoned due to an inability to continue exercising. The time spent in the target hyperthermia range ($38.5 < \text{Trec} < 39.5^{\circ}\text{C}$) differed across conditions ($p<0.01$), with the longest duration observed during 80%HRmax (27 ± 14 min) compared to 70% (7 ± 12 min, $p<0.01$) and 75%HRmax (11 ± 15 min, $p<0.05$), while 85%HRmax was not different (25 ± 12 min, $p=0.95$).

CONCLUSION: Exercise intensity influences physiological strain during 60 minutes of treadmill walking while wearing a PPE in a temperate environment. An intensity of 80%HRmax optimizes time spent at the target core temperature associated with HA without exceeding safety thresholds and maximizing tolerance. These findings provide a foundation for testing the efficacy of accessible and practical HA protocols for occupational and athletic settings.

THERMOREGULATORY, CARDIOVASCULAR AND BIOMECHANICAL RESPONSES OF AMATEUR RUNNERS AT A LARGE CITY MARATHON IN TEMPERATE CONDITIONS

JAMES, C., CHAN-TWIST, I., PAPAMICHAPOPOULOS, C., OBRATOV, D., HU, N., CHAN, J., POLOMOSHNOV, D., KILLOUGHERY, I., VERDOUKAS, P., PEÑA IGLESIAS, D., MILLER, M., PITSILADIS, Y.

HONG KONG BAPTIST UNIVERSITY

INTRODUCTION: Exertional heat illnesses (EHI) remain frequent in endurance sports, posing significant risks to amateur and elite athletes. With climate change, the challenge of safely managing sporting events is set to continue. The current approach for many sports is event modification and/or rescheduling based on environmental conditions. However, exercise intensity is the major determinant of EHI risk, rather than environmental heat stress. Therefore, monitoring individual heat strain is more suitable for understanding risk associated with different sporting activities, varied individual characteristics, and when appraising sporting heat stress policies. Addressing this need, we report thermoregulatory, cardiovascular and biomechanical responses of amateur runners completing in 10 km (10KM), half-marathon (HM) and marathon (M) events in Hong Kong in February 2025. The study aims to differentiate heat strain across different event lengths and identify individual characteristics that exacerbate this strain. We hypothesised the greatest heat strain will be experienced in the 10KM.

METHODS: Eighty-five runners (age 38 ± 13 [15–65] years) ran the 10KM ($n=22$; 8 female, 14 male. Body fat percentage [BF%] $23 \pm 12\%$), HM ($n=32$; 14 female, 18 male. BF% $19 \pm 8\%$) and M ($n=31$; 9 female, 22 male. BF% $15 \pm 6\%$). Self-predicted race times were; 10KM 62 ± 10 min, HM 02:00±00:25 hours and M 03:49±00:40 hours. Runners ingested two telemetry pills to monitor core body temperature (TCORE; pill 1 before bed, pill 2 upon waking on race day) and wore a heart rate monitor (HR), with attached skin temperature sensor (TSKIN). Running biomechanics and kinematics were monitored using shoe-worn sensors. Environmental conditions were measured every 5 km using portable meteorological stations. Races began between 05:30-08:30, with course closing at 14:00. Data were integrated by a bespoke app on a smartwatch and streamed in real-time. Upon finishing, participants indicated EHI symptoms experienced during the race and provided a fingertip blood sample to assess markers of gut injury. Runners completed further surveys 12 hours, 24 hours, 48 hours and 72 hours post-race to track recovery status.

RESULTS: Environmental conditions from 10 weather stations were; ambient temperature $17.9 \pm 3.2^{\circ}\text{C}$, relative humidity $42.6 \pm 9.6\%$ and Wet Bulb Globe Temperature $12.5 \pm 2.9^{\circ}\text{C}$. Preliminary results indicate that the highest TCORE recorded was 40.37°C in the 10KM race, while no runners in the half marathon (HM) or marathon (M) exceeded 40°C . Notably, no cases of exertional heat illness (EHI) were reported.

CONCLUSION: We monitored a large cohort of amateur athletes during a large city marathon to understand the thermal strain and EHI risk factors, including individual characteristics and event distance. Ongoing development of multi-sensor approaches, encompassing thermal, cardiovascular, sudomotor, and biomechanical monitoring, combined with multi-location weather data, is needed to understand EHI risk across various sports for amateur and elite athletes.

THERMONEUTRALITY BLUNTS AEROBIC EXERCISE TRAINING-INDUCED MITOCHONDRIAL ADAPTATIONS IN MOUSE SKELETAL MUSCLE AND ADIPOSE TISSUE

KUPRATY, A., SIMIONATO BRUNETTA, H., DESORMEAUX, G., COYLE-ASBIL, B., HOLLOWAY, G.

UNIVERSITY OF GUELPH

INTRODUCTION: Aerobic exercise induces mitochondrial biogenesis and increases oxidative phosphorylation (Holloszy, 1967) in several tissues (e.g., adipose tissue, skeletal muscle, heart). However, aerobic training studies in rodents are often conducted at room temperature (22°C) resulting in thermogenic stress that may impact training adaptations. Specifically, housing mice at thermoneutrality seems to generally dampen the magnitude of training adaptations, however, its effect on mitochondrial adaptations to exercise remains unclear (McKie et al., 2019). Given this knowledge gap, we examined the impact of exercise training on mitochondrial bioenergetics in brown adipose tissue (BAT), inguinal white adipose tissue (iWAT), and permeabilized skeletal muscle fibres in mice housed at thermoneutrality.

METHODS: Male C57BL/6N mice housed at thermoneutrality (28°C ; $n=22$) were randomly assigned to remain sedentary or undergo a 4-week moderate-intensity endurance training protocol, which consisted of forced treadmill running

(3x/week, 60% of maximal baseline speed, increasing weekly) and free access to voluntary running wheels. Whole body energy expenditure and adipose tissue morphology were assessed in addition to mitochondrial respiratory function in permeabilized skeletal muscle fibres, BAT and iWAT. As a measure of in vivo mitochondrial function in BAT, we also assessed whole-body energy expenditure following a single dose of CL-316, 243, a highly specific beta 3-adrenergic agonist that stimulates BAT thermogenesis.

RESULTS: Trained mice had improved exercise performance (run time to exhaustion) but training did not alter resting or CL316, 243-stimulated whole-body energy expenditure. In skeletal muscle, mitochondrial ADP sensitivity and creatine-supported respiration were not altered. In BAT and iWAT, there were no differences in basal (state 2), maximal (state 3) or uncoupled (2,4-dinitrophenol) mitochondrial oxygen consumption following training. This response was not affected by the addition of creatine to optimize ADP transport or by GDP to inhibit uncoupling in BAT.

CONCLUSION: Despite an increase in exercise performance following training at thermoneutrality, in vivo indices of BAT thermogenesis and in vitro assessments of mitochondrial bioenergetics in several tissues were unchanged. This suggests that the sustained performance benefit of training in thermoneutral conditions is likely not due to functional adaptations in skeletal muscle, iWAT or BAT mitochondria.

EFFECT OF EXERCISE TEMPERATURE ON THE CONTINUOUS MEASUREMENT OF THE NaCl CONCENTRATION IN SWEAT IN TRAINED MALE ATHLETES

FERRARI, A., BAQUET, G., RANCE, M., SORG, M., BERTHOIN, S., GARNIER, J.P., RATEL, S.

UNIVERSITY OF LILLE: UNIVERSITE DE LILLE

INTRODUCTION: The human body primarily regulates core temperature through evaporation sweat loss, especially during physical activity. Previous studies suggested that an increased sweat rate (SR) leads to higher sweat-related sodium chloride (NaCl) concentration due to reduced NaCl reabsorption in sweat glands. In the heat, a rise in body core temperature and loss of body water via sweating are consequences of prolonged exercise. However, current methods for assessing SR and NaCl concentration in sweat do not allow real-time measurement, limiting the ability to make immediate adjustments in hydration or electrolyte management. This study aimed to compare the impact of ambient temperature on the evolution of SR and NaCl concentration in sweat using the BeOne armband, a device that continuously measures sweating throughout exercise in real time.

METHODS: Fifteen well-trained male athletes (age: 19.3 ± 5.1 y; VO_2max : 71.1 ± 5.0 mL.min⁻¹.kg⁻¹) performed a 45-minute cycling exercise at 50% of power output at which VO_2max was reached under two environmental conditions: a thermoneutral climate (N: $24 \pm 1^\circ\text{C}$, $30.0 \pm 3\%$ RH) and a hot climate (H: $35 \pm 1^\circ\text{C}$, $30 \pm 3\%$ RH). During sessions NaCl concentration was continuously monitored using the BeOne armband, while whole-body SR was assessed via body mass changes. Core temperature (T_c), skin temperature (T_s), heart rate (HR), and heat production (indirect calorimetry) were also measured.

RESULTS: Whole-body SR was significantly higher in H than N (969 ± 363 vs. 634 ± 195 mL, $p < 0.001$, respectively). NaCl concentration in sweat was significantly greater both at the onset (40.7 ± 16.5 vs. 33.8 ± 8.4 mmol.L⁻¹) and at the end of the cycling exercise (59.3 ± 23.8 vs. 44.8 ± 15.8 mmol.L⁻¹) in H compared to N ($p < 0.001$ for both). The rate of increase in NaCl concentration was also significantly higher in H than N (0.56 ± 0.27 vs. 0.34 ± 0.32 mmol.L⁻¹.min⁻¹, $p < 0.001$, respectively). T_c peak (38.34 ± 0.36 vs. $37.94 \pm 0.38^\circ\text{C}$), T_s peak (36.73 ± 0.38 vs. $34.89 \pm 0.54^\circ\text{C}$), HR (163 ± 11 vs. 144 ± 11 bpm) and rating of perceived exertion (14.6 ± 2.1 vs. 12.7 ± 2.4) were significantly higher at the end of exercise in H ($p < 0.001$ for all). Finally, heat production was significantly greater throughout the entire session in H compared to N (530 ± 71 vs. 496 ± 60 kcal, $p < 0.01$).

CONCLUSION: Whole-body SR was associated with increased NaCl concentration in sweat. The progressive rise in NaCl concentration during exercise suggests an overall increase in SR to regulate body temperature and mitigate thermal and cardiovascular strain. These findings contribute to a better comprehension of the association between SR and sweat composition, therefore improving the monitoring of athlete thermoregulation and electrolyte balance in real time exercise conditions.

CAN CIRCUMSTANCES OR A RECURRENCE OF EXERTIONAL HEAT STROKE PREDICT HEAT INTOLERANCE?

MARCEL-MILLET, P., TUIFUA, L., DEROUCK, T., LEPETIT, B., MALGOYRE, A.

INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES

INTRODUCTION: Exertional heat stroke (EHS) is a medical emergency characterized by hyperthermia ($>40^\circ\text{C}$) and central nervous system dysfunction. During return to duty or play after EHS, heat tolerance tests (HTT) assess thermoregulatory function to determine heat tolerance or intolerance status. However, EHS circumstances are rarely considered, despite they could indicate whether or not a thermoregulatory disorder should be suspected. The study aimed to assess the significance of EHS circumstances on thermal responses during an HTT.

METHODS: Fifty-six participants (5 females) were divided into three groups: eighteen healthy military personnel without a history of heat illness constituted the control group (CONT); twenty-one military personnel with a previous EHS episode with risky conditions (high ambient temperature, high humidity, encapsulated clothing, dehydrated state, etc.) constituted the simple EHS group (SIMP-EHS); seventeen military personnel with a previous EHS episode (or a recurrence) without favorable circumstances constituted the complex EHS group (COMP-EHS). After anthropometric assessments, the final rectal temperature (T_{rec}), whole-body sweat loss and oxygen consumption were measured during an HTT (two-hour treadmill

walking at 5 km·h⁻¹, with a 2% slope, at a temperature of 40°C and 40% relative humidity). Heat tolerance status was analyzed both as a dichotomous variable (heat tolerant versus heat intolerant if Trec failed to plateau at or below 38.5°C) and as a continuous variable (final Trec).

RESULTS: No anthropometric characteristics (age, body mass, body mass index, body fat, body surface area, etc.) differed between groups ($p>0.05$). Heat intolerance was found in 7 out of 18 (39%), 7 out of 21 (33%), and 11 out of 17 (65%) participants in the CONT, SIMP-EHS and COMP-EHS groups, respectively. Final Trec was significantly higher in the COMP-EHS group ($38.8 \pm 0.63^\circ\text{C}$) than in the CONT ($38.3 \pm 0.42^\circ\text{C}$; $p<0.05$) and SIMP-EHS ($38.3 \pm 0.52^\circ\text{C}$; $p<0.01$) groups. Similarly, COMP-EHS final Trec ($39.2 \pm 0.37^\circ\text{C}$) was higher than in the CONT ($38.7 \pm 0.24^\circ\text{C}$; $p<0.01$) and tended to be higher than in the SIMP-EHS group ($38.9 \pm 0.33^\circ\text{C}$; $p=0.083$). Neither sweat loss nor energy expenditure differed between groups ($p>0.05$). Regression analyses identified body fat percentage, sweat loss (in mL·kg⁻¹) and energy expenditure (in W·m⁻²) as significant ($p<0.001$) predictors of final Trec. Moreover, a history of complex EHS was also a significant ($p<0.001$) predictor of final Trec when included in the model, unlike a general history of EHS.

CONCLUSION: Final Trec comparison and regressions analyses indicate altered thermoregulatory function in the COMP-EHS group. In contrast, a history of simple EHS does not appear to predispose individuals to heat intolerance compared to those without a history of heat illness. These findings may have implications for clinical guidelines regarding heat tolerance testing.

HIGH INTENSITY INTERVAL EXERCISE AND HOT WATER IMMERSION FOR OPTIMISING CARDIOVASCULAR HEALTH OUTCOMES

PHILPOT, G., BALTHAZAR, S., PRICE, B., LUCAS, S., COTTER, J., AKERMAN, A., LUCAS, R.
UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Combining exercise and hot water immersion (HWI) may have additive benefits for acute cardiovascular function beyond those demonstrated with HWI alone (1,2). The objective of this study was to assess if a combination of exercise and HWI (ExHWI) augmented cardiovascular responses as compared to time-matched HWI (HWI60).

METHODS: Eleven participants (6 females, 24 ± 5 y, 24 ± 2 kg/m², 38 ± 6 mL/kg/min) completed two pseudorandomised experimental trials. ExHWI consisted of 30 min high intensity interval exercise (5x1 min intervals at 100% Wmax [277 ± 73 W]) interspersed with 4 min active recovery at 35% Wmax followed by 30 min neck-level HWI (41°C). HWI60 involved 30 min neck-level followed by 30 min waist-level HWI. Estimated marginal means of group differences in blood pressure (BP), flow mediated dilation (FMD), plasma volume (PV), mood and psychophysical responses were compared at baseline, during (30 and 60 min) and post-intervention (2, 30, 45, 60 min and 24 h) using linear mixed-effects models.

RESULTS: Rectal temperature increased by $1.6 \pm 0.3^\circ\text{C}$ in ExHWI and $1.3 \pm 0.7^\circ\text{C}$ in HWI60 at 60 min and remained elevated until >45 min-post (all $P<0.01$), with no difference between conditions (all $P>0.99$). Heart rate (HR) increased in both conditions and was higher in ExHWI than HWI60 from exercise onset until 2 min-post (all $P<0.01$). Sweat loss was not different ($P=0.71$) between ExHWI (0.9 ± 0.4 kg) and HWI60 (0.8 ± 0.3 kg). Compared to baseline, PV was decreased at 30 min-post in HWI60 ($-8 \pm 6\%$, $P<0.01$) but not in ExHWI ($-3 \pm 3\%$, $P>0.99$), and no difference was observed at 24 h-post (both $P>0.99$). Compared to baseline, exercise increased SBP at 30 min in ExHWI (114 ± 11 vs. 175 ± 24 mm Hg; $P<0.01$), whereas DBP was decreased at 30 min in HWI60 (63 ± 7 vs. 40 ± 5 mm Hg; $P<0.01$). In both conditions, DBP was decreased at 60 min (ExHWI: 40 ± 4 , HWI60: 38 ± 5 mm Hg) and 2 min-post (ExHWI: 41 ± 6 , HWI60: 45 ± 8 mm Hg, all $P<0.01$). SBP and DBP were not different from baseline at 45 min-post (ExHWI: 110 ± 10 , 63 ± 5 mm Hg, HWI60: 108 ± 10 , 64 ± 7 mm Hg) or 24 h-post (ExHWI: 111 ± 10 , 64 ± 6 mm Hg, HWI60: 111 ± 11 , 62 ± 7 mm Hg; all $P>0.99$). Brachial artery diameter and antegrade shear rate were elevated at 30 min-post in ExHWI, with retrograde shear rate decreasing at 30 min-post in both conditions (all $P \leq 0.02$). FMD and mood were unaffected across both trials. Perceived temperature increased similarly between conditions while thermal discomfort was slightly higher in ExHWI than in HWI60 at 60 min ($P=0.02$).

CONCLUSION: Both ExHWI and HWI60 elicited similar levels of thermal strain, but ExHWI resulted in a greater cardiovascular load, indicated by a higher HR response and more pronounced blood flow/pressure perturbations. Despite this, ExHWI did not augment BP or FMD responses 24 h-post. Further work is needed to identify if combining exercise with HWI has additional benefits over exercise or HWI alone.

ASSOCIATIONS OF PHYSICAL ACTIVITY, SEDENTARY BEHAVIOUR AND DIFFERENT TYPES OF SMARTPHONE APPS USAGE AMONG CHINESE YOUNG ADULTS

XIANG, F., MENG YAO, S.

SHANGHAI JIAO TONG UNIVERSITY

Background: Previous studies suggest that smartphone use does not inherently reduce physical activity or increase sedentary behavior among young adults. The impact on health behaviors varies by app type. This study examines the association of physical activity, sedentary behavior and use of different smartphone apps among young adults.

Methods: This study followed 345 university students aged 18-22 for 7 days. Physical activity (PA), and sedentary behavior (SB) were objectively measured using the ActiGraph GT3X-BT accelerometer. Smartphone app usage was tracked via objective daily survey logs. After the 7-day tracking period, semi-structured interviews were conducted to gather detailed information on app usage and physical activity. Data analysis was performed using SPSS 26.0 and R software.

Results: In 248 participants (139 males, 109 females), Males had higher daily energy expenditure and more SB time compared to females, who spent more time in light-intensity physical activity (LPA) but less in vigorous-intensity physical activity (VPA). Males showed a positive correlation between entertainment app usage and SB time ($r = 0.271$, $p = 0.017$) and a negative correlation with sedentary interval (SI) ($r = -0.266$, $p = 0.019$). In females, social app usage correlated with increased LPA ($r = 0.321$, $p < 0.001$) and VPA was positively correlated with screen time (ST) ($r = 0.195$, $p = 0.042$). App usage also influenced SB patterns, particularly in active individuals. After controlling for confounding factors, gaming app usage in males who inactive decreased LPA (0.341 min, $p = 0.036$). In females, social app usage increased LPA (0.112 min, $p = 0.018$) but decreased VPA (0.012 min, $p = 0.011$) in those who inactive. ST was linked to an increase in SB time and to a decrease in SI time in both genders.

Conclusions: Complex associations between the different smartphone apps, sedentary behavior and physical activity in young adults, the type of app used is likewise crucial as screen time.

THE RELATIONSHIP BETWEEN 24-HOUR BEHAVIOURS AND WORK PRODUCTIVITY ON THE DAY WORKING FROM HOME

ZOU, C.

UNIVERSITY OF TSUKUBA

INTRODUCTION: After the outbreak of COVID-19, working from home (WFH) has become a prevalent working pattern in the UK, introducing both challenges and opportunities for employees' daily movements and work outcomes. This cross-sectional study aimed to investigate the relationship between 24-hour behaviours, including sleep, sedentary behaviour, and physical activity, and work productivity among University of Edinburgh staff working from home.

METHODS: Forty-seven participants (72.3% female, 85.1% white) who worked remotely at least one day per week completed a self-reported questionnaire. The online questionnaire collected demographic information, and data from the Past-day Adults' Sedentary Time Questionnaire, the International Physical Activity Questionnaire, and the Health and Work Questionnaire. Descriptive statistics, independent t-tests, and Pearson correlation analyses were performed to explore associations between 24-hour behaviours and productivity outcomes.

RESULTS: The majority of participants (74.5%) reported sleeping more than 7 hours during WFH days; however, 95% experienced poor sleep quality. Sedentary behaviour levels were high, with 93.6% of participants spending over 8 hours sedentary, whilst most staff (89.4%) met physical activity guidelines of 150 minutes of moderate-to-vigorous physical activity (MVPA) per week. However, no statistically significant correlations were observed between 24-hour behaviours and productivity ($p > 0.05$).

Conclusion

While no significant associations were identified, these findings highlight high levels of sedentary behaviour and poor sleep quality among WFH employees. As hybrid working patterns become increasingly common, further research is needed to explore the nuanced impacts of 24-hour behaviours on productivity and to develop targeted interventions promoting active lifestyles during remote work.

SOCIODEMOGRAPHIC DIFFERENCES IN TIME USE OF 24-HOUR MOVEMENT BEHAVIOURS: A DESCRIPTIVE STUDY AMONG JAPANESE ADULTS

LIU, Y., SHIBATA, A., ISHII, K., KUROSAWA, S., OKA, K.

WASEDA UNIVERSITY

INTRODUCTION: Adults' daily time spent in sedentary behaviour (SB), sleep, light-intensity physical activity (LPA), and moderate-to-vigorous physical activity (MVPA) is collectively termed 24-hour movement behaviours in a compositional nature. Differences in individuals' daily behaviours across their sociodemographic factors are linked to health inequalities. Therefore, understanding these differences using a compositional data analysis approach is critical for addressing health disparities.

METHODS: This cross-sectional study analysed data from 2,718 Japanese adults aged 20–59, collected via an online survey conducted in 2023. Participants' time spent in 24-hour movement behaviours (SB, Sleep, LPA, and MVPA) was expressed as geometric means. Compositional multivariate analysis of covariance (MANCOVA) was used to compare behaviour components across sociodemographic factors (sex, age group, education levels, marital status, living arrangement, annual income, occupational type, and residential area). Back-transformed isometric log-ratio differences with bootstrap 95% confidence intervals were calculated to identify significant differences in movement behaviours between factors' levels. [1]

RESULTS: Participants spent an average of 29.5%, 33.6%, 0.6%, and 36.3% of their day in SB, sleep, MVPA, and LPA, respectively. Significant variations were observed across sex, marital status, living arrangement, and occupation types. Compared with average means, females spent 27.5% less time in MVPA, while unmarried individuals and those living alone exhibited higher SB (+8.9% and +8.9%) and lower LPA (-8.4% and -8.3%). Desk-based workers reported 20.5% more SB, whereas physically demanding jobs were associated with higher MVPA and LPA but reduced sleep time. Although non-significant, trends suggested that individuals with higher education and income levels and those in urban areas were more active.

CONCLUSION: This study first explored the correlates of diverse sociodemographic factors on Japanese adults time use in 24-hour movement behaviours, highlighting the role of sociodemographic factors in shaping time-use behaviours. The present findings underscore the need for targeted public health strategies, such as promoting physical activity in female, socially isolated individuals and reducing SB in desk-based workers, to address health disparities effectively among the Japanese population.

A comparison of standard and compositional data analysis in studies addressing group differences in sedentary behavior and physical activity. *The international journal of behavioral nutrition and physical activity*, 15(1), 53. <https://doi.org/10.1186/s12966-018-0685-1>

ACTIVITY PURPOSE AND SPORTS BEHAVIORAL CHARACTERISTICS OF BEACHBALL PARTICIPANTS

NAKAMURA, Y., TAKEDA, T., KAWANISHI, M.

HOKUSHO UNIVERSITY

INTRODUCTION: Beachball is a minor sport like volleyball that was invented in Asahi Town, Toyama Prefecture, Japan in 1978. It was originally a sport for agricultural workers to relieve back pain, but it has now spread nationwide and is contributing to regional development in various regions. In a previous study, Ingledew & Markland (2008) revealed that sports behavior such as personal attributes and participation frequency differ depending on the purpose of activity in major sports, but there has been no verification of minor sports. The purpose of this study was to clarify the sports behavior characteristics of Beachball participants as a minor sport from the activity purpose, and to contribute to the future promotion of regional sports.

METHODS: The survey was conducted by questionnaire surveying 407 participants of tournaments held in Japan between August and September 2024, and 314 valid responses (77.1%) were obtained. The questionnaires were distributed and collected directly to participants at the reception desk of the tournament. The survey included personal attributes, activity purpose, and sports behavior (number of tournaments participated per year, number of practice sessions, competitive experience, years on a team, and self-evaluation of skills). Activity purpose were classified into four intentional groups (1. enjoyment, 2. winning, 3. health promotion, 4. purpose of life). The χ^2 test and one-way ANOVA were conducted with these as dependent variables and personal attributes and sports behavior as independent variables.

RESULTS: Overall attributes, 47.5% were male and 52.5% were female. The average age was 48.69 years old. The most common activity purpose was for enjoyment group, accounting for 41.4% of the total, followed by the winning group (28.3%), the health promotion group (20.2%), and the purpose of life group (10.1%). In the analysis of activity purpose, attributes, and sports behavior, the first significant difference in attributes was age ($p < .001$), with the winning group being the youngest at 45.15 years old on average compared to the health promotion and purpose in life groups. In terms of sports behavior, there was a significant difference ($p < .001$) in the number of tournaments participated per year, with the winning group participating 7.80 times, which was more than the health promotion group (4.85 times). There was also a significant difference ($p < .05$) in self-evaluation of skills (5-point scale), with the winning group perceiving themselves as having a higher skill level than the health promotion group. There were no significant differences in other sports behavior factors.

CONCLUSION: The relationship between the activity purpose and sports behavior of participants in Beachball, the inclination toward winning was reflected in their sports behavior in the same way as in major sports.

DEVELOPMENT AND EFFECTIVENESS VERIFICATION OF TENNIS PRACTICE SUPPORT SYSTEM USING VR

INOUE, Y., KAWAKUBO, Y.

OSAKA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Many people are aware of their lack of exercise, but find it difficult to exercise continuously. In recent years, sports training has been conducted using Virtual Reality (VR) technology. The advantages of VR include the ability to practice in confined spaces, under any weather conditions, and even alone. Based on the benefits above, we decided to develop a tennis practice support system using VR with the aim of enabling enjoyable and continuous physical activity. The effectiveness of the developed system was verified by quantifying the hit rate to the racket and the number of successful ball returns to the opponents court. In addition, we also examined the participants' gaze during the tennis exercise.

METHODS: Sixteen university students participated in the experiment. They wore a head-mounted display, held Meta Quest Touch Pro controllers in both hands, grabbed a VR racket, and practiced volleys and strokes. Balls were launched at three-second intervals from a ball launcher in the VR space, and the participants returned the ball to a target on the opponents court. Training consisted of pre-test, practice, and post-test. In the pre-test and post-test, the players played 50 strokes and 50 volleys, respectively. In the practice session, they played 100 strokes and 100 volleys. Two modes of target movement were conducted: the first was a mode in which the target moved randomly for each ball, and the second was a focused mode in which the target moved every five balls so that the participants could concentrate on one spot at a time. The participants were divided into two groups: a random group and a focused group. The measurement items were eye gaze, electrocardiogram, stroke and volley performance, and responses from post-experience questionnaire.

Results and Discussion: Both groups showed a significant increase in stroke and volley scores in the post-test compared to the pre-test. However, no significant differences were observed between the groups. The increase in scores in the post-test suggests that the developed practice system may have been effective. However, since no significant differences were shown between the target movement modes, it is necessary to study more effective ways of moving the target. The results of the eye movement showed that the players took a closer look at the racket and the ball launcher than the target with significant differences in the eye movement between these objects. Both groups tended to focus more on the target in the post-test than in the pre-test. The heart rate during the exercise showed an increase of about 10 beats per minute compared to that at rest. However, some participants reported that the intensity of the exercise felt low in the post-experience questionnaire, suggesting the need to increase the intensity of the exercise by randomizing the position of the ball.

GREEN PHYSICAL ACTIVITY FOR A SUSTAINABLE ENGAGEMENT TO TRAINING AND REDUCED HEALTH INEQUALITIES

GARNIER, S., JOFFROY, S., AUNEAU, G., MAURIEGE, P.

UNIVERSITÉ DE TOULOUSE

INTRODUCTION: Sustainable commitment to physical activity (PA) for inactive people is a public health challenge. PA is beneficial to health and well-being and conversely, physical inactivity increases risk for noncommunicable diseases and other poor health outcomes. Brisk walking is considered the most popular, accessible form of physical activity potential to reduce disparities in health related to lack of PA (Lee et al., 2008). The positive long-term effects of an outdoor brisk walking program include maintenance of weight loss, as well as improvements in cardiorespiratory fitness and perceived health. These effects were observed after two years, and a large proportion of the women continued to practice PA at least 60 min/week (Garnier et al., 2024). However, do women continue to exercise outdoors or indoors? Does their practice depend more particularly on the education level or age? Does the sustained engagement in PA increase social inequalities in health? The aim of this study is to determine the location (indoor/outdoor) of PA two years after a brisk walking program once the education level and age are considered.

METHODS: Among the 91 sedentary postmenopausal (61 ± 6 yr) women with moderate obesity ($BMI = 30 \pm 5$ kg/m²), 30 % had primary education level, 56 % secondary education level, and 14 % higher education level. Participants were subjected to a 16-week outdoor walking program (green PA) (3 sessions of 45 min/week at 60 % of their heart rate reserve). Two years later, women were asked additional questions about the nature and duration of the physical activity performed. Categorical variables were analyzed using chi-square test.

RESULTS: Results from the additional questions asked about PA engagement two years later showed that among the 91 women, 59 practiced outdoor PA. Among them, 55 continued to walk regularly and 4 combined walking and running; 6 practiced indoor (exercising consisting of warm-up, full body exercise, coordination, balance, stretching (90 min/week)) and outdoor PA (walking (45 min/week)); 5 women practiced indoor PA exercising only (120 min/week) and 21 women no longer practiced. No significant differences were observed once the education level and age were considered.

DISCUSSION: Our data show long term engagement in outdoor PA two years after a brisk walking program, without any increase in social inequalities in health. In conclusion, green PA leads to long-term engagement in PA.

EXPLORING TEACHER PRACTICE IN THE ACTIVE SCHOOL PROGRAM, "RUN, JUMP & FUN", IMPLEMENTING EXTRA DAILY MODERATE-TO-VIGOROUS PHYSICAL ACTIVITY IN 3RD-GRADE CLASSES

SOHL JEPPESEN, L., SANDFELD, J., BUGGE, A.

UNIVERSITY COLLEGE COPENHAGEN

INTRODUCTION: Schools are considered a favorable setting for engaging all children in physical activity (PA). PA can potentially enhance childrens fitness, well-being, and learning. However, to achieve these benefits, it is essential to provide feasible interventions that teachers are capable of implementing. This study aimed to explore how teachers adopted and implemented a school-based intervention for 3rd-grade students, incorporating daily sessions of moderate-to-vigorous physical activity (MVPA).

METHODS: An intervention, "Run, Jump & Fun", consisting of 4 x 30 minutes per week, was implemented in the school day for one school year. The intervention characteristics were MVPA with educational goals underpinning the activities, such as self-determination and cooperation among the students. Teachers received training in the intervention elements throughout the school year, with three courses lasting a total of 15 hours. Five semi-structured interviews were conducted with participating teachers (n=6) at four different schools at the end of the school year. The interviews were transcribed using the AI-driven transcription tool Good Tape (goodtape.io, Denmark) and manually adjusted for errors by the first author. The interviews underwent a thematic analysis across the constructs of implementation outcomes of adoption and implementation and their impact on students in 3rd-grade.

RESULTS: Three overarching themes emerged through the analysis: 1) Teacher practice of implementing MVPA, covering successes and failures, the "golden activities," time constraints, sustainment, and personal drive for the intervention; 2) Adoption of daily activities, covering the use of movement and sports pedagogy and the affordance of tools and materials; and 3) The interventions impact on students, revealing students attitudes, physical and mental progression, and general development.

Discussion: The three themes covered issues concerning positive experiences enabling the new practice and only a small number of negative experiences perceived as barriers. Teachers reported positive outcomes regarding students being more active and robust in physical activities with peers. Teachers enjoyed initiating and developing activities with MVPA and felt that they progressed in their profession. Teachers reported challenges with appropriateness concerning the schools time allocation and curricular demands.

Some teachers expressed an ambition to better integrate the intervention into their academic teaching since the schools key purpose is to educate students academically.

CONCLUSION: Overall, the intervention was perceived as feasible and valuable, particularly concerning childrens general development and physical activity levels. Teachers experienced a lack of time in the schedule to incorporate the effort and desired an intervention focusing more on learning at the expense of MVPA.

RESEARCH ON THE OPTIMAL PATH OF FUNDING SUPPLY FOR PUBLIC SPORTS SERVICES IN SHANGHAI BASED ON THE LAGRANGE MULTIPLIER METHOD

HAONAN, L., YUAN, L., JIANBO, Z., ZIXI, G., SHAOHUA, Z.

CHINA UNIVERSITY OF GEOSCIENCES

INTRODUCTION: As an important part of the public service system, public sports service is an important means to improve the quality of life and health of residents. In the process of accelerating the construction of a world-famous sports city in Shanghai, public sports services have ushered in the development opportunities, but the existing supply structure is single and overly relies on tangible services and other problems, which are not able to effectively meet the needs of the public. This paper takes Shanghais public sports services as the research object, focusing on how to optimise the proportion of resources allocated to tangible and intangible public sports service provision under the limited financial budget, exploring the path to improve the overall effectiveness of public sports services, and providing scientific basis and policy suggestions for building a higher level of public fitness service system for the whole population.

METHODS: Based on the supply and demand theory and Pareto optimality theory, and combining the Lagrange multiplier method and the multi-dimensional mathematical optimisation model of Cobb-Douglas production function, the study follows the principle of 'problem diagnosis - theoretical assumptions - variable construction - model analysis Following the logical framework of 'problem diagnosis-theoretical assumptions-variable construction-model analysis-application analysis', and combining quantitative methods such as multiple regression analysis and correlation test, we extract the interactions among variables and their effects on the overall utility, and finally construct a functional model with multiple constraints to describe the trade-offs among various elements in the process of optimising the supply of facilities, and put forward a proposal for public sports service supply optimisation based on the Pareto optimisation theory. The optimal solution for the supply of public sports services is proposed based on Pareto optimisation theory.

RESULTS: This study concludes that the optimal allocation of funding for tangible and intangible service provision is approximately 5,182,500 yuan for tangible public sports services and 16,722,100 yuan for intangible services, with a ratio of approximately 1:3.23. This result suggests that with a limited fiscal budget, the government should prioritise increasing funding for intangible public sports services in order to maximise utility.

Discussion: ① The diminishing marginal utility of tangible service supply is significant. ② Intangible service allocation is the key to utility maximisation. ③ Multiple driving forces drive the transformation of financial structure: from 'hardware' to

'software'. ④ The government should optimise its budget allocation strategy to give priority to the provision of intangible services. In conclusion, this study provides a theoretical basis and a practical path for the transformation of the public sports service provision model, emphasising the synergistic development of maximising residents utility and social benefits through strategic investment in intangible services.

THE INFLUENCE OF AESTHETIC-CULTURAL DANCE MEDIATION ON BODY IMAGE AND SELF-ESTEEM IN PEOPLE WITH OBESITY: RESULTS OF AN INTERVENTION STUDY

HEYN, L., RUDI, H.

JOHANNES GUTENBERG-UNIVERSITÄT MAINZ

Background: Dance with an aesthetic-cultural approach (Rudi, 2021) enables people to engage directly and creatively with movement and their own body. This non-verbal experience allows for critical-reflective self-awareness and supports people in developing a personal connection to their movement and sensation (Kappert, 1990). In particular, for obese individuals who have difficulties in body perception (Syper et al., 2023), it opens up the possibility of rediscovering vibrant physicality and identity and of distancing themselves from physical discomfort. These experiences are relevant in the context of body image and self-esteem (ibid.), because body image influences affective attitudes and emotional well-being, which in turn affects self-esteem as a stable trait, well-being and self-satisfaction (Frey, 2016).

Method: The intervention study in a mixed-method design aims to use semi-structured guided interviews, body image drawings created by subjects to visually capture their individual feelings, and diary entries for reflection to examine the development of subjective attributions of meaning and to assess the influence on body image and self-esteem.

Results: Initial results show a positive effect of the dance intervention on body perception and emotional experience. Participants reported an improved connection to their own body and increased self-acceptance. The detailed analysis of the data and an insight into the research results of a more extensive study based on this research will be presented in the lecture.

Conclusions: The results show that creative movement classes can promote emotional well-being and contribute to positive self-perception.

DID PHYSICAL ACTIVITY, SLEEP, AND MENTAL HEALTH IMPROVE AMONG CHINESE UNIVERSITY STUDENTS IN THE POST-COVID-19 ERA? A LONGITUDINAL COHORT STUDY

WANG, H., DING, Y., DAI, Y., FAN, Z., WEN, S., WANG, X., YUAN, J., WU, Y., YU, L.

BEIJING SPORT UNIVERSITY

Background

The COVID-19 pandemic seriously impacted peoples lifestyles, leading to changes in physical activity, sleep and mental health. This study aimed to assess the recovery of these indicators in Chinese university students post-COVID-19 pandemic, and explore the association between lifestyle changes and psychological problems.

METHODS: A two-wave longitudinal study was conducted with 2,748 college students in Hebei, China. Self-report questionnaires measured physical activity, sleep and psychological variables (depression, anxiety symptoms, and perceived stress) in 2022 and 2024. McNemar chi-square test compared differences between the two waves. Additionally, univariate and multivariate logistic regression analyses were performed to examine the independent and joint associations between changes in lifestyle behaviors and psychological problems across this period.

RESULTS: Proportion of physical inactivity decreased from 22.5% to 16.2%, and poor sleep quality reduced from 18.3% to 16.2% after the pandemic ($P < 0.05$). Depression and anxiety also declined ($P < 0.05$), while perceived stress remained high (64.5%). Compared to consistently inactive students, those becoming physically active (depression OR = 40, anxiety OR = 0.34, stress 0.56) and those persistently active (depression OR = 0.43, anxiety OR = 0.38, stress 0.47) had reduced psychological symptoms. However, after adjusting for confounders, the association between improved physical activity and mental health problems was insignificant ($p > 0.05$). Improved sleep (depression OR = 0.42, anxiety OR = 0.24, stress 0.42) and consistently good sleep (depression OR = 0.20, anxiety OR = 0.20, stress 0.37) also demonstrated a protective effect after fully adjusting for demographics and socioeconomic status.

Conclusions

This study found that high perceived stress persisted. Although physical activity improved across this period, its change was not significantly associated with mental health after adjustments. However, improved sleep quality was significantly associated with reductions in depression, anxiety, and perceived stress. These findings highlight the importance of sleep and physical activity in mental health recovery post-pandemic and the need for targeted interventions.

EMPOWERING/DISEMPOWERING MOTIVATIONAL CLIMATES, PSYCHOLOGY SAFETY, AND THE QUALITY OF ATHLETE ENGAGEMENT IN SPORT

DUDA, J., MOORE, W.

UNIVERSITY OF BIRMINGHAM **EAST CAROLINA UNIVERSITY

INTRODUCTION: Grounded in the theoretically integrated framework of the motivational climate (Duda, Balaguer & Appleton, 2024), research has found athletes to report greater well being and exhibit more adaptive engagement in sport when the coach-created climate is empowering. Disempowering climates have been linked to athlete ill-being and desires to discontinue one's involvement. This study investigated whether differential mental health and participation-related outcomes (enjoyment, commitment, dropout intentions) associated with empowering and disempowering motivational climates are explained (mediated) by the degree to which the coach creates an environment marked by 'psychological safety.' In psychologically safe sporting environments (Vella et al., 2022), there is open communication and athletes feel safe and able to take interpersonal risks including talking to and receiving support from the coach about mental health issues.

METHODS: 516 participants (45% women; M age = 21.3 yrs) British athletes who competed in a variety of sports at the local community (25%), regional (44%), national (26%), and international (6%) levels completed an online survey comprising validated scales tapping the targeted variables.

RESULTS: All scale scores had acceptable reliability ($\alpha > .70$). A path analysis was conducted; direct and indirect effects were tested for significance at $p < .01$. An empowering motivational climate significantly predicted a perceived psychologically safe environment ($B = .59$), which positively predicted enjoyment ($B = .93$) and commitment to one's sport ($B = .59$) and negatively predicted intention to dropout ($B = -.91$). The hypothesized indirect relationships to the outcomes via psychological safety were supported. A disempowering motivational climate did not significantly predict psychological safety but, consistent with previous research, was a negative predictor of enjoyment ($B = -.66$) and commitment ($B = -.80$) and positively related ($B = 1.57$) to dropout intentions.

Discussion: The findings provide an empirical link between the coach-created motivational climate (particularly its empowering features) and the degree to which athletes perceive their coach to create a 'mentally healthy' environment, based on the recent conceptualisation of 'psychological safety' in sport. Athletes were optimally engaged (they enjoyed and were committed to their sport and expressed lower intentions to dropout) when coaches are empowering and they feel their sport experience is psychologically safe. Disempowering coach behaviours linked to indicators of compromised sport participation.

SHOW ME YOUR GAME ! A CREATIVE PROTOCOL ON ATHLETES PERCEPTIONS DURING «LA FINALE DES JEUX DU QUÉBEC»

STOLOFF, S., GIRARD, S., ROSS, A., RIVARD, M.C., LEMOYNE, J.

UNIVERSITÉ DU QUÉBEC À TROIS-RIVIÈRES

Despite the importance of organized sports among young Quebecers, a number of issues are leading to their decline during adolescence. Youth participation in organized sports is linked to indicators of mental health and well-being, yet competitive sporting events can be the source of increased stress and may also be responsible for an increase in anxiety trait in young athletes. Self-determination theory, achievement goal theory and well-being theory, serve as theoretical underpinnings. The general objective of this project is to document, according to the athletes perception, the quality of their experience during the Finale des Jeux du Québec on four levels : emotional (e.g. well-being, pleasure, pride), social (e.g. quality of relationships), motivational (e.g. satisfaction of needs, climate) and sport related accomplishment (e.g. performance, feeling of sporting competence). This general objective is broken down into three sub-objectives: 1) identify the athletes' level of appreciation at the competitive event ; 2) identify the quality of their experience from an emotional, social, motivational and sporting point of views; and 3) describe the athletes experience during the event. The competitive sporting event is the 59th Finale des Jeux du Québec, where near 3000 athletes, between 12 and 17, will be invited to participate. For the planned methodology, athletes will be invited to participate in six different creative methods for data collection stations (S), four of which will be located in the Athletes Village (S1 - Judge your Games, S2 - Paper pellet, S3 - Press Conference, S4 - Photo Booth) and two in the competition sites (S5 - Vox pop, S6 - Answers for the Mascot). The main results of this research project will 1) highlight the factors contributing to positive experiences for athletes participating in a national competitive event, as well as the negative factors to be considered; 2) establish parameters for leading

sports organizations and associations in order to promote a stimulating, respectful and caring environment that suits the developmental level of young athletes; and 3) provide coaches with guidelines for creating motivating environments that foster the satisfaction of young athletes psychological needs and encourage self-determined motivation, well-being and long-term commitment to sport.

THE MEDIATING ROLE OF OPTIMISM AND PESSIMISM ON THE EFFECT OF MENTAL WELL-BEING OF PSYCHOLOGICAL PERFORMANCE IN ACTIVE ATHLETES

ADIOLOGULLARI, I., ARINDI, E., OZGIDER, C.

CANAKKALE ONSEKIZ MART UNIVERSITY

INTRODUCTION: This study aims to examine the mediating role of optimism and pessimism on the effect of mental well-being of psychological performance in active athletes.

METHODS: A total of 739 licensed athletes actively competing in Çanakkale province participated in the study, including 413 men and 326 women aged between 18 and 35. Among the participants, 406 were engaged in team sports (basketball, football, volleyball, handball), while 333 were involved in individual sports (athletics, tennis, boxing, wrestling, taekwondo, swimming). The data were collected using the Mental Well-Being Scale, Psychological Performance Assessment Scale, Optimism Scale and Pessimism Scale. Descriptive statistics, group comparisons, and correlation analyses were conducted using SPSS, while mediation analyses were performed using AMOS. The bootstrap confidence interval method was applied to test the significance of the observed effect sizes.

RESULTS: The findings revealed that optimism and pessimism had an indirect effect on the relationship between mental well-being and psychological performance. Optimism positively influenced psychological performance, whereas pessimism negatively affected it. The analyses indicated that higher levels of mental well-being significantly and positively influenced psychological performance through optimism ($p < 0.05$; $\beta = 0.06$), while pessimism had a small to moderate negative impact ($p < 0.05$; $\beta = -0.06$).

CONCLUSION: These results suggest that promoting optimism and reducing pessimism can play a crucial role in enhancing athletes psychological performance.

ATHLETICS: THE ENJOYMENT OF TRAINING AND COMPETITION

PLESTED-ALVAREZ, M., ALVAREZ-DUQUE, M.E.

UNIVERSITY OF ANTIOQUIA, EDUCATION FACULTY

The study of the psycho-social and emotional circumstances of 12 female athletes between 20 and 73 years old, most of whom participated in a previous study, allowed common concepts to be determined based on the interest expressed in continuing training, even with the weeks of vacation, as an intermediate, at the End of 2024. Their sporting interests vary in different modalities, from short-distance sprints to half-marathon competitions. In comparative function, fatigue or physical discomfort was only a characteristic at the beginning of the process, as it was overcome as the weeks went by.

A fundamental basis was documentary research, supported by authors such as Sandra Rojas, Norbert Stein, Margot Niessen, Budin, López-Cruz, Alvarez-Duque, Galinski & Giraldo-Pérez, and Vallejo & Plested, carried out through tracking and terminological analysis in athletics contexts.

This allowed corroboration of the importance and applicability of emotional intelligence in these sports training processes for athletic competition, that is, intrapersonal and interpersonal elements such as self-regulation of emotions, concentration, self-motivation, and decision-making. These tools are absolutely practical when applied, even in daily life. The specific contexts determined in the preliminary surveys, interviews, videos, photographs, facial and body expressions, and the correlation of the evaluation carried out by the instructor were also studied. These were fundamental in the situated study of the concepts that guided the research, whose methodological development allowed the findings to be ratified.

Some conclusions: The performance comparison between the youngest and the oldest did not show significant progress in terms of reducing running time in training or competitions; it can be said that they continue to be stable in their abilities.

The motivation for athletics for their emotional and physical well-being did make a big difference in the range studied. Throughout the group, there was a noticeable increase in joy, satisfaction, and the desire to continue challenging themselves in their sporting endeavors.

UNLOCKING STUDENT POTENTIAL: THE IMPACT OF NUTRITION, SLEEP, AND WELL-BEING ON ACADEMIC SUCCESS

BARDINI, S., GINESTRETTI, L., LAZZARI, J., SANTAMBROGIO, M.

POLITECNICO DI MILANO

INTRODUCTION: In the context of the LEONARDO project in Politecnico di Milano, we believe that research and education, can be integrated to create productive and virtuous cycles. Expanding this concept, we focus on a third axis: personal well-being. This vision aims to enhance students awareness of their health and abilities, recognizing that personal success is not only defined by technical skills but also by holistic well-being. LEONARDO acknowledges that technical skills are just one component of personal success and integrates well-being into the academic experience. It emphasizes the importance of health, nutrition, and sleep in boosting cognitive performance and overall success. In this context, we conducted a study to explore how an integrated approach can improve cognitive performance and academic success. The goal was to develop a tool that monitors nutrition, sleep, and physical activity, providing a personalized system that supports students well-being. This approach highlights that well-being is not only physical fitness but also cognitive and emotional balance, impacting academic performance and daily functioning

METHODS: LEONARDO emphasizes nutrition and sleep as key to well-being. It organizes sessions with nutritionists to educate students on food's impact on performance. Partnering with a company, it provides pre-prepared lunch boxes, ensuring balanced meals that enhance focus and sleep quality. Proper nutrition stabilizes energy, reducing late-night snacking and improving rest. LEONARDO also researches sleep's impact, equipping students with strategies to optimize rest, boost performance, and well-being.

RESULTS: The study showed a significant improvement in cognitive performance, with notable enhancements in verbal reasoning, memory, and attention. The cognitive tests revealed measurable increases in performance compared to the initial phase, confirming the intervention's effectiveness. Even within the first four weeks, a continuous improvement trend was observed. Data from wearable devices indicated noticeable improvements in sleep quality, including increased sleep duration and reduced nighttime awakenings. These findings highlight the positive impact of the intervention on students overall health. Together, these results underscore the importance of integrating nutrition and sleep as key factors in improving cognitive performance and well-being.

CONCLUSION: This study emphasizes the critical role of nutrition and sleep in supporting cognitive function and overall health. The integrated approach combining personalized nutrition, sleep monitoring, and cognitive assessments proved effective in improving cognitive performance across domains. By enhancing both diet and sleep quality, students experienced better academic performance, improved mental clarity, and better physical and emotional health. These findings suggest that universities should adopt integrated approaches to support students holistic well-being.

PRE-ACL SURGERY PSYCHOLOGICAL DISTRESS AND THE PSYCHOLOGICAL READINESS TO RETURN TO SPORT: THE MODERATION ROLE OF SOCIAL SUPPORT.

MALLIA, L., GALLI, F., MARI, F., DI MAURO, I., DE MARIA, A.

UNIVERSITY OF FORO ITALICO

Literature reported several empirical evidence among the pivotal role of the psychological factors in the athletes' return to sport process after anterior cruciate ligament reconstruction (ACLR), with particular attention to the psychological readiness [1]. The present study explores the role of pre-surgery psychological distress on the future psychological readiness trying to understand the possible moderation effect of social support, also controlling for other important variables in this process, such as fear of movement, self-efficacy on knees function and knee perceived functionality.

Forty-one patients (mean age = 27.7 ± 12.7 years; 80,5% male) who have undergone ACL reconstruction surgery with the same surgical staff were enrolled in the study.

Participants were asked to respond to a set of questionnaires before the ACL reconstruction surgery (i.e., Pre-Surgery Assessment) and after 30 days of the surgery (Post-Surgery Assessment).

Pre-Surgery assessment included: a) psychological distress, namely anxiety and depression (Hospital Anxiety and Depression Scale – HADS); b) perceived social support (Multidimensional Scale of Perceived Social Support- MSPSS). Post-Surgery assessment included: d) psychological readiness in terms of emotions, confidence in performance, and risk appraisal with respect to return to sport after ACL reconstruction (Return to Sport after Injury Scale-ACL– RSI); e) fear of movement, or (re)injury (Tampa Scale of Kinesiophobia - TSK); f) perceived self-efficacy of knee function after ACL injury (Knee Self-Efficacy Scale- KSES); g) symptoms, function, and sports activity (International Knee Documentation Committee -IKDC).

Separated partial correlations were carried out for the two groups (HIGH Vs. LOW perceived support group) connecting psychological distress (i.e., Anxiety and Depression) with the psychological readiness to return to sport statistically controlling for TSK, KSES and IKDC. The partial correlations showed that for patients perceiving relatively HIGH support the psychological distress is not significantly related to their psychological readiness to return to sport 30 days after the surgery ($r = -.271$; $p = .349$). Otherwise, analyzing data of patients perceiving relatively LOW support, clearly emerged that their psychological distress before the ACL surgery is strongly and statistically significantly negatively associated with the readiness to return to sport after the surgery ($r = -.728$; $p = .011$).

The study attested the moderation role of perceived social support that seems to buffer the negative impact of psychological distress on return to sport. Results suggested the importance to consider and care the patients' psychological distress as early as in the first stages of the surgical treatment also fostering the social support around the patient.

IMPACT OF SOCIAL ISOLATION ON PHYSICAL ACTIVITY ADHERENCE: BIOPSYCHOSOCIAL FACTORS INFLUENCING LIFE-STYLES AMONG BRAZILIANS

TAKITO, M., NERI, L., FRANCHINI, I., PRADO, R., SILVEIRA, R.

SCHOOL OF PHYSICAL EDUCATION AND SPORT OF UNIVERSITY OF SAO PAULO

INTRODUCTION: Social isolation during the Covid-19 pandemic has required resilience to adhere to healthy habits, including physical activity levels. This study aimed to assess changes in physical activity adherence during this period, focusing on biological, psychological, and social factors.

METHODS: This cross-sectional study included 3,898 adults (n=2,289 physically active; n=1,609 insufficiently active). Participants completed an online survey assessing self-reported data on anthropometric and socioeconomic variables (sex, age, body mass index [BMI], educational attainment, and fear of COVID-19 effects) and exercise-related behaviors before (Transtheoretical Model of Behavioral Change [TTM], and Physical Activity Enjoyment Scale [PACES] for prior exercise experiences) and during social isolation (beliefs regarding attitude, subjective norm, and perceived control), including physical activity levels in both periods. Statistical analyses compared physically active and insufficiently active groups, while a Multilayer Perceptron algorithm identified the most relevant characteristics for significant comparisons in each group.

RESULTS: Overall, the sample showed a significant decrease in physical activity levels from before to during social isolation ($p < 0.001$ for duration, frequency, and intensity). Except for BMI, the insufficiently active group showed worse values in all variables ($p < 0.05$). The Multilayer Perceptron algorithm ranked the most important characteristics as: 1st) Lower perceived control beliefs, a lower percentage of subjects in the maintenance stage of the TTM, and lower scores on process change; 2nd) Lower educational attainment, a higher rate of subjects exhibiting fear of the effects of COVID-19, and a higher proportion of women; 3rd) Lower attitude beliefs, younger age, lower enjoyment from exercise experiences, lower self-efficacy, lower decisional balance, and lower subjective norm beliefs. The insufficiently active group exhibited greater fluctuation in their physical activity behaviors, while the physically active group showed opposite characteristics during the isolation period.

Discussion: Social isolation measures during the COVID-19 pandemic significantly reduced physical activity levels in Brazil. Individuals with lower self-efficacy and inconsistent exercise routines were more likely to experience a decline in activity levels. To improve adherence, interventions should target individuals who struggle to maintain physical activity, focusing on perceived control, self-efficacy, and exercise enjoyment. Exercise professionals should enhance these psychological characteristics and provide ongoing support to help individuals sustain physical activity during challenging periods like social isolation. These characteristics reflect the need for resilience to maintain exercise routines in adverse situations, such as the pandemic.

SANETPERF: A VIRTUAL REALITY AND MENTAL PREPARATION APPROACH TO ENHANCE MENTAL HEALTH AND SPORTS PERFORMANCE

RIM, R.

INSERM U1075 COMETE - UNIVERSITÉ DE CAEN NORMANDIE

SanEtPerf: A virtual reality and mental preparation approach to enhance mental health and sports performance

Rim Ridane

Inserm U1075 COMETE - Université de Caen Normandie

INTRODUCTION: Optimizing mental health is essential for elite athletes performance, yet it is often overlooked in favor of physical and technical training.

Studies, such as the Drake Football Study, emphasize the need for long-term psychological monitoring in football players (Gouttebauge et al., 2019). Virtual reality (VR) has shown promising results in cognitive and motor training under stress (Neumann et al., 2018), while mental preparation (MP) enhances emotional resilience and cognitive efficiency (Ross-Stewart et al., 2018). The SanEtPerf project aims to evaluate the effectiveness of a combined VR and MP protocol in regulating stress, improving sleep quality, and optimizing sports performance in professional footballers.

METHODS: A sample of male and female football players from Stade Malherbe de Caen (N = 22) will participate in a crossover experimental design. The study consists of three phases:

Pre-test: Collection of anthropometric data, body composition, biomechanical measures, self-reported stress (STAI), and actigraphy-based sleep monitoring.

Intervention: Athletes undergo five VR-based stress exposure sessions, incorporating decision-making under pressure, coupled with mental preparation strategies such as cognitive reframing and attentional control.

Post-test: Reassessment of the same variables to quantify the impact of the intervention on emotional regulation, sleep efficiency, and motor performance.

Expected RESULTS: This study hypothesizes that:

VR exposure combined with MP will significantly reduce stress and anxiety levels in high-pressure environments.

Improved emotional regulation will enhance sleep quality, leading to better recovery.

Athletes will show improved motor performance under stress, as assessed through biomechanical testing.

Discussion: The interplay between mental resilience, stress regulation, and performance optimization is a crucial aspect of high-level sports. Findings from SanEtPerf will contribute to a deeper understanding of how technological and psychological interventions can synergistically enhance athletes well-being and competitive abilities. If validated, this protocol could be applied broadly across various elite sports to provide scalable, personalized training tools for mental health and performance enhancement.

CONCLUSION: By integrating neuroscience, immersive technology, and sports science, SanEtPerf proposes a novel and interdisciplinary approach to optimize both mental well-being and motor performance. These findings will be presented at ECSS 2025 in Rimini, contributing to discussions on VR-based interventions in elite sports training.

EFFECTS OF AN EXERCISE INTERVENTION ON DEPRESSIVE SYMPTOMS, CORTISOL AND SCREEN TIME OF YOUNG ADULTS: A RANDOMISED CONTROLLED TRIAL

ENSLIN, L., KRUGER, A., CZYZ, S., MOSS, S.

NORTH WEST UNIVERSITY

INTRODUCTION: Depression has become a prevalent and debilitating public health condition and the predominant cause of suicide globally, affecting mostly young adults (1). Increased screen time may contribute to depressive symptoms (2). Pharmacological interventions are the first-line treatment, while exercise interventions in adults show promise as an effective alternative treatment option (3). Limited research exists about the effects of a supervised exercise intervention on symptoms of depression, cortisol and screen time in young adults (3). This study aimed to examine the effect of a supervised aerobic exercise intervention on depressive symptoms in young South African adults aged 18-25 years.

METHODS: Seventy-nine (n=79) young adults between 18-25 years (21.8 ± 1.8 years) were randomly assigned to a 12-week supervised aerobic exercise (AE) intervention (n=43) or a control group (n=36). Participants with a Beck's Depression Inventory (BDI)-score of >10 were included in the study. Cortisol, objective habitual physical activity (ActiHeart®) and screen time were measured at baseline and after the 12-week intervention. The intervention consisted of three 60-minute exercise sessions per week. Descriptive statistics and independent T-tests determined statistically significant changes in the outcome variables of the control group compared to the AE group.

RESULTS: The average BDI-score at baseline was 20.95 ± 8.35 points. Cortisol concentrations were 459.7 ± 166.58 nmol/L while engaging in 90.94 ± 86.91 min/week of moderate-to-vigorous physical activity (MVPA) and 3151 ± 2982 min/week screen time. BDI ($t_{52} = -5.45$, $p=0.027$; $d=0.7$) and screen time ($t_{52} = -608.35$, $p=0.005$; $d=0.6$) decreased significantly from pre- to post-intervention in the exercise group compared to the control group. None of the other variables reported significant changes.

CONCLUSION: Twelve weeks of a supervised aerobic exercise intervention significantly decreased depressive symptoms and screen time in young adults. Exercise as a first-line treatment should be considered to prevent detrimental effects of early pharmacological interventions on health outcomes.

NEGATIVE EFFECT OF FMT FROM EXERCISED MICE ON SDS INDUCED DEPRESSION-LIKE BEHAVIOR

WATANABE, C., OYANAGI, E., KONO, T., HAMADA, H., KAWASHIMA, M., AOKI, T., KREMENIK, M.J., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

322 million people worldwide have reported feeling depressed according to the World Health Organization. Recently, we reported that exercise habits may prevent depressive-like behavior via gut microbiota and short chain fatty acids in mice. In this study, we examined whether fecal microbiota transplantation (FMT) from mice with voluntary wheel running could prevent depressive-like behavior in social defeat stress (SDS) mice. Donor mice (C57BL/6, 4week, male) were treated with voluntary wheel running (WR) and sedentary control (C) for 10 weeks. Recipient mice (C57BL/6, 4week, male) were divided into two groups, the CTP and W RTP. The recipient mice were administered an antibiotic solution for 7 days, and then FMT was performed. The CTP group received the transplanted mouse stool from the C donor group and the W RTP group from

the WR donor group once a week for a total of 3 weeks, respectively. After the FMT, the recipient mice were loaded with SDS for 10 days. These SDS treated mice were then subjected to physical interactions with ICR mice for 5 min, and then the mice were housed on the opposite side of a stress cage for 24-h. After that depressive-like behavior in recipient mice was measured using the sucrose preference and the social interaction tests. After these behavioral tests, the mRNA expression of the *Bdnf*, *Tnf- α* , *5-ht 1a* and *Fndc5* in the brains and the fecal microbiota of recipient mice were analyzed. The sucrose preference test, no significant difference between the CTP and WRTP groups was found. However, the social interaction test scores of the WRTP group were significantly lower than that of the CTP group. The *Bdnf*, *Tnf- α* , *5-ht 1a* and *Fndc5* expressions in the hippocampus of the recipient mice showed no difference between the CTP and WRTP groups. The FMT altered the β -diversity from the recipient mice. In the WRTP group, several *f_Lachnospiraceae* were decreased compared to the CTP group. A correlation between the decrease in *Lachnospiraceae* and the decrease in the social score was shown. Furthermore, a positive correlation between the *Ruminococcus* and the *5-ht 1a* expression in hippocampus was observed. Associations between *Lachnospiraceae* and depression or mental disorders were reported. *Lachnospiraceae* and *Ruminococcus* had lower relative abundance in the WRTP group. We previously reported that an increase in *Lachnospiraceae* was observed in exercised mice exposed to SDS. Accordingly, the reason that WRTP did not prevent SDS-induced depressive-like behavior might be because the running wheels were not set up in their cages after the mice were exposed to SDS. On the other hand, recent studies reported direct or indirect results showing the preventive depressive-like behavioral effects of exercise. Protective depression may require not only changes in gut microbiota but also regular exercise. Our results suggested that the FMT from donor mice with wheel running exercise habits might not protect SDS-induced depressive-like behavior.

DYNAMICS OF EFFORT AND PLEASURE APPRAISALS IN THE CONTEXT OF PHYSICAL EXERCISE AMONG INDIVIDUALS WITH SCHIZOPHRENIA

THONON, B., BREVERS, D.

UCLouvain

People diagnosed with schizophrenia tend to be more sedentary and less physically active than the general population. This lack of physical activity contributes to poor physical health and higher mortality rates. Increasing physical activity is therefore essential for this population. However, the perception of physical exertion in individuals with schizophrenia has been largely overlooked in exercise research. Perceived effort plays a crucial role in the pleasure experienced during physical activity, which is a key predictor of long-term engagement.

This study aims to (1) examine the relationships between anticipated pleasure and effort before a walking session, experienced pleasure and effort, prediction errors (i.e., discrepancy between anticipated and actual effort), exertion (heart rate), and walking performance (distance, duration, speed); (2) investigate how these variables influence each other from one session to the next. Participants with schizophrenia (estimated $n = 20$) will complete daily walking sessions (≥ 10 minutes) for 3 to 4 weeks. Each participant will wear a heart rate monitor and use an app (Formyfit) to track walking parameters (distance, duration, speed). Perceived effort and pleasure will be assessed immediately before and after each session.

We will use network analyses (multilevel vector autoregressive analyses for intense longitudinal data) and estimate (1) contemporary and (2) temporal networks to explore the interactions and dynamics between our variables of interest over time. The data are currently being collected, and the results will be presented during the ECSS Congress. Data collection is ongoing, and findings will be presented at the ECSS Congress.

This study will enhance our understanding of how individuals with schizophrenia perceive effort and pleasure during physical activity. By identifying key factors influencing these perceptions, we aim to inform targeted interventions to promote sustained physical activity in this population.

LOOKING FOR RELIEF WHEN YOU EXERCISE COMPULSIVELY – A STUDY REVIEW

JAROCK-LIDZBARSKA, M., WILCZYŃSKA, D., ALARCÓN, D.

GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Exercise addiction is classified as a behavioral problem that can have negative consequences, affecting daily life and optimal functioning. Despite its significant impact on psychological and physical health, there is limited knowledge about effective treatment methods for this condition. The purpose of this review is to present the current state of research on psychotherapeutic interventions for exercise addiction.

METHODS: Scientific electronic databases were searched, and a total of 11 articles that met the inclusion criteria were selected. Three of these publications (published between 1995 and 2023) reported studies that investigated psychotherapeutic interventions—Rational Emotive Behavior Therapy (REBT), Cognitive Behavioral Therapy (CBT), and Motivational Interviewing (MI)—in small groups of participants. Additionally, eight publications (published between 1990 and 2017) described the use of psychotherapeutic interventions (CBT and MI) and were selected for analysis. This review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. The Cochrane Collaboration tool was used to assess the risk of bias and evaluate study quality. Statistical analyses were performed using the R software package.

RESULTS: Rational Emotive Behavior Therapy (REBT), Cognitive Behavioral Therapy (CBT), and Motivational Interviewing (MI) were used to help individuals struggling with primary and secondary exercise addiction reduce their negative symptoms. The findings showed promising results, which may support the long-term maintenance of recovery.

CONCLUSION: More high-quality studies are needed to evaluate the effectiveness of psychotherapeutic interventions in reducing the negative symptoms of exercise addiction. It is essential to support individuals with both primary and secondary exercise dependency and to develop an effective treatment program.

GENERAL ASPECTS FOCUSED ON PSYCHOLOGICAL AND EATING DISORDERS OF PEOPLE WHO PRACTICE BODYBUILDING; DESCRIPTIVE MONOGRAPHIC REVIEW

LEDEZMA GUTIERREZ, D.

UNIVERSIDAD DEL VALLE DE MEXICO Y ESCUELA UNIVERSITARIA REAL MADRID

Abstract: The objective of this work is to describe the relationship between psychological disorders and eating disorders (ED) in bodybuilders. In order to raise this objective, a descriptive monographic review work was carried out, for which certain bibliography was selected and delimited in search of data in order to provide an answer to the uncertainty of the proposed research. The information search strategy was carried out in 2 databases: PubMed and Google Scholar, searching for information in Spanish and English, taking into account the following inclusion and exclusion criteria. Inclusion criteria: articles related to the practice of bodybuilding, articles related to sports psychology, bodybuilding and psychological disorders, articles related to sports supplementation in bodybuilding and articles related to eating disorders. (TCA). Exclusion criteria: athletes under 18 years of age, articles on psychological and nutritional disorders focused on other sports, people who do not do physical exercise. The study sample is made up of 18 articles by different authors.

Intake of dietary supplements; Sport nutrition, Psysical activity, Nutritional Science and sport, Dietary supplements, eating disorder in bodybuilding (TCA in bodybuilding), Body image, Body image, Bigorexia in bodybuilding, muscle dysmorphia, behavior in bodybuilders, behavior in bodybuildings.

The results achieved, starting with the analysis of the study carried out by Alonso Andrade, García et al. 2012 and Devrim et al. 2018 it is confirmed that bodybuilders carry out practices that are considered high risk for health and in the psychological aspect with the study carried out by Arbinada and caracuel 2008, it is shown that bodybuilders are more realistic, practical, objective, utilitarian, concrete, organized and disciplined and that the majority of these athletes present vigorexia and body image disorder.

GRITTY AND GAME SMART: PSYCHOLOGICAL MECHANISMS TO EXPLAIN THE RELATIVE AGE REVERSAL IN ELITE MALE YOUTH SOCCER

HENDRY, D., LARKIN, P., OCONNOR, D., WILLIAMS, A.M., VACI, N., BILALIC, M.

NORTHUMBRIA UNIVERSITY

Introduction

The relative age effect (RAE) represents a selection bias favouring individuals born earlier in a selection period (e.g., January–March) over those born later (e.g., October–December). Despite being highly prevalent in elite youth sports, research increasingly highlights a relative age reversal at the adult and professional levels. While various theoretical positions have been proposed for this reversal, there is a notable lack of empirically supported psychological explanations for its effects.

Methods

Elite male Australian youth soccer players (n = 388) completed a battery of lab-based, soccer-specific perceptual cognitive tests (e.g., anticipation, pattern recall) and the Short-Grit Scale (Duckworth et al., 2009) at age 14 yrs (M age = 13.8, SD = .8) in October 2013. Players were categorised into 4 quartiles of the selection year; Q1 (Jan – March), Q2 (April – Jun), Q3 (July – Sept) and Q4 (Oct – Dec). All players were then followed up 10 years after (January 2024) initial data collection to establish their current expertise status (professional, semi-professional, drop-out).

Results

A higher percentage of late born players (Q4) reached professional status and fewer dropped out from football than earlier born peers (Q1). Relatively younger player (Q4) scored higher on measures of grit (p = .001) and its sub factors con-

sistency of interest ($p < .001$), and perseverance of effort ($p < .05$) compared to Q1 players. They also scored higher on lab-based tests of perceptual-cognitive skill including knowledge of situational probabilities ($p = .01$), and pattern recognition ($p = .04$), but not anticipation or decision making (p 's $> .05$)

Discussion

Although the relative effect appears to persist in adulthood, it is noteworthy that Q4 players are proportionately more likely to advance to professional status and less likely to drop out than earlier born players. Thus, indicating an earlier filtration process for late born players. Findings also provide empirical evidence to support psychological explanations for the relative age reversal effect amongst a sample of highly skilled football players. Late born players were grittier and appeared to have higher game intelligence skills than early born players, suggesting that these psychological factors may act as compensatory mechanisms against their purported chronological disadvantages.

TITLE: PERSONALITY TRAITS OF MULTI-MARATHONERS: A TIPI PERSPECTIVE

LUNDY, L., REILLY, R., FLEMING, N., WILCZYNSKA, D.

TRINITY COLLEGE DUBLIN

Objectives: Multi-marathoners is a sport for athletes dedicated to completing 100 or more marathons. This study investigates the distinct personality traits of multi-marathoners, compares them to public norms, and identifies specific groupings that highlight potential risks, vulnerabilities, and strengths. The findings also explore the implications of these traits on participation, performance, and overall well-being.

Methods: A cross-sectional survey was conducted targeting the global multi-marathon community, utilising the Ten Item Personality Inventory (TIPI) (1). The study included 593 survey respondents (56% men, 44% women; mean age = 53.87 years, SD = 9.91) with an average marathon completion count of 146.52 from 22 countries, capturing the diverse demographic of the global multi-marathon community. Statistical analyses were performed using Mann-Whitney U tests, ANOVA Aligned Rank Transform (ART) tests, and Spearman's ρ correlations. These correlation analyses were further supplemented with data from a previous study on the demographics and behaviors of multi-marathoners, which included information on motivation, injuries and recoveries, diet, and chronic health conditions such as heart disease and high blood pressure. (2). Latent Class Analysis (LCA) was then used to identify subgroups with shared personality traits.

Results: LCA identified four latent groups, each exhibiting unique combinations of high conscientiousness, low emotional stability, low openness, and varying levels of agreeableness and extraversion. Compared to the general population, multi-marathoners demonstrated significantly higher conscientiousness ($F(1,591) = 2.42, p < 0.001$) and lower emotional stability ($F(1,591) = 5.525, p < 0.001$). Across all age groups and genders, agreeableness and emotional stability were notably lower ($p < 0.001$). Women showed higher conscientiousness and agreeableness than men. ANOVA ART tests revealed significant age-related differences in extraversion, agreeableness, and emotional stability ($p < 0.05$), with post-hoc analyses confirming that women had significantly higher agreeableness ($W = 50809, p < 0.001$).

Conclusion: High conscientiousness reflects the self-discipline of multi-marathoners, while low emotional stability indicates potential challenges in stress management. The identified latent groups reveal vulnerabilities, such as increased risks of stress and injury, highlighting the need for interventions like resilience training. Future research should focus on longitudinal studies and the validation of short-form assessment tools to better support well-being (1, 2).

POSTURE AND PERSONALITY. A PILOT STUDY AMONG YOUNG DIGITAL NATIVES

NART, A., SARTOR, C.

UNIVERSITY OF PADUA

Introduction

Posture reflects the way the body positions itself and moves in space. It is a complex expression of our being, influenced by internal (psychological and emotional) and external (cultural and social) factors. The aim of the present empirical study was to investigate the connection between perceived posture in everyday contexts (home, school and technology-related habits) and individual personality by integrating the theoretical perspectives of embodied cognition, emotional expression, and kinesthesia.

METHODS: The online questionnaire Posture and Personality, based on a 1-5 Likert scale, was submitted to a representative sample of 37 students (F 21; M 16) - randomly selected from a group of 150 students from three secondary schools - aged about 18 years old and the data collected were processed using the statistical software RStudio. The Posture and Personality Questionnaire is the combination of two questionnaires already validated in scientific literature (Schwertner et al. 2018 and Morizot, 2014). The self-report was administered online (by WhatsApp, Instagram) via QR Code distribution.

Results

The results indicated significant correlations between perceived posture and specific personality traits, such as: extroversion, agreeableness, conscientiousness, neuroticism, openness to experience. In particular, among many significant data, neuroticism emerged as the most influential variable in determining individuals' total posture ($r=.87$; $p<.0001$) and extraversion as the relevant trait in postural control in the classroom ($r=.71$; $p<.001$), while conscientiousness acquired greater importance in the transport of objects ($r=.79$; $p<.001$). The use of technology related with posture showed that the neuroticism variable is associated with a contracted posture when using digital devices ($r=.77$; $p<.001$), while conscientiousness favours a more ergonomic attitude ($r=.73$; $p<.001$).

Conclusions

The statistical analysis revealed interesting dynamics between personality trait variables and the different postural contexts under examination. The neuroticism variable stands out as the most influential in determining participants' total posture, suggesting consistence in its cross-sectional effects on various aspects of daily posture. The analysis conducted showed that the types distinguishing individual's personality can help us predict the outcome of their posture in daily contexts. The results suggest the importance of considering the body, particularly the sensorimotor system, as an integral part of the mental system, in line with embodied cognition approaches. Movement education would improve not only young people's awareness of their posture, but it could also promote active lifestyles, healthy habits and increasingly widespread emotional well-being among students.

PHYSICAL ACTIVITY IS AN IMPORTANT RESOURCE FOR IMPROVING WORK PERFORMANCE AND SERVES AS A MEANS FOR RESILIENCE AND RECOVERY AMONG MARKETING EMPLOYEES IN STRESSFUL BUSINESS CAREERS.

SOLLERHED, A.

KRISTIANSTAD UNIVERSITY

INTRODUCTION: Appearance and body language are key components of non-verbal communication and play a crucial role in the marketing and business sector, where individual employees represent the company brand. Despite their importance, organizational support from companies appears to be minimal or non-existent, leaving stress-coping and recovery strategies largely to the individual.

Aim

The aim of this study was to explore experiences and perceptions of work stress and resources for work resilience and recovery among employees in the marketing and business sector, where appearance and body language are key components of non-verbal communication.

Methods

Interviews were conducted with 15 marketing and communication employees (five males, ten females) at multinational companies. The employees were either marketing managers or marketing officers with 4-39 years of work experience. The interviews varied in length and depth, generally lasting between 40 and 120 minutes. They were digitally recorded and transcribed verbatim before analysis. The transcripts were analyzed using a combination of thematic and qualitative content analysis.

Results

The analyses revealed two main themes with subthemes:

1. Perceived stressful work demands (Adaptation to situation and culture; Gender roles).
2. Perceived resources for work and recovery (Experience and age benefits; Physical activity resources).

Discussion: Marketing employees perceive their work as stressful due to various dilemmas related to representing the company. Their engagement in maintaining a good appearance and representing the company's brand effectively, along with self-protection to achieve a sense of ability and control in different situations, led them to create their own job resources. They associated success in their careers with being in good shape, fit, and feeling strong. Physical activity was a conscious strategy related to their work life. Fitness provided them with a sense of capability and control in their work. They invested time, commitment, money, and effort to be representative and to look good and appropriate for work. They perceived their appearance as part of the company brand, where both their competence and appearance were in focus.

CONCLUSION: Physical activity and fitness were seen as prerequisites for better work performance, good appearance, and self-confidence at work. A well-trained and fit body was important for status and authority in business and for coping with stressful situations. Physical activity was also viewed as the most important resource for resilience, recovery, and recharging energy for work. Therefore, organizational support from business-driven companies needs to be more comprehensive in supporting employees opportunities for physical activity.

LATENT PROFILES OF INTERPERSONAL EMOTION REGULATION IN ADOLESCENT ATHLETES: EXPLORING DENSITY, CENTRALITY, AND FRAGMENTATION IN TEAM DYNAMICS

ROMERO, V., GERVILLA, Y., RAMIS, Y., LÓPEZ DE SUBIJANA, C., TORREGROSSA, M., LLABRÉS, J., MOLINA, J., PORTILLO, J., PONS, J.

UNIVERSITAT DE LES ILLES BALEARS

INTRODUCTION: Efforts have been made to identify factors that protect adolescent's mental health, with the beneficial role of sports being emphasized (Simpson et al., 2024). Emotional regulation has been observed to play a key role in adoles-

cents' well-being and mental health (Bird et al., 2021). Given that adolescence is the stage when peers exert the greatest influence, it is important to explore profiles of interpersonal emotional regulation within sports teams (Tamminen et al., 2016).

Method: A total of 2043 adolescent athletes (56.9% men, $M_{age}=15.9$) from 225 Spanish teams responded to the Emotion Regulation of Others and Self-Questionnaire (EROS). Social Network Analysis was used to analyze interpersonal emotion regulation, including density (connections in the team vs. total possible connections), centrality (connections of a player with teammates), and fragmentation (how divided the team is into disconnected components). Latent profile analysis (LPA) identified profiles of interpersonal regulation using centrality. ANOVA was used to examine differences between profiles in continuous variables (density and fragmentation), and chi-square tested differences in the categorical variable (gender).

RESULTS: The best-fitting model identified four patterns of emotional regulation (ER) among the players. Profile 1 includes athletes whose ER is generally low, 'Low regulators', Profile 2 includes those with generally average ER, 'Average regulators', Profile 3 includes athletes who stand out for their high worsening ER, 'Negative regulators' and Profile 4 includes athletes distinguished by their high improving ER, 'Positive regulators'. The profiles did not differ in terms of the density of ER of improvement (e.g. helping and listening to teammates), but differences were observed in the density scores of ER of worsening (e.g. complaining about the teammates). Players in the Negative regulators profile tend to belong to teams with higher ER of worsening. Additionally, players in the Low regulators and Negative regulators profiles tend to belong to teams with greater fragmentation in improvement efforts (i.e., lower connection between teammates), whereas regarding worsening efforts, Negative regulators tend to belong to teams with higher connection between teammates (i.e., lower fragmentation). Gender differences were observed across the profiles [$\chi^2(3) = 31.4, p < .001$], with the greatest disparity found in 'Negative regulators', where women represent only 18.5%.

Discussion: These results highlight the variance in interpersonal emotional regulation behaviors among athletes and their relationship with their team's emotion regulation dynamics. The findings suggest a connection between athletes tendency to regulate their teammates' emotions and the overall emotional climate of the team. Future studies should explore how these different profiles relate to the mental health of young athletes.

SPORT AND LEISURE SOCIAL PROJECTS IN BRAZIL: SOCIAL REPRESENTATIONS OF PARTICIPANTS

MARINHO, A., CUNHA, B.F., LUIZ, M.E.T., MARTINS, S.M.

STATE UNIVERSITY OF SANTA CATARINA

Introduction: Social projects are public interventions that aim to continue the process of comprehensive development of young people outside of the school environment. Among the different types of social projects are those related to sports and leisure. In Brazil, sports and leisure are social rights provided for in the Brazilian Federal Constitution of 1988. When understood as distinct, complex, and plural phenomena, leisure and sports can act as facilitators of pedagogical and educational actions, promoting social and moral values, in addition to physical and cognitive capacities. In the Brazilian reality, social sports and leisure projects are suitable opportunities for this practice, as they serve children and adolescents in situations of social vulnerability, with the perspective of providing them with alternative educational possibilities. The success of these projects is based on the dialogue established between the institutional proposals and the expectations of their participants, considering their experiences, needs and meanings, which can be identified through ongoing conversations and observations. Given these considerations, this study aimed to investigate the social representations that students of social sports and leisure projects have about these projects.

Methodology: This descriptive-exploratory field study employs a qualitative approach to data, grounded in the Theory of Social Representations (Jodelet, 2001). Data collection was conducted through focus groups with 84 students participating in nine government-funded social sports and leisure projects, which are offered free of charge to the population in the city of São José (SC), southern Brazil. The data were organized using NVivo software, version 14, and analyzed through the content analysis technique (Bardin, 2016).

Results: As a result, the responses were grouped into two main categories, considered core representations: "spaces for self-realization" and "interpersonal relationships." These findings indicate that the social projects investigated serve as learning environments where participants primarily develop motor skills to enhance their sports performance during leisure activities. Additionally, they function as spaces for social interaction, fostering peer engagement, enjoyment, and moments of relaxation.

Conclusion: We emphasize the importance of social projects that establish ongoing dialogue with their participants. This continuous engagement allows for a better understanding of the diverse contexts in which they operate, enabling the systematization of interventions based on significant elements that contribute to the projects' longevity.

REVIEW OF THE HISTORY, OPPORTUNITIES, CHALLENGES, AND DEVELOPMENT STRATEGIES OF WOMENS PARTICIPATION IN WINTER SPORTS AROUND THE WORLD

LIU, Y.

UNIVERSIDADE DA CORUÑA

research objective

This article summarizes the development process of womens participation in winter sports around the world, analyzes the opportunities and challenges of womens participation in winter sports at the current stage, and studies the development strategies for womens participation in winter sports around the world.

Research object : Female athletes participating in world winter sports ; research method ; Literature review method, data induction and statistical analysis method, expert discussion Method: Research results ; Early participation (late 19th century to early 20th century): In the early stages of winter ice and snow sports, womens participation was relatively low. However, with the gradual change of social concepts and the rise of womens rights movements, women have gradually begun to participate in winter ice and snow sports.

Enhancement of athletic level (mid-20th century): With the popularization of winter ice and snow sports and advances in technology, womens athletic level in these sports gradually improved. For example, in events such as skiing and figure skating, female athletes begin to demonstrate skills and abilities comparable to male athletes.

Breakthrough on the international stage (late 20th century early 21st century): Womens performance in winter ice and snow sports began to gain recognition on the international stage. For example, in the Winter Olympics and other international events, female athletes began to win medals and honors, breaking the male monopoly in these fields.

Popularization and professionalization (21st century present): With the further popularization of winter ice and snow sports and social support for womens participation in sports, the participation and professionalization of women in these sports continue to increase. At the same time, the image of women in winter ice and snow sports has gradually shifted from traditional "softness" to a combination of "strength and skill".

Overall, the development path of womens participation in winter ice and snow sports worldwide is a gradual process from initial participation, improvement of competitive level, breakthroughs on the international

OXYTOCIN AS A POTENTIAL MEDIATOR BETWEEN AEROBIC FITNESS AND SOCIAL FUNCTIONING IN SCHIZOPHRENIA

CHENG, M., GOH, K., CHEN, C., WANG, C., YANG, C.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Although the positive effects of aerobic fitness on social functioning in individuals with schizophrenia have been extensively studied, the underlying biological mechanisms remain unclear. Specifically, it is unclear whether oxytocin plays a critical role in this relationship. To address this research gap, we investigated whether plasma oxytocin levels mediate the relationship between aerobic fitness and social functioning.

METHODS: The study recruited a cohort of 72 individuals with schizophrenia. Aerobic fitness was assessed using the six-minute walk test, and social functioning was evaluated with the Social Functioning Scale. To determine whether oxytocin mediates the relationship between aerobic fitness and social functioning, a mediation analysis was conducted using the bootstrapping method of Process SPSS macro.

RESULTS: In patients with schizophrenia, aerobic fitness was positively correlated with the oxytocin levels ($r = .25$, $p = .04$) and SFS scores ($r = .30$, $p = .01$). A mediation model was constructed to explore these association. Results showed significant regression coefficient between aerobic fitness and plasma oxytocin levels ($p = .04$) and between plasma oxytocin levels and social functioning ($p = .007$). The bootstrapped unstandardized indirect effect was also significant ($\beta = .21$, $SE = .28$, 95% CI [.0022, .47]) after controlled gender. These results indicated that plasma oxytocin levels partially mediate the effect of aerobic fitness on social functioning.

CONCLUSION: Our findings suggest that plasma oxytocin partially mediates the relationship between aerobic fitness and social functioning, suggesting that individuals with higher physical fitness may experience elevated oxytocin levels, which would, in turn, enhance social functioning in schizophrenia. These results provide novel insights into the interplay between physical fitness and neurophysiological processes, highlighting oxytocin as a key biological mechanism linking physical health to social behavior. Such insights provide important significant potential for interventions aimed at improving social functioning in schizophrenia.

Invited Symposium

IS-AP04 Advancing Performance: The Applied Use of Wearable Technologies in Sports Science

ACCURACY AND PRACTICAL APPLICATIONS OF WEARABLE SMART WATCH TECHNOLOGY IN SPORTS SCIENCE

LEPLEY, A.

UNIVERSITY OF MICHIGAN

Wearable technology is widely used by athletes and physically active individuals to monitor their health and fitness, record and document workouts, and enhance the overall exercise experience. Smart watch wearable technology has become increasingly popular in both recreational and professional sports settings due to its accessibility, ease of use, and ability to continuously track a variety of physiological parameters. However, questions remain regarding the accuracy and reliability of the physiological and performance metrics these devices provide. This session will explore the capabilities and limitations of smart watches in the context of sports science, with a focus on evaluating their accuracy in measuring key parameters such as heart rate, energy expenditure, sleep patterns, and physical activity levels. Dr. Lepley will present research comparing the data accuracy of smartwatches with that of gold-standard laboratory equipment, including electrocardiograms (ECGs), metabolic carts, and motion capture systems. Emphasis will be placed on identifying the conditions under which smart watch accuracy excels or falters, such as environment, participant skin tone, task completed, etc. and how these devices can be best utilized by researchers, coaches, and athletes to gather actionable data. Practical case studies will illustrate how smartwatches are currently being used to monitor athletes' health and performance during training and competition. Additionally, the session will discuss user compliance and other practical considerations for implementing smartwatch technology in long-term monitoring protocols. Dr. Lepley aims to provide attendees with insights into the practical application of smart watch data for personalizing training programs, assessing workload, and evaluating recovery, while also addressing the key accuracy concerns that can influence decision-making in both research and practice. Dr. Lepley will also discuss emerging trends and future directions, such as the potential for non-invasive biomarkers, real-time injury prediction algorithms, and the use of wearables to enhance the mental as well as physical performance of athletes.

PLAYER TRACKING TECHNOLOGY FOR TEAM TACTICAL ANALYSIS

OLTHOF, S.

LIVERPOOL JOHN MOORES UNIVERSITY

The implementation of sports technology has transformed how teams and individual athletes approach performance optimization. From real-time tracking devices to advanced video analytics, modern sports technologies offer a wealth of data-driven insights that enable coaches and sports scientists to make informed decisions aimed at maximizing performance outcomes. This session will focus on the practical integration of player tracking technology into team environments and training programs, highlighting their impact on improving both player and team performance from a tactical perspective. Player tracking technology has traditionally been employed to evaluate the physical exertion and workload of athletes during both training and competition. However, its utility extends far beyond physical metrics. By examining spatial and temporal data, team tactical analysis can provide insights to coaches in collective behavior during competition and game formats during training sessions. This enables a holistic approach to integrating player tracking technology in the coaching process, where tactical analysis can support the decision-making in training program design. Dr. Olthof will explore how wearable technologies such as Global or Local Positioning Systems (GPS and LPS, respectively), are being used for tactical analysis. She will demonstrate how GPS and LPS data can be used to analyze team dynamics and player movements during competition and training sessions, providing a comprehensive view of team tactics. This can provide feedback to coaches and players on tactical performance during match-play and training sessions, facilitating adjustments during training sessions and competition. The presentation will illustrate how the integration of these technologies has led to improved training strategies for elite team sport athletes. Topics covered in this presentation will include technology and analytics for team tactical performance, the use of game formats for match preparation, and optimizing training strategies for talent development. In addition, this session will address practical aspects of using wearable technology for tactical analysis, such as ensuring data synchronisation, analyzing offensive and defensive phases of the competition, and making the insights accessible and actionable for coaches and players. Ultimately, the presentation aims to provide an insight in the variety of applications of player tracking technology in a team sport environment and the applications of tactical analysis for training program optimization in team sports.

USING WEARABLE DEVICES FOR HOLISTIC ATHLETE MONITORING: STRATEGIES FOR INTEGRATION

COUTTS, A.

UNIVERSITY OF TECHNOLOGY, SYDNEY

Wearable technologies are commonly utilized tools for monitoring and assessing athletes during training and competition. These are often employed to assess athletes' readiness to perform and reduce injury risk. Over the past two decades, these devices have significantly impacted the role of the sport scientist, transforming how coaches, sports scientists, and medical professionals monitor athletes. This presentation will explore how wearable devices can be integrated into a comprehensive athlete monitoring system. Initially, we will provide a framework for designing such systems before outlining best practice approaches for selecting, applying, and integrating measures into athlete monitoring systems. Wearables are central to athlete monitoring as they provide real-time, objective data on training loads as well as measuring athletes responses to training. However, the ease of use and availability of these tools often lead to challenges due to the sheer volume of data, the integration of blackbox algorithms and continual creation of new metrics. Without appropriate selection and application, this data can create unnecessary noise that can interfere with decision-making processes. Furthermore, with the rise in artificial intelligence and promise of injury prediction models highlights the need for quality data systems. Without these best practice approaches, the false promises will ultimately result in loss of trust in monitoring from both athletes and coaches. To address this risk, this presentation will emphasize an athlete-centered, holistic approach to monitoring, advocating for the judicious selection of essential data. We will also examine athletes' perspectives on the effectiveness of monitoring that can be used to improve current methodologies. This session is designed for sports scientists, coaches, and medical professionals seeking to optimize the potential of wearable technologies within a holistic, evidence-based approach to athlete monitoring. We will highlight the importance of interdisciplinary collaboration between sport scientists, data scientists, coaches, and medical professionals, to ensure that ethical, safe, and effective methods are applied. Real-world examples of successful implementation of wearables in athlete monitoring will be discussed to provide attendees with practical insights.

Invited Symposium

IS-BM08 Brain & Body Bootcamp: Revolutionizing Fitness with Exergames!

MOVING BEYOND SCREENS: UNLEASHING THE POWER OF EXERGAMES FOR HEALTH AND WELLNESS

DE BRUIN, E.

INSTITUTE OF HUMAN MOVEMENT SCIENCES AND SPORT, ETH

Technological innovations (e.g. exergames) provide new options to engage older adults in motor-cognitive training [1]. Simultaneous motor-cognitive training is considered promising to prevent both the decline in physical and cognitive functioning in older adults and can be highly motivating when applied in form of exergaming. A systematic review found exergames appearing to be more effective on global cognitive performance than conventional physical training. Furthermore, neurophysiological benefits were mainly seen following exergaming [2,3]. These benefits are believed to be caused by the unique opportunity for trainees to interact in an enriched environment that, in turn, provides structured, scalable training opportunities augmented by multi-sensory feedback to enhance skill learning and neuroplasticity through repeated practice [4]. Here we explore several mechanisms why video game-based exergame training necessitating subject's ability to lift the toes and to place the feet on different target zones can lead to improved brain and physical function. The physical exercise involved promotes cardiovascular health, enhances coordination, and increases strength and endurance, which contributes to overall physical fitness. Simultaneously, the cognitive aspects of gaming—such as problem-solving, strategy formation, and rapid decision-making—stimulate brain activity and can improve neuroplasticity, attention, and memory. Positive effects in the nervous system are due to stimulating neural pathways through concurrent movement, thinking and coordination. [1] Dove et al. JMIR, 19: p. e3, 2017 [2] Soares et al. Arch Gerontol Geriatr 97: 10485, 2021; [3] Davis et al. J of ACH 72:1-9, 2022; [3]; [4] Aminov et al. JNER 15: p. 29, 2018.

GAIT-RELATED ELECTROPHYSIOLOGICAL ADAPTATIONS FOLLOWING EXERGAME TRAINING

GENNARO, F.

UNIVERSITY OF PADUA

Electrophysiological assessments, such as Electroencephalography (EEG) and Electromyography (EMG), can be employed in movement-related tasks such as walking, thanks to recent advances in hardware design and signal processing, which helped to overcome previous existing data collection and analysis limitations. That is, acquiring cerebral activity during movement represented a challenging condition for decades. due to the inherently present physiological and not physiological artifactual activity [1]. Gait is a locomotor task driven by neural inputs directed to skeletal muscles, and exergames can be designed for gait training purposes [2] as well as targeting central nervous system (CNS) potential adaptations [3]. Here we explore results from an exergame training intervention, where the employed videogame required the older adult's subject ability to lift the toes and to place the feet on different target zones as a requirement to successfully play the game [4]. We illustrate gait-related electrophysiological adaptations following exergame training, and we introduce prospects of using a combination of several electrophysiological measurement devices as well. In our study CNS adaptations

are assessed by means of a paired set of two bipolar EMG sensors. This configuration is required to run intramuscular coherence analysis (IMC), which represents a useful (but proxy) method to assess neural drive to specific muscles during gait tasks. We show that IMC significantly changes following exergame training, during dual-task but not during single task gait. These findings are important, since the former is greatly impaired in older adults, involving more cognitive resources compared to normal gait, but gait-related IMC can adapt following exergame training. That is, consistently playing exergame over several weeks can lead to changes in the central drive to ankle dorsiflexors during dual-task gait. This shows that exergame-based training in upright standing position, which includes movement pattern resembling "gait initiation", can improve neural drive to the lower extremities in older adults. Whether combining EMG and EEG assessments (i.e. Corticomuscular Coherence) can yield similar results remains to be still elucidated, promising results of this approach have been already shown in other contexts (e.g. sarcopenia). Interestingly, mounting evidence hints towards the feasibility of using EEG playing exergame as well, showing interesting potential cognitive and motor adaptations. EXAMINING COGNITIVE AND MOTOR ENGAGEMENT IN EXERGAMING

SKJÆRET-MARONI, N.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

Exergaming has gained traction as a dual-purpose activity for enhancing both physical and cognitive health, especially among older adults [1]. Characteristics of different games and game settings affect physical and cognitive activity [2]. Here we explore how different exergame types, such as balance and stepping games, influence brain and physical activity through real-time EEG analysis. EEG provides a dynamic and non-invasive method to capture the neural responses of players, focusing on cognitive engagement markers like theta and alpha rhythms. Frontal theta and central/parietal alpha frequencies are key indicators of cognitive processing in working memory tasks for both young and older adults [3,4]. While frontal theta power increases with cognitive demands and task difficulty, alpha oscillations decrease with increased information processing [3,5]. Our studies shows that exergaming can significantly increase frontal theta power, indicating heightened cognitive demand and attentional processes during gameplay. These neural responses suggest that exergaming, by requiring attention and motor coordination, promotes active cognitive engagement beyond the physical movements alone. Our findings also highlight the varying impact of game difficulty and type on neural activation, underscoring the importance of tailoring exergames to individual abilities and rehabilitation goals. This research supports the potential of exergaming as a structured, interactive intervention to foster cognitive and motor health, while underscoring the importance of tailoring exergame interventions to optimize both cognitive and physical outcomes in older adults. Oral Presentations

FORCE EXPRESSION APPLICATIONS IN CYCLING

BERTOLLO, M., BERNARDI, G., CAPOALE, A., FERRO, M., AMATORI, S., BUGLIONE, M., POMPA, D.

UNIVERSITY G. DANNUNZIO OF CHIETI-PESCARA

INTRODUCTION: Research in Sports has explored a few frameworks for understanding the force domains, primarily focusing on strength qualities¹ (e.g., isometric mid-thigh pull). In contrast, Bosco² proposed a physiological categorization of force expressions based on concentric propulsive time, applicable to various sports movements (e.g., running, jumping). However, this framework has not been applied to cycling, where research has focused on the relationship between rate of torque production (RTD) and strength measurements³, rather than concentric muscle action. This study investigates the relationship between torque application and different pedaling cadences (RPM) in skilled cyclists, employing a multivariate approach to analyze force expression across varying pedal loads

METHODS: Nineteen highly trained⁴ cyclists completed the trials using an ergometer capable of independent 1000 Hz frequency sampling for each pedal and precise RPM manipulation to impose varying pedal loads. Following familiarization, cyclists performed six trials (three per leg, alternating) of a single maximal-effort downstroke at 30, 60, 90, and 100 RPM in a counterbalanced order. Only propulsive phase (torque > 0 N*m) of the targeted leg was analyzed. Outcome measures included kinetic torque-time variables: peak torque (PT), average rate of torque development (avgRTD; $\Delta\text{torque}/\Delta\text{time}$), impulse (Im; $\Delta\text{torque} \times \Delta\text{time}$), and propulsive time (t). Data analysis was conducted using a custom MATLAB script, with statistical testing performed via RM-MANOVA in SPSS.

RESULTS: RM-MANOVA revealed a significant multivariate effect of RPM on the combined dependent variables (Pillai's Trace = .997, $p < .001$), with strong effect sizes (Partial Eta Squared = .997). Univariate tests confirmed significant differences across RPM conditions for PT ($p < .001$), Im ($p < .001$), t ($p < .001$), and avgRTD ($p = .035$). Propulsive time values

increased with decreasing RPM: t30RPM (.926 $\pm$.188 s), t60RPM (.617 $\pm$.080 s), t90RPM (.483 $\pm$.046 s), and t100RPM (.431 $\pm$.020 s). Notably, PT and Im increased with higher RPM, while avgRTD peaked at 60 RPM (658 N/s). Post-hoc contrasts revealed significant differences between all RPM levels for PT and Im ($p < .001$), while avgRTD showed significant differences only between extreme RPM conditions ($p < .001$).

CONCLUSION: This study demonstrates that RPM significantly influences force expression during single-leg maximal-effort pedal strokes in highly trained cyclists. Lower RPMs were associated with greater PT and Im, indicating maximal strength expression. The highest RTD occurred at 90 RPM, suggesting an optimal cadence for explosive strength expression. These findings highlight the importance of RPM-specific adaptations in cycling performance. Future research should compare cyclists across expertise levels, competition disciplines, and age groups, providing deeper insights into force expression during cycling.

LEG MUSCLE ACTIVATION ACROSS CYCLING POSTURES AND PEDALING STRATEGIES IN RECREATIONAL MALE AND FEMALE CYCLISTS

CHEN, M., LEE, Y., SHIANG, T., FUCHS, P.X.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Cyclists adjust body posture and pedaling strategy to counter air resistance and adapt to varying terrains, which influences performance and injury risk. Changes in cycling posture appears to affect muscle activation in novice but not elite cyclists, who exhibit superior neuromuscular control to maintain performance [1]. Sex may play a role in the effects of posture and pedaling on muscular activation as females exhibit greater pelvic motion in dropped postures and at higher intensities than males [2]. Examining the influence of posture and pedaling strategy on muscle activation in males and females may guide the development of targeted training programs. This study aimed to investigate the effects of different cycling postures, cadences, and resistances on muscle activation in male and female recreational cyclists.

METHODS: Eighteen recreational cyclists (nine males, nine females) completed 18 cycling bouts on a training stand in three postures (neutral, comfort, dropped) and six pedaling strategies (combinations of three cadences (self-selected, slow, fast) and two resistance levels (heavy, light)) in randomized order. Surface electromyography (1000 Hz) obtained mean muscle activation of the biceps femoris (BF), vastus lateralis (VL), rectus femoris (RF), tibialis anterior (TA), and gastrocnemius (GAS) during 15 stable pedaling cycles. Data were normalized to maximal muscle activation during 10-second maximum-effort sprints. A three-way repeated-measures ANOVA examined the effects of posture, pedaling, and sex on muscle activation at $\alpha = .05$.

RESULTS: Postures did not affect muscle activation ($p = .05-.91$, $\eta^2 p = .01-.17$) except for right leg RF ($p < .05$, $\eta^2 p = .19$), with no significant Bonferroni-corrected post-hoc comparison ($p = .06-.10$, $\eta^2 p = .02$). Pedaling strategies affected both legs' BF ($p < .001$, $\eta^2 p = .62-.70$), RF ($p < .001$, $\eta^2 p = .71-.71$), TA ($p < .001$, $\eta^2 p = .59-.67$), GAS ($p < .001$; $\eta^2 p = .51-.66$), and VL ($p < .001$; $\eta^2 p = .13-.86$) activation. Sex interacted with the effects of pedaling strategy on RF activation in both legs ($p < .05$; $\eta^2 p = .18-.29$). Females demonstrated greater left leg RF activation during heavy resistance at all cadences and greater right leg RF activation during all pedaling strategies than males ($p < .05$, $\eta^2 p = .27-.28$).

CONCLUSION: The effects of posture have been marginal, whereas pedaling strategy greatly influenced muscle activation. Females exhibited higher RF activation than males, particularly at heavy resistance (significant in both legs), emphasizing the importance of RF functionality in females and suggesting special consideration of RF in training regimes for females. As pedaling strategies affected RF activation differently between sexes, cadence and resistance should be adjusted considering sex-specific adaptation for trainings that target RF.

EFFECTS OF DIFFERENT SADDLE HEIGHT DETERMINATION METHODS ON LOWER LIMB MECHANICS AND PHYSIOLOGICAL PERFORMANCE IN CYCLING

FAY, L., RAPPELT, L., HEINKE, L., JAVANMARDI, S., HELD, S., BAUMGART, C., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: An adequate saddle height is crucial for cycling performance, comfort, and injury prevention [2]. Despite its importance, most methods for determining saddle height have been developed through practical experience rather than scientific evidence [3]. This study examined the impact of four different saddle height determination methods (LeMond LM; Trochanteric TM; Heel HM; Minimal knee angle ($\alpha = 30^\circ$) AM) on cycling biomechanics and physiological responses.

METHODS: In an acute randomized crossover design, 23 physically active individuals ($f = 11$; $m = 12$; age: 22 ± 1.9 years; body mass 71.3 ± 9.6 kg; height 174 ± 8.7 cm) cycled on an adjustable trainer at the four different saddle heights and two

resistance levels (low: 100% of body mass in Watts; high: 200% of body mass in Watts). Heart rate, oxygen uptake, perceived exertion, and discomfort for each saddle height were analyzed using an ANOVA, while differences in electromyography (EMG) data of the lower extremity muscles (Vastus Lateralis and Medialis Obliquus, Gastrocnemius Medialis, Rectus Femoris, Semitendinosus, Tibialis Anterior), knee and ankle angles, and torque were analyzed continuously over the revolution using statistical parametric mapping (SPM).

RESULTS: The largest differences in saddle height were found between AM and TM (98.4 ± 4.6 vs. 102.9 ± 4.2 cm; 4.5%, SMD = 1.02, $p < .01$). Oxygen uptake showed significant differences at low load between AM and TM (1.45 ± 0.21 vs. 1.55 ± 0.25 l/min, SMD = 0.43, $p < .02$), but no significant differences at high load. Discomfort [1-10; very comfortable - uncomfortable] was rated significantly higher for LM (5.52 ± 2.50) and TM (6.13 ± 2.44) compared to HM (3.70 ± 1.82) and AM (4.01 ± 2.39) (SMD = .83 -1.13; $p < .05$). No significant differences in RPE were found. At low load for torque, the one-way repeated measures ANOVA using SPM1D revealed a significant main effect of saddle height (SPM{F}; $df = 3, 66$; FWHM = 23.89; 7.49 resels) with a critical threshold (SPM.z* = 5.24 at $\alpha = 0.05$) (set-level $p = 0.001$; cluster-level $p < 0.001$ and 0.036) between 123° and 173° . Subsequent paired t-tests showed significant differences between AM and TM ($t^* = 3.84$, $df = 1, 43.545$, $p = 0.004$).

CONCLUSION: Methods resulting in higher saddle heights were associated with increased discomfort. The results indicated superior cycling efficiency and comfort in favor of AM and HM. Therefore, practitioners should consider saddle height adjustments based on knee flexion angle ($\sim 30^\circ$) to optimize cycling efficiency, comfort, and injury prevention.

ENHANCING TRAINING OUTCOMES WITH SUPERIMPOSED ADAPTIVE FUNCTIONAL ELECTRICAL STIMULATION DURING CYCLING: A COMPARISON TO CYCLING ALONE

BOSIO, A., TOMMASINI, E., MORELLI, A., MISSAGLIA, S., TAVIAN, D., VAGO, P., PECCI, C., RAMPININI, E.
MAPEI SPORT RESEARCH CENTRE

INTRODUCTION: Percutaneous Neuromuscular electrical stimulation (NMES) is used in sports medicine both for strength training and rehabilitation (1). The effects of NMES during cycling showed a higher metabolic and cardiorespiratory response compared to a control condition. However, training studies failed to show a higher effectiveness of this method compared to normal cycling (2). This might be due to the time asynchrony between NMES and voluntary contraction. The aim of the present training study (6 weeks/2-3 sessions per week) was to investigate the effects of a novel Adaptive Functional Electrical Stimulation Kinesitherapy (AFESK™) that can trigger the electrical stimulus in synchrony with the voluntary contraction of the stimulated muscles.

METHODS: Sixteen males (age 39 ± 10 years, VO_{2peak} 48.0 ± 4.8 ml·min·Kg⁻¹) were randomly allocated to either a control (CON) group performing 4x5 min intervals at 60% aerobic peak power output (3 min recovery, 40% PPO) or an experimental (EXP) group performing the same training protocol with superimposed AFESK™ on leg muscles. Before and after the training period, aerobic and anaerobic lactate thresholds, 6 seconds sprint, 5km time trial performance were assessed during cycling. Similarly, the neuromuscular function of the knee extensors muscles (NMF) including maximal voluntary contraction (MVC), activation level (VA) and electrically evoked twitch responses (1, 10, 100 Hz), was investigated in isometric conditions. Change scores between post and pre assessments were determined in each group and for each dependent variable, then compared using Mann-Whitney U test. Data are presented as mean $\pm$ standard deviation.

RESULTS: Power outputs at aerobic (CON $+4 \pm 19$ W vs EXP $+27 \pm 22$ W, $p=0.031$) and anaerobic (CON $+1 \pm 14$ W vs EXP $+28 \pm 23$ W, $p=0.021$) lactate thresholds statistically increased only in EXP. Mean maximal 6 seconds cycling power output statistically ($p=0.028$) increased in EXP ($+26 \pm 29$ W) but not in CON (-3 ± 23 W). The 5km time trial did not statistically change (CON $+1 \pm 15$ s vs EXP -8 ± 8 s, $p=0.226$). The training period did not impacted on maximal voluntary contraction (CON -1 ± 45 Nm vs EXP -8 ± 30 Nm, $p = 1.000$) and maximal voluntary activation levels (CON $-1 \pm 4\%$ vs EXP $+3 \pm 6\%$, $p=0.161$) in both groups but reduced evoked twitch responses at 1 Hz (CON $+3 \pm 6$ Nm vs EXP -2 ± 4 Nm, $p=0.038$) and at 100 Hz (CON $+4 \pm 9$ Nm vs EXP -7 ± 7 Nm, $p=0.038$) in EXP.

CONCLUSION: This is the first study suggesting a beneficial impact of electrical stimulation used during cycling training. The enhanced training effects encountered in EXP at the Aerobic and Anaerobic thresholds might be partly ascribed to a slightly higher level of muscle strain, and consequent fatigue, caused by the administration of AFESK™. This could represent a stronger stimulus promoting muscle adaptations. Further studies showing similar results are necessary to confirm the use of AFESK™ as a tool to potentiate the training effects in cycling.

CONCENTRIC VERSUS ECCENTRIC CYCLING: A COMPARATIVE ANALYSIS OF CARDIOPULMONARY RESPONSES AT MAXIMAL INTENSITY

GHIOTTO, L., BUDEL, L., D'EMANUELE, S., INGLIS, E.C., POGLIAGHI, S., SCHENA, F., TARPERI, C.

UNIVERSITY OF VERONA

INTRODUCTION: Several studies (1,2) have shown that eccentric cycling requires a lower metabolic demand compared to concentric exercise when performed at equivalent power outputs. However, cardiovascular and pulmonary responses differ between these two exercise modalities under maximal-intensity protocols to exhaustion have been much less studied. Therefore, the present study was aimed to investigate the metabolic responses elicited during incremental tests conducted in both concentric and eccentric modes.

METHODS: 15 participants (F=4; M=11; 23 ± 3 years; 1.77 ± 0.09 m; 71.3 ± 14.5 kg) performed in two separate weeks, both concentric (CONC) and eccentric (ECC) cycling tests until reaching task failure (Monark COSMED for the concentric and Cyclus 2 for the eccentric modalities), starting by a 75W and incrementing the workload by 25W every minute. Throughout the tests, gas exchange, heart rate (HR) and power output were continuously monitored by a CPET cart (QuarkB2; COSMED, Rome, Italy). The normality of the data was evaluated using the Kolmogorov-Smirnov test, and significant differences among the variables were determined via ANOVA.

RESULTS: Peak power output (PPO) in the ECC condition ($p=0.25$, $\eta^2 = 0.11$) was 7% lower (329 ± 60 W) than in the CONC (353 ± 76 W) condition, although this difference was not statistically significant. In contrast, there were significant differences between the ECC and CONC cycling tests in other parameters. For instance, peak oxygen consumption ($\dot{V}O_{2peak}$) was 37% lower for ECC (2385 ± 403 mL/min) compared to CONC condition (3804 ± 797 mL/min). Additionally, maximal ventilation ($\dot{V}Emax$) in ECC (60 ± 10 L/min) was 60% lower than in CONC (150 ± 29 L/min), and maximal heart rate (HR_{max}) was 18% lower in ECC (149 ± 20 bpm) compared to CONC (183 ± 15 bpm).

CONCLUSION: During a maximal incremental test, metabolic responses exhibit distinct differences between eccentric and concentric exercise modalities. Contrary to the limited evidence available (3), our results indicate a comparable PPO between the two conditions. However, we demonstrated that $\dot{V}O_{2peak}$, $\dot{V}Emax$, and HR_{max} values are lower. Our results confirmed that the ventilatory thresholds (VT1 and VT2) are clearly identifiable during concentric modality but remain undetectable when the same test is performed in eccentric modality.

These findings suggest further investigations are necessary, both in maximal and submaximal contexts in order to better understand the cardiometabolic responses to these two exercise modalities to optimize training program effects while minimizing risks, especially in pathological populations.

OP-AP36 Recovery and Performance Enhancement

OPTIMAL RECOVERY INTERVALS FOR POST-ACTIVATION PERFORMANCE ENHANCEMENT VARY GREATLY AMONG INDIVIDUALS: ANALYSIS OF A LARGE SAMPLE

LIMA, L., MANTOVANI, G., GOLÇALVES, M., FONTANETTI, G.

UNIVERSITY OF SÃO PAULO

INTRODUCTION: Responsiveness to post-activation performance enhancement is mediated by moderators such as training experience, conditioning activity (CA) volume and intensity, and post-CA recovery interval. In a recent meta-analysis, Xu et al. [1] provided an evidence-based framework for designing effective PAPE protocols for both clinical and research purposes. Their finding indicated that, regardless of CA type, the optimal post-CA recovery interval (OPT) ranges between 2.5 and 11 minutes, peaking at 5.5 minutes. Given the high inter-individual variability in PAPE responsiveness and the relatively wide range of OPT observed by Xu et al. [1], our aim was to analyze the distribution of the OPT in a large sample. We hypothesized that OPT would not follow a normal distribution.

METHODS: Following familiarization and 1-RM determination sessions, forty-six trained males (23.8 ± 4.0 years, 79.0 ± 12.8 kg, 175 ± 3 cm) who were PAPE responders attended the laboratory on two separate days to complete an experimental and a control session in randomized order. The control session involved assessing countermovement jump (CMJ) performance at baseline, followed by a standardized warm-up comprising five minutes of light cycling and three sets of three unloaded squats. CMJ performance was subsequently assessed at 2, 4, 6, 8, and 10 minutes post-warm-up. In the experimental session, instead of the standardized warm-up, participants performed a CA consisting of three sets of three barbell squats at 87% 1-RM. CMJ performance was assessed at the same time points as in the control session. The recovery interval at which each participant achieved their best CMJ performance was recorded as their OPT. A two-way ANOVA

was conducted to compare CMJ performance between sessions and across recovery intervals. OPT distribution was tested using the Smirnov-Kolmogorov test.

RESULTS: CMJ performance declined two minutes after seated rest (34.7 ± 6.2 vs 33.6 ± 6.6 cm) but returned to baseline levels for the remainder of the control session, indicating that the assessment protocol did not induce significant potentiation. In the experimental session, CMJ performance was significantly higher than baseline (33.3 ± 7.0 cm) at all time points post-CA (2 min: 35.6 ± 6.9 cm; 4 min: 36.1 ± 7.0 cm; 6 min: 35.9 ± 6.7 cm; 8 min: 35.5 ± 6.5 cm; 10 min: 35.1 ± 6.3 cm). The mean, median and mode OPT were 4.8, 4.0, and 4.0, respectively. OPT distribution was non-gaussian ($D[46] = 0.236$, $p < 0.01$).

CONCLUSION: Our findings support the data reported by Xu et al. [1] demonstrating that the mean OPT is approximately 5.5 minutes post-CA. Our hypothesis that OPT distribution would not be normal was confirmed by the obtained data, suggesting that individualized post-CA recovery intervals should be adopted when designing protocols aimed at inducing PAPE.

DOES ACUTE SLEEP RESTRICTION NEGATIVELY AFFECT MAXIMAL STRENGTH, MUSCLE POWER, STRENGTH ENDURANCE, AND PSYCHOLOGICAL READINESS IN RESISTANCE-TRAINED WOMEN? PRELIMINARY RESULTS OF RANDOMIZED CONTROL

KOMAREK, Z., LIPOWSKA, M.2, WIECEK, M.2, SPIESZNY, M.1, HOLDA, M.3, VITALE, J.1,4, FILIP-STACHNIK, A.1,5
1,2 UNIVERSITY OF PHYSICAL CULTURE IN KRAKOW, POLAND; 3 JAGIELLONIAN UNIVERSITY, KRAKOW, POLAND; 4 SCHUL-
THESS KLINIK, ZÜRICH, SWITZERLAND; 5 ACADEMY OF PHYSICAL EDUCATION IN KATOWICE, POLAND

INTRODUCTION: Sleep is essential for optimal physical and cognitive performance, yet its effects on resistance exercise performance remain unclear in women. This study aimed to investigate the effects of acute sleep restriction on maximal strength, muscle power, and strength endurance in resistance-trained women.

METHODS: Eight resistance-trained women (age: 25 ± 4 years; BMI: 23.0 ± 2.8 kg/m²) participated in a randomized, counterbalanced, crossover study, completing two identical experimental sessions under different sleep conditions: a) night of habitual sleep (HS) and b) acute sleep restriction (SR) at the beginning of the night (i.e. 3 hours less than habitual sleep with a delayed bedtime). Sleep was monitored using wristwatch actigraphy (MotionWatch8, CamNtech, Neurotechnology Ltd., Cambridge, UK) to ensure compliance. Each session took place at the same time (~09:00am) and included: a) one repetition maximum test (1RM) in bench press exercise; b) three sets of three repetitions of explosive bench press exercise at 50% 1RM; c) countermovement jump (CMJ) and d) strength endurance test in the bench press exercise at 50% 1RM. Before testing, participants completed: a) the Readiness-to-Train Questionnaire (RTT-Q) and b) the Self-Assessment Manikin questionnaire (SAM) to assess arousal and valence. Immediately after testing, ratings of perceived exertion (RPE; 6-20) and pain levels on visual analogue scale (VAS; 0-10) were obtained. Difference between conditions was determined by paired T-tests or Wilcoxon tests according to data distribution, except explosive bench press exercise, where a two-way ANOVA was applied. Effect sizes (ES) were calculated using Hedge's.

RESULTS: No significant differences between HS and SR conditions were observed in: a) 1RM (45.9 ± 5.1 kg vs 44.4 ± 5.6 kg; $p=0.14$; $ES=0.26$; $\Delta=-3.3\%$); b) peak (1.52 ± 0.15 m/s vs. 1.42 ± 0.23 m/s; $p=0.13$; $ES=0.49$; $\Delta=-6.6\%$), and mean (1.12 ± 0.11 m/s vs. 1.00 ± 0.15 m/s; $p=0.05$; $ES=0.86$; $\Delta=-10.7\%$) bar velocity during explosive bench press exercise; c) CMJ (28.6 ± 4.8 cm vs 29.0 ± 6.3 cm; $p=0.22$; $ES=-0.07$; $\Delta=1.4\%$) and d) number of repetitions during strength endurance test (37 ± 9 vs 34 ± 6 ; $p=0.22$; $ES=0.37$; $\Delta=-8.1\%$). Significant differences between HS and SR conditions were noted on SAM scores for arousal (62 ± 19 arbitrary unit a.u.) vs 36 ± 12 a.u. ; $p=0.01$; $ES=1.55$), dominance (71 ± 21 a.u. vs 43 ± 19 a.u.; $p=0.02$; $ES=1.32$) and valence (77 ± 22 a.u. vs 45 ± 27 a.u. ; $p=0.01$; $ES=1.23$), without changes in RTT-Q, RPE and VAS.

CONCLUSION: Acute sleep restriction (3-hour reduction) does not significantly impair maximal strength, muscle power, or strength endurance in resistance-trained women. However, reduced emotional state scores indicate a negative impact on mood and psychological readiness. While short-term sleep loss may not immediately affect physical performance, it could influence motivation and long-term outcomes. Further research is needed to explore the relationship between emotional state and resistance training performance after sleep restriction.

ACUTE EFFECTS OF DIFFERENT STRETCHING TECHNIQUES ON REGIONAL MUSCLE STIFFNESS OF THE GASTROCNEMIUS MEDIALIS ASSESSED WITH SHEAR-WAVE ELASTOGRAPHY

LONGO, S., CÈ, E., PAU, S., BATTIOLI, R., CORATELLA, G., PADOVAN, R., TONINELLI, N., SCONFENZA, L.M., ESPOSITO, F.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Stretching can acutely increase the maximum range of motion (ROM_{max}). However, its effects on muscle mechanical properties vary depending on the type, intensity, and duration of the stretching maneuver. Shear-wave elastography (SWE) was used to assess muscle stiffness by measuring ultrasound wave speed through the tissue. This speed can be converted into modulus (μ , kPa), providing an estimate of tissue elasticity. Recently, SWE has been applied to investigate stretch-induced changes in muscle stiffness. Since different muscle regions may exhibit different μ values, we examined whether three stretching protocols affected μ differently in two muscle regions.

METHODS: Twelve participants (8 men, 4 women; mean $\pm$ SD: age = 23.9 $\pm$ 2.4 years, body mass = 69.8 $\pm$ 10.6 kg, height = 172.0 $\pm$ 8.5 cm) completed three stretching sessions on separate days. ROMmax was assessed. GM stiffness (μ) was measured using SWE (V8, Samsung Healthcare, Seoul, Korea) at both a neutral ankle angle (90°) and at 80%ROMmax in the middle muscle portion (GMmid) and the muscular region of the GM myotendinous junction (MTJ). Measurements were taken PRE and immediately POST 5 $\times$ 30-s passive static stretching (PS30, 30-s inter-set rest), 5 $\times$ 45-s PS (PS45, 15-s inter-set rest), and 5 $\times$ 30-rep dynamic stretching (DS, 30-s inter-set rest). The order was randomized. The same absolute angle at 80%ROMmax was used in POST evaluations. Within-day reliability was assessed before stretching using intraclass correlation coefficient (ICC) analysis. Data were analysed with repeated-measures ANOVA (within-factors: stretching type, region, ankle angle, time) at $p < 0.05$, with Bonferroni correction for pairwise comparisons.

RESULTS: ICCs were >0.80 for all parameters. No significant differences were found at PRE across the three days ($p > 0.05$). No main interactions were observed ($p > 0.05$). PS30 increased ROMmax (8.4%, $p < 0.01$) and decreased GMmid μ at 80%ROMmax (-17.6%, $p < 0.01$). PS45 increased ROMmax (7.8%, $p < 0.01$) and decreased GMmid μ at 80%ROMmax (-14.2%, $p < 0.01$), as well as MTJ μ at both 90° (-13.4%, $p < 0.01$) and 80%ROMmax (-8.6%, $p < 0.01$). DS increased ROMmax (11.1%, $p < 0.01$) and reduced GMmid μ at 80%ROMmax (-12.5%, $p < 0.01$) and MTJ μ at 90° (-12.7%, $p < 0.01$), while the decrease at 80%ROMmax was not significant (-8.3%, $p > 0.05$).

CONCLUSION: This study highlights that stretching-induced changes in muscle stiffness can be region-specific and depend on the protocol used. Longer-duration static stretching was more effective in reducing stiffness across GM regions. Dynamic stretching improved ROMmax but had a more limited impact on muscle stiffness, particularly at the MTJ. However, the small sample size and variability in μ may have influenced these findings.

TRAINING LOAD AND RECOVERY IN ELITE VOLLEYBALL PLAYERS: NEUROMUSCULAR, PSYCHOLOGICAL, AND SOCIAL PERSPECTIVES

REBELO, A., PEREIRA, J.R., VANDE BROEK, G., COELHO-E-SILVA, M.J., ELFERINK-GEMSER, M., VALENTE-DOS-SANTOS, J.
UNIVERSIDADE LUSÓFONA

INTRODUCTION: Optimizing recovery is important for sustaining performance and minimizing injury risk in elite team sports. Training load is commonly divided into internal (ITL) and external (ETL) components, both of which influence various aspects of recovery. However, the extent to which ITL and ETL impact neuromuscular, psychological, and social recovery in elite volleyball remains unclear. This study investigated the associations between training load metrics and recovery dimensions over a 105-day competitive period.

METHODS: Fourteen elite male volleyball players participated in 95 training sessions and 18 matches. ITL was assessed using session rating of perceived exertion, while ETL was quantified via inertial measurement units. Neuromuscular recovery was evaluated using countermovement jump (CMJ) metrics, while psychological and social recovery were assessed via the Recovery-Stress Questionnaire for Athletes (RESTQ-Sport). Linear mixed-effects models were used to analyse repeated measures across players and time points. Significance was set at $p < 0.05$.

RESULTS: Chronic ETL negatively affected neuromuscular recovery, with increased ETL associated with longer time to take-off ($\beta = -0.008$, $p = 0.03$) and reduced reactive strength index modified ($\beta = -0.008$, $p = 0.047$). ITL significantly influenced social and psychological recovery, with acute ITL increasing social stress ($\beta = -3.512$, $p = 0.034$) and chronic ITL contributing to higher emotional exhaustion ($\beta = -0.013$, $p = 0.029$). Additionally, an elevated acute:chronic ITL ratio was linked to greater psychological strain ($\beta = 0.021$, $p < 0.001$).

CONCLUSION: These findings highlight the multidimensional impact of training load on recovery. Neuromuscular recovery was primarily influenced by ETL, while ITL played a more significant role in psychological and social stress responses. Coaches and practitioners should integrate objective neuromuscular assessments with subjective monitoring tools to detect fatigue, optimize recovery strategies, and enhance athlete well-being throughout the competitive season.

IMPACT OF MENTAL FATIGUE ON TRAINING VOLUME AND INTENSITY IN RESISTANCE TRAINING: A SEX-BASED ANALYSIS

DELLO STRITTO, E., ROMAGNOLI, R., QUAGLIAROTTI, C., PIACENTINI, M.F.
UNIVERSITY OF ROME

INTRODUCTION: Mental fatigue (MF) is a psychobiological state that arises following prolonged and demanding cognitive activity (1). Although the effects of MF on endurance performance are well recognized (1), there is a lack of research on its effects on resistance training (RT) sessions. Velocity of the first repetition (V1Rep) and training volume (TV) have been shown to be affected by MF but only when sets are performed to failure (2). However, athletes rarely train to failure while they use the V1Rep to set training intensity and the percentage of velocity loss (VL) from the V1Rep to define TV, a practice known as velocity-based training (VBT). Its main benefit is real-time monitoring of daily readiness and fatigue. Therefore, the aim of the present study was to investigate the effect of MF on TV and V1Rep during back squat in males and females, using VL to determine TV. The hypothesis is that MF will decrease TV and V1Rep in both sexes with no difference between sexes.

METHODS: Nineteen experienced resistance-trained athletes (10M, 9F) completed six sessions. The first four familiarized subjects with VBT and VL. In the last two sessions (randomized order), subjects underwent either a MF protocol (45 min AX-CPT) or a control session (CS; 45 min documentary). In both, they performed a standardized warm-up followed by four sets of back squats. The squat sets included two VL conditions (20%VL and 40%VL) and two loads (60% 1RM and 80% 1RM). Repeated measures ANOVA (pre- vs. post-condition) with sex as a between-group factor analyzed MF's impact on VRep and TV. MF was measured via VAS and TV is the total number of repetitions completed across the four squat sets.

RESULTS: MF significantly increased ($p<0.05$) after the AX-CPT session but not after the CS. In the MF condition, TV significantly decreased for both sexes (M: PRE 29.6 ± 8.3 , POST 25.1 ± 7.3 ; F: PRE 34.7 ± 9.6 , POST 25.6 ± 7.9 ; $p<0.05$) with no significant interaction condition*sex. VRep significantly decreased in males at 60%RM (m/s: M PRE 0.70 ± 0.10 , POST 0.63 ± 0.07) but not in females (m/s: F PRE 0.61 ± 0.07 , POST 0.59 ± 0.08); at 80%RM, VRep significantly decreased in both sexes (m/s: M PRE 0.49 ± 0.05 , POST 0.43 ± 0.05 ; F PRE 0.44 ± 0.08 , POST 0.41 ± 0.07), with a significant sex interaction at 60%RM but not at 80%RM. In the CS, no differences were observed ($p>0.05$).

CONCLUSION: MF decreased the total number of repetitions across the four sets in both sexes. VRep decreased at both 60%1RM and 80%1RM in males, but only at 80%1RM in females. MF may affect sexes differently, notably at VRep at 60%1RM, where males decline more than females. Evidence on sex differences in MF is scarce and sometimes contradictory, warranting further research. Regardless, MF negatively impacts RT sessions, making it essential to avoid cognitively demanding tasks before RT or adopt strategies to counteract MF.

EFFECT OF LOAD-VELOCITY PROFILING METHODS ON BENCH PRESS 1-RM ASSESSMENT

GROSSI, T., MICHELI, L.1, SHOAEI, V.1, FERRI MARINI, C.2,3, LUCERTINI, F.1

1UNIVERSITY OF URBINO CARLO BO; 2UNIVERSITY OF GRONINGEN; 3UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: Individual load-velocity profiles (LVP), which is measured during multiple sets with incremental load repetitions performed at maximal velocity, have been proposed as an accurate method to assess muscular fitness and one-repetition maximum (1-RM). LVP can be assessed using several protocols consisting of different load increments patterns and reps to be performed. The commonly used strategies to assess the LVPs are to adjust the load increments using either the a) repetition mean propulsive velocity (MPV) performed at the different loads (standardized LVP [LVPSTND]) [1] or b) individuals' %1-RM using multiple (LVPMULT) [2] or two (LVP2-POINT) [3] loads. Despite variations in sets and repetitions, no study has examined whether testing protocols affect 1-RM load and velocity (V1-RM). This study investigates the impact of different LVP methods on these measures.

METHODS: Fifteen healthy males (25.9 ± 3.9 yrs) visited the lab 4 times, separated by at least 48 h of rest. On day 1, participants 1-RMs (89.5 ± 15.9 kg) were assessed and they familiarized with the Smith machine bench press exercise and trained to push the barbell as explosively as possible during the concentric phase. On days 2 to 4 (random order), participants' LVPs were assessed using: LVPSTND (load increments: 10 kg for $MPV>0.5$ m/s, 1-5 kg for $MPV<0.5$ m/s; reps: 3 for $MPV>1.0$ m/s, 2 for MVP between 0.65-1.0 m/s, 1 for $MPV<0.65$ m/s), LVPMULT (20, 40, 60, 80, 90% of 1-RM), and LVP2-POINT (50 and 80% of 1-RM) methods, and 1-RM load and V1-RM were assessed. The execution velocity was measured using a linear position transducer (Vitruve, Madrid, Spain) attached to the barbell of a Smith machine. After assessing the normality of the distribution of the variables, 1-RM loads across methods were compared using a repeated-measure ANOVA followed by Bonferroni corrected pairwise post-hoc comparisons, while V1-RM were compared across methods using the Friedman test.

RESULTS: The LVP testing method affected ($F(2,28)=3.476$, $\eta^2=0.199$, $p=0.045$) 1-RM load. Bonferroni comparisons showed that solely the LVP2-POINT 1-RM (93.3 ± 16.8 kg) was significantly higher ($p=0.044$) than the LVPSTND 1-RM (90.6 ± 16.2 kg), whereas there were no differences between LVPMULT (92.3 ± 16.2 kg) and LVP2-POINT ($p=1.000$) or LVPSTND ($p=0.331$). Conversely, V1-RM measured using LVPSTND (0.15 ± 0.03 m/s), LVPMULT (0.14 ± 0.04 m/s), and LVP2-POINT (0.16 ± 0.04 m/s) were not different ($\chi^2(2)=0.792$, $p=0.673$).

CONCLUSION: This study indicates that while the testing protocol used to assess LVP does not influence V1-RM it affects 1-RM load. In particular, the LVP2-POINT seems to allow an accurate estimation of 1-RM while minimizing fatigue. Therefore, LVP2-POINT could offer not only a higher, hence more accurate, 1-RM estimation, but also a more feasible and time-saving strategy to assess 1-RM due to the fewer sets needed.

THE PREDICTIVE VALIDITY OF BACK SQUAT ONE-REPETITION MAXIMUM ESTIMATION USING OPTIMAL MINIMUM VELOCITY THRESHOLD: IS IT OPTIMAL OR COMPLEX AND NONBENEFICIAL?

HOMER, K., SENTÜRK, D., AKYILDIZ, D., JUKIC, I.

EDITH COWAN UNIVERSITY

INTRODUCTION: The load-velocity relationship (LVR) is used to predict one-repetition maximum (1RM); however, it often yields inaccurate estimations. The minimum velocity threshold (i.e., the velocity at 1RM [MVT]) has been used to make predictions, whereby poor MVT reliability may contribute to erroneous predictions and limit application. To enhance predictions, optimal MVT-the velocity where the difference between actual and predicted 1RM from the same 1RM test is zero-has been proposed. Unlike some other prediction methods, optimal MVT needs to be established in a preliminary 1RM test and requires multiple loads to be performed within subsequent sessions. Currently, the predictive validity of optimal MVT across multiple testing sessions is unknown. Thus, the utility of various 1RM prediction models using optimal MVT in both the free-weight (FW) and Smith-machine (SM) back squat was investigated.

METHODS: In this counterbalanced, randomised, crossover design, 14 trained males (FW 1RM=132.5±28.5kg; SM 1RM=163.9±30.4kg) performed a familiarisation session followed by three sessions each of FW and SM back squat 1RM testing separated by 72 hours and alternating between the exercises. Loads of 20, 40, 60, 80, 90, and 100% of 1RM were performed each visit with the load and concentric mean velocity recorded. The reliability of MVT was determined via intra-class correlation coefficient (ICC) and coefficient of variation (CV) with ICC>0.9 and CV<10% deemed reliable. Optimal MVT for both exercises was determined from the day one LVR and subsequently used to predict day two and three 1RMs from the submaximal loads in these sessions. Optimal MVT from linear regression was used in the linear multiple-point and two-point models, while polynomial multiple-point models used the polynomial regression-derived optimal MVT. Additionally, both individual and group mean optimal MVT was used for all models. The percentage difference between the actual and estimated 1RM on each day was used to determine model error (E) for each participant with E<2.5% considered excellent, 2.5-5% acceptable, and >5% unacceptable.

RESULTS: Both FW (ICC=0.92, CV=6.62%) and SM (ICC=0.91, CV=5.38%) MVT were deemed reliable. From all prediction models, only the FW individual 40-90% multiple-point linear and SM individual 20&90% two-point models had all participants within the acceptable threshold across both days. None of the polynomial models for either exercise had all participants in the acceptable threshold and generally displayed greater E than the linear and two-point models.

CONCLUSION: The predictive validity of all but two of the 1RM prediction models using optimal MVT from day one was unacceptable, despite the high MVT reliability within our trained population. Our findings indicate that using optimal MVT to estimate FW and SM 1RM may not be suitable, as it adds complexity without eliminating the need for a submaximal load near 1RM (i.e., 90% 1RM) to ensure acceptable predictive validity.

TRAINING-INDUCED CHANGES IN THE FORCE-VELOCITY PROFILE OF THE LOWER-LIMB LEAD THE STEP-SPECIFIC ADAPTATIONS OF SPRINT ACCELERATION KINETICS

KATSUGE, M., KUROSAKI, H., KAMBAYASHI, S., KITAMURA, H., NAITO, R., HIRATA, K., HIRAYAMA, K.

WASEDA UNIVERSITY

INTRODUCTION: Greater sprint acceleration is achieved by producing large horizontal ground reaction forces (GRFs). Recently, our group found that higher maximal strength and power of the lower-limb, assessed by the force-velocity (F-V) profile in vertical jumps, are associated with greater horizontal GRF during the earlier and later steps of sprint acceleration, respectively. This study examined the effects of maximal strength training and power training on the F-V profile of the lower-limb and sprint acceleration kinetics.

METHODS: Twenty-three healthy adults (7 females and 16 males, 23 ± 3 years) were assigned into the following three groups: jump squat group (JSQG, n = 7); back squat group (BSQG, n = 8); control group (CG, n = 8). JSQG and BSQG trained three times per week for 11 weeks, performing jump squats (0% and 20% 1RM, 3–5 sets × 4–6 reps at each load) and back squats (85% 1RM, 4 sets × 3–4 reps), respectively. CG was instructed to maintain their daily routines. Before and after the intervention, participants performed 15-m sprint accelerations to evaluate mean horizontal and resultant GRFs and mean angles of the GRF vector during the propulsive phase for the first and ninth steps. Jump squats were performed to evaluate the F-V profile of the lower-limb. Theoretical maximum force (F0), velocity (V0), and power (Pmax) were derived from the F-V profile. Generalized linear mixed-effects models were used to examine main and interaction effects (F-V profile: group × time; 15-m sprint acceleration: group × time × step). Between-group differences in percentage changes were compared using one-way analysis of variance or Kruskal-Wallis test. Cohen's d effect sizes were calculated to interpret the magnitude of the between-group differences in percentage changes.

RESULTS: Significant main effects of time were observed for F0, horizontal and resultant GRFs, and the angle of the GRF vector (p = 0.002–0.048), with no significant interaction effects. Between-group differences in percentage changes were not found for any variable of the F-V profile and sprint acceleration. For the F-V profile, JSQG and BSQG showed moderate changes in F0 compared to CG (d = 0.62 and 0.67). JSQG also showed small changes in Pmax compared to BSQG and CG (d = 0.43 and 0.30). For sprint acceleration, JSQG and BSQG showed small to moderate changes in the horizontal and resultant GRFs for the first step compared to CG (d = 0.38–0.99). JSQG also showed small to moderate changes in the horizontal and resultant GRFs (d = 0.25–0.66) and the angle of the GRF vector (d = –0.30 and –0.46) for the ninth step compared to BSQG and CG.

CONCLUSION: The present results imply that in healthy adults, maximal strength training enhances F_0 , leading to an increased GRF in the earlier step, whereas power training enhances both F_0 and P_{max} , leading to increased GRFs in both the earlier and later steps during sprint acceleration.

ASSESSING THE GYMAWARE RS LINEAR POSITION TRANSDUCER RELIABILITY AND VALIDITY IN MEASURING COUNTER-MOVEMENT JUMP HEIGHT

AKYILDIZ, Z., SENTURK, D.

AFYON KOCATEPE UNIVERSITY, SPORTS SCIENCE FACULTY

INTRODUCTION: Linear position transducers (LPTs) are portable and practical instruments that measure the displacement and velocity of an object using optical encoding technology. LPTs are widely used in training and athletes physical rehabilitation due to the widespread adoption of velocity-based training. LPTs also measure the distance traveled by the bar, and this function of the LPT can be used to assess vertical jump height before a training session to measure the athletes preparation and recovery. This study aimed to assess the concurrent validity and intra-device reliability of a linear position transducer (LPT) for counter-movement jump (CMJ) height. The Gymaware RS model was analyzed for intra-unit reliability by obtaining data from two devices simultaneously.

METHODS: Twenty-six subjects (22.21 ± 5.3 years) performed five CMJs using a force plate (Forcedecks) concurrently with the LPT to test validity. Data were taken from two units simultaneously to examine their values for inter-unit reliability. **RESULTS:** A paired t-test showed a significant difference between the two devices (Forcedecks and Gymaware RS) for CMJ ($p < 0.001$). Bland-Altman analysis for validity revealed that LPT overestimated jump height for CMJ in both units, Gymaware RS unit 1 (MD = 6.18 cm) and Gymaware RS unit 2 (MD = 6.38 cm). Gymaware RS unit 1 (CV%: 1.41) and Gymaware RS unit 2 (CV%: 1.14) units appear below 5% CV, as does the forcedeck force platform (CV%: 1.41). Reliability of the Gymaware RS unit 1 and Gymaware RS unit 2, intraclass correlation (ICC) for CMJ (ICC = 0.97) was high.

CONCLUSION: The Gymaware RS overestimates jump height but is a reliable tool for tracking changes in jump height to measure performance improvement and monitor fatigue.

RELATIONSHIP BETWEEN LOWER LIMBS DRY-LAND FORCE-VELOCITY PROFILING AND SWIMMING LOAD-VELOCITY PROFILING

ZHANG, D., BIDEAU, N., RAINETEAU, Y., NICOLAS, G.

RENNES UNIVERSITY 2

INTRODUCTION: Characterizing the maximal mechanical capabilities of the neuromuscular system provides valuable insights into sprint swimming. These insights are commonly obtained through dryland and in-water evaluations, considering the relationship between force/load and velocity. To achieve this, load-velocity profiling based on semi-tethered swimming has been successfully employed [1,2]. To date, previous studies have investigated whole-body load-velocity profiles without distinguishing the specific contributions of the legs. However, the lower limbs play a substantial role, contributing 43.8% to the theoretical maximal speed and 37.3% to the theoretical maximal load in front crawl load-velocity profiles of highly trained swimmers [3]. Given the crucial role of the lower limbs in propulsion, this study aims to establish a link between force-velocity (F-V) parameters in dryland conditions and load-velocity (L-V) parameters in swimming, with a specific focus on the lower limbs.

METHODS: Eight participants (16.2 ± 2.1 years; 63.7 ± 6.3 kg; 177.3 ± 5.4 cm) participated in the study. In-water L-V profiles were obtained from maximal sprint exercises in flutter kicks, butterfly kicks, and breaststroke kicks against four loads (0, 1, 2, and 3 kg) using the 1080 Motion device (1080 Motion AB, Lidingö, Sweden). For each stroke, maximal velocity (V_0), maximal load normalized to body mass (rL_0), and the L-V slope were calculated using L-V linear regressions. Additionally, dryland F-V profiles were assessed through countermovement jumps (CMJ) and squat jumps (SJ) with three loads (0, 20, 50 kg) to estimate maximal force normalized to body mass (rF_{max}) and maximal velocity (V_{max}). Correlation analyses were conducted to examine relationships between dryland F-V and in-water L-V parameters. Statistical analyses included Spearman's rank correlation and Kruskal-Wallis tests, with significance set at $p < 0.05$.

RESULTS: Dry-land parameters, V_{max} and rF_{max} exhibited strong correlations with V_0 and rL_0 obtained for flutter kick ($r > 0.7$, $p < 0.05$) while weaker correlations were observed for breaststroke and dolphin kick. Significant differences in L-V variables were measured across the three strokes. The dolphin kick exhibited the highest V_0 , but lowest rL_0 values. The breaststroke kick demonstrated the strongest rL_0 but the lowest V_0 . The flutter kick showed moderate V_0 but was the most affected by the load.

CONCLUSION: Dryland F-V capabilities exhibited the strongest correlation with flutter kick performance. Regardless of whether SJ or CMJ was used, a higher V_{max} was associated with a greater V_0 in the flutter kick. Additionally, a higher rF_{max} in dryland corresponded to a higher rL_0 in water.

A FIVE-WEEK TRAINING INTERVENTION IMPROVED SCANNING BEHAVIOR IN U19 FEMALE FOOTBALL PLAYERS

HINTERMANN, M., ROMANN, M., FUCHSLOCHER, J.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM, SWITZERLAND

INTRODUCTION: Visual exploration, or scanning, plays a crucial role in football, enabling players to assess their surroundings, anticipate, and make better decisions [1-3]. Despite its recognized importance, systematic research on effective training methods for developing this skill remains limited. This study employed a quasi-experimental design to examine changes in scanning behavior before and after a five-week training intervention.

METHODS: A total of 36 U19 female football players (mean $\pm$ SD age: 16.7 $\pm$ 1.2 years) were recruited from two elite national league teams and two grassroots teams. Teams from each level were assigned to either a control or intervention group, with the latter completing 1-2 scanning-focused training sessions per week. These sessions contained exercise and game formats designed to implicitly promote scanning. To assess scanning behavior, 4v4 small-sided games were video recorded pre- and post-intervention. A scan was defined as an active head movement in which a player's face was temporarily directed away from the ball [2]. Two-way analysis of variance (ANOVA) with a Tukey post-hoc test was conducted to assess time $\times$ group effects.

RESULTS: The intervention group showed a significant increase in the mean number of scans from pre- to post-test, regardless of level (pre: 0.88 $\pm$ 0.36, 95% CI [0.70; 1.07]; post: 1.44 $\pm$ 0.52, 95% CI [1.17; 1.70]; $p = 0.002$). The control group also exhibited a slight increase, but the change was not statistically significant (pre: 0.61 $\pm$ 0.27, 95% CI [0.49; 0.72]; post: 0.92 $\pm$ 0.43, 95% CI [0.73; 1.10]; $p = 0.068$).

Further analysis integrating level as an additional factor in the ANOVA revealed a significant time (pre-, post-) $\times$ level interaction ($p = 0.038$), indicating that elite and grassroots players responded differently to the intervention. Among elite players, those in the intervention group performed significantly more scans in the post-test compared to the control group (intervention: 1.72 $\pm$ 0.39, 95% CI [1.48; 1.96]; control: 1.17 $\pm$ 0.43, 95% CI [0.89; 1.45], $p = 0.005$). Additionally, elite players in the intervention group exhibited a significant increase in scanning behavior from pre- to post-test ($p < 0.001$), whereas no significant improvements were observed in grassroots intervention players.

CONCLUSION: A five-week scanning-focused training intervention can significantly improve scanning behavior in young female football players. This intervention can serve as a practical coaching tool for integrating perceptual-cognitive training into on-field training programs. However, the effectiveness of the intervention appears to be more pronounced in elite players, suggesting that level may moderate its impact. Given the small sample size and dropouts during the study, results should be interpreted with caution, and further research is needed to explore the long-term effects and applicability across different levels of competition.

DETERMINING THRESHOLDS FOR MATCH SEQUENCES DURING CONGESTED FIXTURES TO MINIMIZE DECREMENTS IN FOOTBALL PLAYERS LOCOMOTOR PERFORMANCE

SILVA, H., MENEZES, P., ERREKAGORRI, I., NAKAMURA, F.Y., MARCELINO, R.

U/MAIA

INTRODUCTION: The relentless scheduling of football matches has become a growing concern for professionals, as it can drain players' physical performance (1) and heighten their risk of injury (2, 3). Recognizing this, the Fédération Internationale des Associations de Footballeurs Professionnels (FIFPRO) has increasingly urged sporting organizations to heed players' concerns and take meaningful action (4). This work delves into the impact of fixture congestion, examining how recovery time between matches and travel demands influence physical performance, while also identifying potential threshold limits to mitigate these negative effects.

METHODS: Sixty-six elite football players were monitored over two competitive seasons using global navigation satellite systems (WIMU Pro, 10 Hz). Matches were classified based on recovery time (<72h, 72-120h, 121-168h, >168h) and accumulated travel distances in the previous 3, 5, and 7 days (0 km [home matches], 1-250 km, 251-1000 km, >1000 km). Playing positions and match sequences during congested periods were also considered. Locomotor metrics included total distance, distance covered at various speed ranges (14-20 km/h, 20-25 km/h, 25-30 km/h, >30 km/h), maximal velocity, maximal accelerations and decelerations, and the number of accelerations and decelerations between 2-3 m/s². A linear mixed model was applied to each physical variable to assess differences based on recovery intervals, travel distances, playing positions, and match sequences during congested fixtures. Statistical significance was set at $p < 0.05$.

RESULTS: Players performed more decelerations ($2\text{--}3\text{ m/s}^2$) in matches with 121-168 hours of recovery compared to those with less than 72 hours ($p=0.027$). Matches with 72-120 hours of recovery and 251-1000 km of accumulated travel saw higher maximum velocities and greater distances covered at speeds above 30 km/h compared to matches with over 168 hours of recovery across various travel distances (0 km, 251-1000 km, >1000 km) ($p<0.05$). Central defenders and central midfielders exhibited the most significant variations in locomotor activity compared to other positions, though no consistent advantage was found between congested and non-congested fixtures. Crucially, locomotor performance declined noticeably after 3 (<72h) or 4 (<120h) consecutive matches.

CONCLUSION: This work underscores the significant physical strain placed on players during congested fixtures, with notable declines in locomotor performance after 3 (<72h) or 4 (<120h) consecutive matches. The findings highlight the critical need for managing recovery periods to prevent fatigue accumulation and reduce injury risk. To minimize these risks, limiting players to no more than 3 matches with less than 72 hours of recovery, or 4 matches with less than 120 hours of recovery, is recommended as a potential threshold.

COACHING STRATEGIES AND PERFORMANCE IN ELITE ITALIAN FOOTBALL: AN OBSERVATIONAL COMPARATIVE ANALYSIS OF POSSESSION-ORIENTED AND DIRECT-PLAY APPROACHES

RUSCELLO, B., PANTANELLA, L., CANTORE, F., MORGANTI, G., FILETTI, C., PORTA, M., BRIOTTI, G., PADUA, E.

SAN RAFFAELE ROMA OPEN UNIVERSITY, 00166 ROME, ITALY

INTRODUCTION: This study examines the influence of coaching styles on performance patterns in elite Italian mens football by comparing a possession-based "building-from-the-back" approach with a direct style. By analyzing tactical indicators such as ball possession, goal-scoring opportunities, and match outcomes, it underscores the pivotal role of coaches in shaping these styles [1]. Particular attention is paid to the evolving role of goalkeepers in developing offensive phases, as well as to the broader impact of playing style on team success in Italy's Serie A.

METHODS: Observational data were gathered from all 380 games of the 2022-2023 "Serie A" season through publicly available data sources. Teams were sorted based on their preferred style of play by examining the distribution patterns of goalkeepers. Those who preferred short passes were grouped under the build-up play approach (Group 1), and those who used long clearances were grouped under the direct style (Group 2) [2]. Statistical tests applied included Welch's t-test to compare group means, Logistic regression was also applied to estimate the impact of playing style on qualification to major European competitions.

RESULTS: Teams using the "building-from-the-back" strategy achieved superior results across multiple metrics: higher average points (63.8 ± 14.4 vs. 40.2 ± 14.1 , $p < 0.002$), more goals scored (57.3 ± 10.5 vs. 40.1 ± 12.5), and fewer goals conceded (42.4 ± 10.4 vs. 55.0 ± 10.9). Offensive efficiency was also greater, with increased total shots, shot-creating actions, and goal-scoring actions. Ball possession was significantly higher in Group 1 ($53.05\pm4.35\%$ vs. $46.95\pm5.00\%$), demonstrating enhanced control over match tempo [3]. Logistic regression analysis indicated that possession-based teams were 13.5 times more likely to qualify for European competitions, although confidence intervals suggest further validation is needed.

CONCLUSION: While results indicate that possession-based strategies correlate with better performance, the observational nature of this study prevents causal inferences. Tactical decisions made by coaches, particularly in adapting styles to match situations and player capabilities, are crucial in determining success. These findings reinforce the importance of structured coaching methodologies that enhance technical and decision-making abilities within specific tactical frameworks. This study contributes to the discourse on coaching effectiveness, offering empirical evidence for strategic development in elite football. Future research should incorporate longitudinal analyses or experimental interventions to establish causality between playing style and performance outcomes.

GENDER DIFFERENCES IN DIVERGENT THINKING AND MOTOR CREATIVITY AMONG YOUNG BASKETBALL PLAYERS

SKY, B., LEVY, H., SHACHAR, S., BEN ZAKEN, S.

LEVINSKY-WINGATE ACADEMIC COLLEGE

INTRODUCTION: Creativity plays a pivotal role in basketball performance, enabling players to effectively respond to novel situations and challenges during gameplay. Creative acts originate in the mind through divergent and convergent cognitive processes before manifesting as motor behaviors¹. Divergent thinking (DT), which involves the generation of multiple alternative ideas, encompasses dimensions such as fluency (the ability to generate several responses), flexibility (the ability to generate different categories of responses), and originality (the ability to generate unusual responses)². Motor creativity (MC) refers to the production of new motor patterns to solve pre-established problems³. Despite extensive research, gender-specific findings remain inconclusive, especially among athletes⁴. This study aimed to explore gender differences in DT and MC among young basketball players.

METHODS: A total of 162 youth basketball players (86 males, aged 14-18) were divided into National Team (NT; n=82) and League Players (LP; n=80). DT was assessed using the Runco Creative Assessment Battery (rCAB; 2011, www.creativitytestingservices.com), which scored both figural and verbal responses. MC was evaluated through an agility ladder task that measured movement fluency, flexibility, and originality.

RESULTS: Significant gender differences in DT were found, with male NT players outperforming both male LP (7.46 vs. 3.89, 4.44 vs. 2.61, 3.53 vs. 1.31, for figural DT fluency, flexibility and originality respectively, $p<0.05$; 4.74 vs. 2.55, 3.32 vs. 2.06 and 1.92 vs. 0.94 for verbal DT fluency, flexibility and originality respectively, $p<0.05$); and female NT players (4.62, 2.71, 1.53 for figural DT fluency, flexibility and originality respectively; 2.97, 2.20 and 0.83 for verbal DT fluency, flexibility and originality respectively). Notably, female NT and LP players demonstrated similar DT scores. In contrast, no gender differences were observed in MC dimensions. However, LP players exhibited higher MC fluency but lower flexibility than NT players.

CONCLUSION: The results suggest potential gender-specific developmental trajectories in DT at elite levels. However, the absence of gender differences in MC suggest that physical creative expression may develop independently of cognitive creative abilities. These results highlight the complex relationship between gender, competitive level, and different forms of creativity in basketball, suggesting the need for tailored development approaches that consider both cognitive and motor creative abilities across genders and competitive levels.

WHERE IN A HANDBALL MULTI-PHASE ATTACKING SEQUENCE IS THE SPEED-ACCURACY TRADE-OFF?

LIANG, Y., WANG, Y.R., ZHAO, D.Y., ZHOU, R., HILEY, M.J.

ANHUI NORMAL UNIVERSITY

INTRODUCTION: Previous research on throwing in handball has focused on the technique and the speed-accuracy trade-off of the throw in isolation from a typical attacking sequence [1,2]. In such constrained conditions a traditional speed-accuracy trade-off has not been found [1,2]. A typical attacking sequence includes collection of the ball, with up to three steps to evade defenders and perform a shot. The present study aimed to determine whether a speed-accuracy trade-off existed when the player was placed within a game context, and to determine where in the sequence the trade-off occurred.

METHODS: Twenty-seven experienced university handball players, on presentation of a visual stimulus, were required to grasp the ball, step around a virtual defender, then jump shoot between two virtual defenders towards a target within a handball goal, again with a defending virtual goalkeeper. The task was repeated under two conditions, with instructions to prioritize speed or accuracy. High speed video and digitizing was used to record the reaction, approach, throwing, and ball flight time along with the accuracy of the. Additional maximal velocity throws, with no concern for accuracy, were recorded. Two-way repeated measures ANOVAs were used to determine differences in group (male vs. female) and condition (speed vs. accuracy). Significant interactions and main effects were followed-up by Bonferroni post-hoc procedures. Significance was set at $p<0.05$.

RESULTS: A traditional speed-accuracy trade-off was found for the sequence, with both groups (main effect for condition $F_{1,25}=11.40$; $p=0.002$) being quicker (males: 1.85 ± 0.11 s vs. 1.91 ± 0.15 s, females: 1.95 ± 0.06 s vs. 1.97 ± 0.08 s) and less accurate (main effect for condition $F_{1,25}=5.09$; $p=0.033$; males: 0.50 ± 0.13 m vs. 0.45 ± 0.13 m, females: 0.52 ± 0.11 m vs. 0.44 ± 0.15 m) in the speed condition. The reduction in time came from the approach and throw time, with reaction and ball speed remaining consistent across trials (males: 19.45 ± 1.24 m/s vs. 19.47 ± 1.24 m/s, females: 18.39 ± 1.13 m/s vs. 17.08 ± 0.91 m/s).

CONCLUSION: The novel finding of this work is that when placed in a sport specific context, including a typical attacking sequence, and without specific instructions regarding throwing speed (ball speed) players displayed a speed-accuracy trade-off, which has previously not been demonstrated in the literature [1,2]. The handball players, however, maintained their sub-maximal preferred ball speed (approximately 94% of maximum) in the flight phase of the throw, with gains in performance made in the earlier phases of the sequence. The study demonstrates that tasks must be investigated using as close to a real-world situation as possible in order to understand the underlying strategy. In addition, the work provides insights for coaches as to where athletes can make performance improvements.

OP-AP35 Running IV - Trail

ANALYSIS OF THE FORCE-VELOCITY PROFILE IN TRAIL RUNNERS: A PERFORMANCE STUDY

GARCÍA-HERAS, F., VALLE, M., RODRÍGUEZ-MEDINA, J., GUTIÉRREZ-ARROYO, J., CARBALLO-LEYENDA, B., RODRÍGUEZ-MARROYO, J.A.

UNIVERSITY OF LEÓN

INTRODUCTION: Trail running (TR) has grown exponentially in recent years, increasing interest in its performance factors (Babí-Lladós et al., 2021). Strength is crucial for these athletes, especially on uneven terrain (Ehrström et al., 2018), and the Force-Velocity Profile (FVP) is a useful tool to assess neuromuscular balance and its impact on performance (Pastor et al.,

2022). This study analyzed the FVP in trail runners, as well as their body composition and vertical jump ability, identifying common patterns and optimization strategies.

METHODS: A total of 17 trail runners (6 female and 11 male) with at least two years of experience were evaluated. Body composition was assessed using bioelectrical impedance (InBody 770), jump ability with the Bosco Test, and FVP through countermovement jumps (CMJ) with progressive loads (0, 10, 20, and 30% of body weight) on a force platform (Hawkin Dynamics). Theoretical maximum force (F0), theoretical maximum velocity (V0), maximum power (Pmáx), and the imbalance between force and velocity (FVimb) were calculated.

RESULTS: Results showed differences in body composition, with a body fat percentage of $10.17 \pm 2.92\%$ in male and $17.25 \pm 3.95\%$ in female. In the Bosco Test, male achieved greater jump heights in SJ (28.64 ± 4.90 cm), CMJ (32.58 ± 5.24 cm), and DJ (32.91 ± 6.19 cm) compared to female (23.48 ± 5.81 cm, 26.28 ± 6.53 cm, and 27.02 ± 5.00 cm, respectively). In PFV, all runners showed an imbalance with a force deficit (FVimb <100%), with mean F0 values of 28.35 ± 3.79 N/kg in male and 24.73 ± 4.37 N/kg in female, while V0 was slightly higher in female (5.25 ± 2.22 m/s) compared to male (4.90 ± 1.61 m/s). The mean Pmáx was 35.16 ± 11.93 W/kg in male and 30.79 ± 8.62 W/kg in female.

CONCLUSION: The most relevant finding was the generalized imbalance in FVP, with a tendency towards a force deficit. This suggests the need to incorporate specific strength training to optimize TR performance. Evaluating FVP may be key to individualizing training programs and improving physical preparation in this sport. Future research should focus on the application of strength interventions and their impact on performance improvement.

INTENSITY AND LOAD CHARACTERISTICS OF MOUNTAIN RUNNING RACES: DIFFERENCES BETWEEN MENS AND WOMENS RACES

JUAN, R., GUTIÉRREZ-ARROYO, J.1, GARCÍA-HERAS, F.1, CARBALLO-LEYENDA, B.1, RODRÍGUEZ-MARROYO, J.A.1
UNIVERSIDAD DE LEÓN

INTRODUCTION: Mountain running races take place on predefined routes in mountainous terrain, requiring athletes to navigate steep elevations, varied surfaces, and changing weather conditions while optimizing speed and endurance [1]. Heart rate (HR) has traditionally been used to monitor race intensity, though running power has recently emerged as a valuable metric [2]. While previous research has primarily focused on male athletes, competition demands for female runners remain unclear. This study aims to examine sex-based differences in external and internal load during mountain running competitions, considering physiological, performance, and biomechanical variables in races ranging from 20 to 45 km.

METHODS: Twenty-four trained mountain runners (12 men and 12 women) with over four years of experience participated in the study. They trained approximately five days per week, accumulating 5 to 12 hours of training. Body fat percentage was assessed via bioelectrical impedance, and a graded treadmill test was conducted to determine maximal HR and VO2max. Runners competed in two 20-45 km races while wearing GPS and Stryd devices to record HR and running power data. Post-race, rate of perceived exertion (RPE) was collected. Data were analyzed using GoldenCheetah to determine exercise intensity distribution and external/internal load.

RESULTS: Men exhibited significantly higher VO2max, maximal workload, and speeds at ventilatory thresholds ($P < 0.01$), as well as a lower body fat percentage ($P < 0.01$). Women completed races in significantly longer times (31%, $P < 0.01$) and placed lower overall ($P < 0.001$), though no significant differences were observed in relative rankings within each sex. At the same relative intensity, men produced greater running power, resulting in lower RPE/power and %HRmax/power ratios ($P < 0.01$). Men also displayed higher maximal mean power and spent more time at higher power intensities ($P < 0.01$), while women accumulated more time in the 1-3 W/kg power range ($P < 0.01$). External load was higher in men ($P < 0.01$), whereas internal load (assessed via RPE and HR) was similar or lower ($P < 0.05$). Biomechanically, men demonstrated higher cadence, form power, and stiffness ($P < 0.05$), whereas women exhibited longer ground contact times and greater form power relative to running power ($P < 0.05$).

CONCLUSION: This study highlights key physiological, performance, and biomechanical differences between male and female mountain runners. Men exhibit higher maximal power output and external load, while women show distinct intensity distribution and biomechanical patterns. These findings underscore the importance of running power and biomechanics in understanding sex-based performance differences in mountain running.

DEFICIT OF STRENGTH AND RUNNING PERFORMANCE IN HIGHLY TRAINED TRAIL RUNNERS

JAEN-CARRILLO, D., LAWLEY, J.S., SANTOS, L.
UNIVERSITÄT INNSBRUCK

INTRODUCTION: Trail runners develop biomechanical and neuromuscular adaptations to improve performance and reduce muscle damage due to the sport's demands. Key factors include speed, ground contact time (GCT), cadence, and leg stiffness. Shorter GCT and increased leg stiffness enhance elastic energy return, with both reflecting the stretch-shortening cycle (SSC), crucial for running efficiency. Strength, particularly knee extensor strength and Achilles tendon adaptations, is essential for trail running performance. However, the impact of different resistance training loads on performance remains unclear, especially regarding how varying loads affect elastic energy utilization and force production in prolonged versus short efforts. This study aimed to assess the relationship between biomechanical and strength variables at various 1RM percentages in highly trained male trail runners.

METHODS: Fifteen internationally competitive, injury-free trail runners participated in this study. To estimate their one-repetition maximum (1RM) in the half-squat, participants performed the exercise on a Smith Machine. Mean propulsive velocity and peak force were continuously measured at 1,000 Hz using a linear position transducer attached to the barbell. Participants then completed a running session consisting of a 9-minute and a 3-minute run, separated by a 30-minute rest. They refrained from vigorous activity for 24 hours before each test. Spatiotemporal variables and leg stiffness were recorded with a Stryd power meter.

RESULTS: Pearson's correlation analysis identified significant associations between relative load (%1RM) and leg stiffness across different running efforts. Specifically, leg stiffness correlated with loads of 30% ($r=0.533$) and 40% 1RM ($r=0.33$) during the 9-min run and with 40% 1RM ($r=0.547$) during the 3-min run. Regarding SDef, significant correlations were found between SDef at 50%, 60%, and 70% 1RM and leg stiffness during the 9-minute run ($r = 0.539$, $r = 0.560$, and $r = 0.535$, respectively). During the 3-minute run, SDef at 40%, 50%, 60%, and 70% 1RM correlated significantly with GCT ($r=-0.559$, $r=-0.570$, $r=-0.565$, and $r=-0.527$, respectively). Additionally, leg stiffness was significantly associated with SDef at 60% ($r=0.544$) and 70% ($r=0.525$) 1RM.

CONCLUSION: Significant correlations between relative training loads (%1RM), leg stiffness, and GCT emphasized the role of the stretch-shortening cycle (SSC) in performance. Moderate loads (30–40% 1RM) influenced leg stiffness during prolonged running, while higher loads (50–70% 1RM) affected both stiffness and GCT in shorter efforts. These findings suggest that resistance training modulates SSC efficiency, impacting elastic energy utilization and force production. Tailoring resistance training loads to enhance stiffness and SSC function may optimize performance in trail running, providing valuable insights for coaches.

INTERACTION BETWEEN MUSCLE ACTIVITY AND RUNNING ECONOMY DURING DOWNHILL RUNNING

ANDANSON, L., IDDA, G., MILLET, G.Y., LAPOLE, T.
UNIVERSITÉ JEAN MONNET

INTRODUCTION: Running Economy (RE) is a major determinant of performance. A positive relationship between RE and electromyographic (EMG) activity of the knee extensor and plantar flexor muscles has been reported in flat running [1]. To what extent EMG activity explains RE in downhill running, and whether EMG activity can explain the existence of an optimal negative slope (i.e. between -10% to -20%) that minimizes RE [2,3], remain unknown. This study therefore aimed to examine the evolution of RE and EMG activity of knee and plantar flexor muscles, and their correlation, during downhill running at various slopes and speeds.

METHODS: Fourteen healthy participants performed 10 treadmill running trials (5 slopes: 0%, -5%, -10%, -15%, and -20% $\times$ 2 speeds: 10 and 12 km/h) in a randomized order. Each bout lasted 4 minutes and was followed by 5 minutes of rest. VO_2 , EMG activity of the vastus lateralis (VL) and gastrocnemius lateralis (GL), and ground reaction forces were recorded. VO_2 and EMG data were collected and synchronized (Delsys Trigno Link), and ground reaction forces were measured via an instrumented treadmill.

RESULTS: The optimal slopes for RE were identified at $-13.5\% \pm 2.8\%$ and $-15\% \pm 2.3\%$ at 10 km/h and 12 km/h, respectively. Across slopes, RE was strongly and positively correlated with GL EMG ($R_m = 0.70$, $p < 0.001$). The slopes for minimizing GL EMG were found at $-14.8\% \pm 6.1\%$ and $-17.3\% \pm 7.4\%$ at 10 and 12 km/h, respectively. There was conversely only a weak correlation between RE and VL EMG ($R_m = -0.19$, $p = 0.035$), with the slopes minimizing VL EMG being irrelevant ($-1.3\% \pm 6.1\%$ and $-3.5\% \pm 9.6\%$ at 10 km/h and 12 km/h, respectively). Moreover, GL EMG showed a strong positive correlation with propulsive impulse ($R_m = 0.63$, $p < 0.001$), while VL EMG was strongly correlated with braking impulse ($R_m = 0.55$, $p < 0.001$).

CONCLUSION: These findings highlight the complex interplay between muscle activity and RE during downhill running. RE was strongly correlated with GL EMG, suggesting that the decrease in GL EMG with increasing negative slope (i.e. due to less propulsive requirements, as evidenced by the strong positive correlation between GL EMG and propulsive impulse, which gradually decreases as slopes become steeper) likely plays a major role in minimizing RE. Conversely, optimal slopes identified through VL EMG did not correspond with those minimizing RE and whereas VL EMG was only weakly correlated with RE, it showed a strong positive correlation with braking impulse. This emphasizes the quadriceps crucial role in braking forces that gradually increased with steeper negative slopes, yet without any major influence on RE likely because eccentric contractions during the braking phase require minimal metabolic energy.

COMPARISON OF NEUROMUSCULAR FATIGUE AND BIOLOGICAL MARKERS OF MUSCLE DAMAGE BETWEEN MARATHON AND TRAIL RUNNING OF EQUIVALENT EFFORT

METRA, M., LAGOUTE, T., RAVEL, A., FÉASSON, L., BLAGROVE, R., ROSSI, J., MILLET, G.Y.

JEAN MONNET UNIVERSITY

INTRODUCTION: Trail running has gained in popularity since the 2000', becoming progressively as practiced as road running. Sabater et al. (1) showed that elite trail runners exhibit higher maximal power and force, and spend less time training but more time competing annually than elite road runners. While neuromuscular fatigue has been studied in marathon running (2,3) and trail running (4-7), no direct comparison has been done. The study aimed to compare neuromuscular fatigue and biological markers induced by marathon and trail running races of equivalent km-effort (distance in km + positive elevation in m / 100).

METHODS: Well-trained male and female runners, specialized in road or trail running, participated in a 42.7-km treadmill marathon simulation (MAR, n=5), or in a 29-km simulated trail on a treadmill (TS, n=11) or in a 29-km outdoor trail running bout (TN, n=11) with ± 1400 m elevation. The following assessments of neuromuscular function were conducted before (PRE) and immediately after (POST) the run: maximal isometric voluntary contraction (MVC) of the knee extensors (KE) and plantar flexors (PF), and maximal theoretical force (F0), velocity (v0) and power (Pmax) derived from maximal 8-s cycle ergometer sprints. Blood samples were collected to determine Creatine Phosphokinase (CPK) concentration. Kruskal-Wallis tests were performed for groups comparison, followed by Dunn's post hoc tests with Holm correction, when p-values were <0.05 .

RESULTS: The percentage decrease in MVC for KE (MAR: $-36.3 \pm 18.5\%$; TS: $-17.6 \pm 10.6\%$; TN: $-19.5 \pm 8.6\%$) and PF (MAR: $-26.1 \pm 14.4\%$; TS: $-19.5 \pm 15.2\%$; TN: $-21.3 \pm 18.2\%$) were not statistically different between groups. There was also no significant difference in percentage change in F0 (MAR: $-12.6 \pm 14.3\%$; TS: $-5.1 \pm 6.0\%$; TN: $-5.0 \pm 4.4\%$), V0 (MAR: $+9.9 \pm 11.0\%$; TS: $+6.2 \pm 7.3\%$; TN: $+6.3 \pm 2.4\%$) and Pmax (MAR: $-5.2 \pm 7.7\%$; TS: $+0.4 \pm 3.6\%$; TN: $+0.9 \pm 3.7\%$). MAR showed a greater increase in CPK compared to TS (p=0.0139) and TN (p=0.0136), with no difference between TS and TN (p=0.4149).

CONCLUSION: Neuromuscular fatigue and changes in force-velocity profile parameters were similar following marathon and trail running. However, marathon running induced greater muscle damage, potentially explaining the lower number of marathon races than trail running races per year. These preliminary results must be confirmed as type II errors are possible at this stage.

OP-BM08 Ageing II

AGING EFFECTS ON MUSCLE SIZE AND STRENGTH: A COMPARISON OF MASTICATORY AND LOCOMOTOR MUSCLES

SCHAUN, G., RAIDL, P., SLUNECKO, M., CSAPO, R.

UNIVERSITY OF VIENNA

INTRODUCTION: Aging is associated with decreased physical activity, leading to muscle mass and strength loss, particularly in the lower extremities. However, the masseter, continuously engaged in mastication, may be less affected, making it a potential model for studying age-related muscle changes with minimal bias from activity. This cross-sectional study examines aging impact on masseter size and strength compared to the quadriceps femoris, a muscle more influenced by activity levels.

METHODS: Thirty women were recruited and categorized into three age groups: young (26 ± 1.8 years), middle-aged (44.1 ± 3.4 years), and older (69.5 ± 3.1 years). Quadriceps and masseter cross-sectional area (CSA) were assessed via ultrasound, lower limb maximal isometric strength (MVIC) via an isokinetic dynamometer, and masseter strength via a bite force sensor. Muscle size and strength were expressed relative to the young group's mean. Data were analyzed using two-way mixed-factorial ANOVAs (3 groups $\times$ 2 muscles or 3 groups $\times$ 2 strength tests) in SPSS ($\alpha = 0.05$). Sidak's post hoc

tests were used for pairwise comparisons. Cohen's d effect sizes were calculated to quantify the magnitude of differences between age groups.

RESULTS: Both muscles exhibited a progressive reduction in size across age groups. Quadriceps CSA in the middle-aged and older participants was found to be $75 \pm 14\%$ and $56 \pm 13\%$ of that in the young participants (all $p < 0.05$). Similarly, masseter CSA in the middle-aged and older participants corresponded to $94 \pm 15\%$ and $79 \pm 14\%$ of that in the young individuals (all $p < 0.05$). Although the group $\times$ muscle interaction was not significant ($p = 0.110$), effect sizes were larger for the quadriceps (young vs. middle-aged: 1.56, young vs. old: 2.95, middle-aged vs. old: 1.47) than for the masseter (young vs. middle-aged: 0.29, young vs. old: 1.08, middle-aged vs. old: 1.09). For strength measures, no significant group $\times$ strength test interaction was observed ($p = 0.541$), but a significant main effect of group was found ($p < 0.001$). Strength was significantly lower in middle-aged and older participants compared to young adults (MVIC: $81 \pm 14\%$ and $62 \pm 16\%$; bite force: $75 \pm 15\%$ and $68 \pm 31\%$; all $p < 0.05$), with no significant differences between middle-aged and older participants ($p = 0.186$). Effect sizes were comparable between MVIC and bite force for the young vs. middle-aged comparison (MVIC = 1.20, bite force = 1.33), whereas a larger effect was observed for MVIC (1.25) than for bite force (0.27) when comparing middle-aged to older adults.

CONCLUSION: This study demonstrates a progressive age-related decline in muscle size and strength. Although the lack of significant group $\times$ muscle interactions suggests limited statistical power, larger effect sizes in the quadriceps indicate a more pronounced reduction as compared to the masseter muscle. Further research is needed to determine whether aging affects these muscles differently and to explore the underlying mechanisms driving these differences.

HD-SEMG: A POTENTIAL TOOL TO CONFIRM THE FUNCTIONAL IMPAIRMENT THAT LEADS TO MUSCLE DYSFUNCTION IN ELDERLY

MAGRIS, R., BOZZATO, M., SPINELLO, G., SAMPIERI, A., GONNELLI, F., DELLA COSTA, V.G., VALLI, G., MARTINO, G., DE VITO, G.

UNIVERSITY OF PADUA

INTRODUCTION: The age-related decline in muscle mass and function known as sarcopenia contributes greatly to the loss of quality of life within the older population(1). The pathogenesis of these alterations is related to several known factors contributing to varying degrees. Typical tests used to diagnose sarcopenia are based on muscle mass indexes (e.g. appendicular skeletal mass, ASM) and functional abilities (e.g. handgrip, HG). Nevertheless, these parameters cannot discriminate muscle alterations that lead to functional disability. Recent evidence suggests changes in neurophysiological processes to be major contributors (2). Therefore, the aim of this study is to explore possible correlations between motor units (MUs) properties and typical sarcopenic indexes in a non-sarcopenic group of elderly.

METHODS: Fifty-two non-sarcopenic elder subjects (43F/9M, age=72.1 $\pm$ 5.0 years, BMI=25.24 $\pm$ 2.69 kg/m²) performed isometric knee extension maximal voluntary contractions (MVC) and trapezoidal contractions at 25% of the MVC. During the MVCs, maximum torque (MT) and rate of force development at 200ms (RFD200) were determined. MU properties (i.e. recruitment and de-recruitment threshold, discharge rate during steady state, mean discharge rate) of the vastus lateralis (VL) were obtained during the submaximal contractions using high-density EMG. Moreover, participants underwent a dual-energy X-ray absorptiometry (DXA) scan to determine the ASM and performed HG and chair stand tests. Muscle architecture of VL was also assessed at rest at 50% of the femur length. Pearson's correlation coefficient was used to determine the association between MU properties and DXA and functional and muscle architecture parameters

RESULTS: Recruitment and de-recruitment thresholds are related to ASM ($r=-0.30, P=0.048$; $r=-0.33, P=0.030$), HG ($r=-0.32, P=0.036$; $r=-0.35, P=0.020$), MT ($r=-0.67, P<0.001$; $r=-0.63, P<0.001$) and RFD200 ($r=-0.31, P=0.040$; $r=-0.32, P=0.035$). Moreover, the recruitment threshold is associated with VL thickness ($r=-0.31, P=0.044$) and the de-recruitment threshold correlates with the chair stand score ($r=-0.32, P=0.031$). The discharge rates (i.e. mean and during the steady state) correlate with the fascicle length ($r=-0.30, P=0.049$; $r=-0.31, P=0.044$). All the relationships are classified as weak correlations, except those that include the MT, which are strong correlations.

CONCLUSION: In the elderly, MU properties of VL could represent significant parameters related to functional abilities and skeletal muscle mass. Our results suggest that among the MU properties, recruitment and de-recruitment thresholds of MU can relate better to functional scores and anthropometric characteristics than other. Nevertheless, further studies are necessary to improve the knowledge about muscle alterations related to functional disability in the elderly including a population of sarcopenic individuals.

DOES OLDER AGE AFFECT HIGH-DENSITY EMG-FORCE COHERENCE OF THE LUMBAR ERECTOR SPINAE DURING FATIGUE?

PARRELLA, M., BORZUOLA, R.1, SICILIANO, F.P.1, ARVANITIDIS, M.2, NUCCIO, S.1, JIMÉNEZ-GRANDE, D.2, FALLA, D.2, PIA-CENTINI, M.F.1, MACALUSO, A.1

1 UNIVERSITÀ DEGLI STUDI DI ROMA FORO ITALICO, ROME, ITALY; 2 UNIVERSITY OF BIRMINGHAM, BIRMINGHAM, UK.

INTRODUCTION: Proper control of the trunk muscles is essential for maintaining stability and performing daily activities, particularly in the presence of muscle fatigue1. However, the effects of ageing on trunk muscle force control remain largely

unexplored. Force control primarily depends on the common synaptic input received by motoneurons² and therefore high-density surface electromyography (HDsEMG)-force relationships provide insights into the association between muscle activity and the generated force. This study investigates the relationship between oscillations in lumbar erector spinae (LES) HDsEMG activity and force in young and older participants during a fatiguing task.

METHODS: Twelve older (O, age: 69 ± 4) and twelve young (Y, age: 26 ± 2) participants performed an isometric trunk extension at 30% of their maximal voluntary isometric force until failure. HDsEMG signals were recorded using a 13×5 grid of electrodes placed over the LES. Muscle fibre conduction velocity (MFCV) values were measured. Force steadiness was quantified using the coefficient of variation of force (CoV). Coherence analysis was applied to examine the relationship between HDsEMG and force signals in the delta (0-5 Hz) frequency bandwidth. A mixed-model ANOVA was used to analyse differences in MFCV, CoV and coherence values (Coh) over time (3 epochs of equal duration) and between groups. The Wilcoxon test was used to compare endurance time between groups. Regression analysis examined the association between the percent variation in Coh and CoV values from the beginning to the end of the task.

RESULTS: Endurance time did not differ between groups (O: 90.56 ± 34.75 s; Y: 100.71 ± 49.20 s; $p=0.41$). MFCV significantly decreased throughout the fatiguing task in both groups ($p<0.01$), indicating LES fatigue. CoV increased significantly at the end of the task in both groups ($p<0.01$) with O showing greater values than Y ($p<0.01$). Coh values decreased significantly at the end of the task in both groups ($p<0.01$), with a significant Time*Group interaction ($p<0.05$) revealing lower Coh values in O in the middle phase of the contraction. Lastly, a greater decline in Coh was associated with a larger increase in CoV values in both O ($R^2=0.86$; $p<0.01$) and Y ($R^2=0.75$; $p<0.01$).

CONCLUSION: Despite similar endurance between groups, older participants showed greater force variability. In both groups, coherence values declined with fatigue, likely reflecting the recruitment of synergistic muscles to prolong endurance. However, this decline occurred earlier in older participants, suggesting earlier disruptions in common synaptic input to the LES. This may contribute to the age-related increase in force variability, as the decline in coherence is associated to greater force fluctuations.

MOTOR PERFORMANCE IMPROVEMENT WITH ENDURANCE TRAINING IN OLDER ADULTS: POSSIBLE ROLE OF THE SOMA-TO-MOTOR NETWORK

CAPUTO, O., SARTO, F., MARINO, M., MARTINO, G., FRANCHI, M.V., TEDESCO, G., FORTE, R., DE VITO, G., ANGRILLI, A., NARICI, M.V.

UNIVERSITY OF PADUA

INTRODUCTION: Ageing leads to cognitive and motor alterations, while aerobic exercise serves as an effective countermeasure, supporting brain health (1). No studies have so far examined the chronic effect of aerobic exercise on the brain connectivity for the neuronal networks involved in the planning and execution of voluntary movements. Therefore, this study investigated whether endurance training could enhance the motor performance and functional connectivity particularly within the somato-motor network in older adults.

METHODS: 24 endurance older athletes (EA, 50% females, competitive runners, swimmers and cyclists, 65.71 ± 4.14 yrs.) and 24 age-matched untrained controls (UT, 50% females, 68.13 ± 4.34 yrs.) were recruited. We recorded quadriceps femoris (QF) force during isometric maximum voluntary contraction (MVC) and normalized it for the Cross Sectional Area, acquired by ultrasonography. Physical performance was assessed using the chair-to-stand test (CST) and the Star Excursion Balance Test (SEBT). Then, participants underwent a resting-state electroencephalography (EEG) acquisition to compute the functional connectivity between the Supplementary Motor Area (SMA) and primary and secondary somatosensory cortices (S1 and S2), and Eriksen flanker test (2), a cognitive test that evaluates the response speed to congruent/incongruent visual stimuli via a bimanual task. Lastly, we measured the concentration of Brain Derived Neurotrophic Factor (BDNF) and Vascular Endothelial Growth Factor (VEGF) in serum, being recognized as neuroprotective factors.

RESULTS: EA showed greater QF force (14.59%) and, in the first 200 ms of muscle contraction, the rate of force development significantly differed between groups ($p<0.0001$). CST time was lower (-18.12%) and SEBT score was higher in EA (8.42%). Then, EA performed better in the flanker test, with a 9.7% faster response to visual stimuli. For EA vs UT, the power analysis over time of the EEG signals in different frequency bands revealed: (i) a higher connectivity between SMA and IS2 in beta1 (13-20Hz), (ii) a lower connectivity between SMA and rS1 and IS1 and rS2 in delta (1-4Hz), (iii) a lower connectivity within S1 and between IS1 and S2 in gamma (30-50Hz). BDNF did not differ between the two groups, whereas a trend for VEGF to lower in EA vs UT was observed.

CONCLUSION: Endurance-trained older adults exhibited improved motor performance and response speed compared to age-matched untrained individuals. Our EEG findings suggest that this improvement may be mediated by changes in the somato-motor network that assists the primary motor cortex to generate voluntary movements by integrating sensory stimuli. Indeed, the combination of low connectivity in beta1 and high connectivity in gamma may imply an increased motor memory consolidation and decreased effort in movement planning and execution, respectively (3).

THE IMPACT OF AGEING IN HEAVINESS PERCEPTION

ALBERGONI, A., BOVE, M., BISIO, A.

UNIVERSITY OF GENOA

INTRODUCTION: Perception of heaviness is influenced by the actions we perform and how we process visual and proprioceptive information. Both the expectation of the weight of the object being moved and the dynamic information from interacting with it determine the perception (1). Ageing leads to changes in proprioceptive structures (2), a decrease in strength and a consequent impoverishment of the motor experience. The aim of this work is to test how the perception of the weight of an object changes with age.

METHODS: Twenty-six volunteers were enrolled and divided into two groups according to their age, young adults (n=13, 7 female, mean age = 25±4 years) and older adults (n=13, 9 female, mean age: 69±5 years). They performed a weight estimation task; they were asked to lift a box from a desk to their chest with both arms and to estimate the weight of the box. The box weights were 4 kg, 7 kg or 10 kg. The perception of heaviness was assessed based on the load estimation error. A 1kg-box was used as a reference and for familiarisation.

RESULTS: The ANOVA showed a main effect of group (p=0.03), with the older group having a higher error than the younger group. Furthermore, the error was greater when they lifted 10kg than 7kg (p=0.001) and 4kg (p<0.001).

CONCLUSION: The present results show that the perceived heaviness of objects is altered in older adults compared to young adults. These results suggest that age plays a key role in perceiving the object weight, which affects the ability to adequately assess loading. A decline in this ability may suggest an overestimation of one's own strength capacity, and could affect the correct handling of heavy objects with a consequent increase in the risk of injury during activities of daily living.

OP-MH30 Metabolic Syndrome and Diabetes II

INCIDENTAL PHYSICAL ACTIVITY AND TYPE 2 DIABETES: A PROSPECTIVE COHORT STUDY

SABAG, A., BISWAS, R.K., AHMADI, M.N., KOEMEL, N.A., STAMATAKIS, E.

THE UNIVERSITY OF SYDNEY

INTRODUCTION: Type 2 diabetes (T2D) is a leading contributor to premature death and disability worldwide. While structured exercise is a critical component of T2D care and prevention, the health effects of incidental physical activity, such as commuting, domestic, or occupational activity are less understood. Therefore, this study aimed to determine the association between device-measured incidental physical activity and T2D incidence in adults.

METHODS: We were able to study the effects of incidental physical activity by restricting analyses to consenting UK Biobank accelerometry sub-study participants who self-reported not engaging in any structured exercise (including sports, gyms, and fitness classes). Participants were excluded if, at baseline, they had prevalent T2D, were undergoing exogenous insulin therapy, or were diagnosed with T2D within 12 months of follow-up. Device-captured incidental physical activity duration was quantified in minutes/day and intensities were categorised into light, moderate, and vigorous (LIPA, MIPA and VIPA) using a validated two-stage machine learning-based intensity and posture classification schema. Additional analyses were conducted by stratifying participants into two groups based on whether they met the moderate-to-vigorous physical activity (MVPA) guidelines. T2D diagnosis was obtained from multiple data sources, including self-reports, primary care records, and hospital inpatient records. The reference group included participants who did not engage in MIPA or VIPA.

RESULTS: The analysis included 23,100 non-exercisers, 748 of whom developed T2D over a 7.9-year follow-up period. MIPA and VIPA, but not LIPA, exhibited near-linear inverse associations with T2D risk. Compared to undertaking no MIPA or VIPA, the median 2.8 minutes of VIPA was associated with a hazard ratio (HR) of 0.57 (95%CI: 0.47 to 0.69) and the median 24.2 minutes of MIPA was associated with a HR of 0.53 (95%CI 0.41 to 0.69). Participants who met or did not meet the MVPA guidelines displayed strong inverse associations between VIPA and T2D (HR 0.64, 95%CI: 0.47 to 0.86 and HR 0.67, 95%CI: 0.52 to 0.88, respectively). However, the dose-response curve was steeper among those who did not meet the physical activity guidelines, and required less time for the same risk reduction (4.02 min/day and 1.43 min/day, respectively).

CONCLUSION: The results of this study demonstrate the importance of incidental MVPA within the context of T2D prevention by showing that even small amounts may be associated with a stark reduction in T2D incidence. These findings support public health recommendations that any MVPA is better than none, especially among individuals who do not meet current physical activity recommendations.

PHYSIOLOGICAL AND GLYCEMIC RESPONSES TO WHEY PROTEIN DURING EXERCISE IN TYPE 1 DIABETES

HENNESSY, D., AGNOLETTI, L., SCHOFIELD, C., DAO, G., KONG, Y.W., APOSTOLOPOULOS, J., NGAN, J., O'NEAL, D., KOW-ALSKI, G., BRUCE, C., SMART, C., ZAHARIEVA, D., MORRISON, D.

UNIVERSITY OF MELBOURNE AND DEAKIN UNIVERSITY

INTRODUCTION: Exercise-induced hypoglycemia remains a significant challenge for individuals with type 1 diabetes (T1D), even with advanced technology such as automated insulin delivery (AID) systems. A key contributor to hypoglycemia risk in T1D is an impaired glucagon response. In T1D the glucagon response to protein ingestion (unlike exercise or hypoglycemia) remains intact, and ingestion of rapidly digestible protein (such as whey protein), which has potent glycemic action may represent a novel strategy to mitigate exercise-induced hypoglycemia in T1D.

METHODS: An ongoing multi-stage, block-randomized, crossover study is being conducted in adults with T1D using the Medtronic 780G AID system. After a cardiopulmonary exercise test, all participants completed two 60-minute moderate-intensity (50% VO₂max) exercise sessions, as well as two 60-minute seated rest sessions in the afternoon. Each session was performed 4 h post a standardized meal with a temporary glucose target set 2 h prior to the session to minimize insulin on board, and 10g fast-acting carbohydrate was given 10min pre-exercise if sensor glucose was <7.0mmol/L. Each session included consumption of either 0.5g/kg body weight of whey protein with water (rest-protein and exercise-protein) or water only (rest-control and exercise-control) 30 minutes before exercise/rest. Blood samples were taken pre-ingestion (-30min), exercise/rest commencement (0min), 30, 60 and 90min for plasma glucagon quantification. Continuous glucose monitoring (CGM) was used to collect interstitial glucose readings every 5min throughout.

RESULTS: Preliminary data is available from five adults with T1D (5 male, mean; HbA_{1c} 6.8%, age 58.6 yrs, body mass 80kg, BMI 26kg/m², VO₂max, 36.3) who completed all exercise sessions (n=2 completed both rest sessions). The mean $\pm$ SD protein dose was 40 $\pm$ 4g. Fast-acting carbohydrate was supplemented pre-exercise for CGM glucose <7.0mmol/L once (n=1 exercise-control, n=0 exercise-protein). The average change in CGM glucose from start to end of exercise (i.e. 0-60min) was lower for protein ingestion (-0.40 $\pm$ 1.04 mmol/L, mean $\pm$ SD, n=5) vs control (-2.94 $\pm$ 1.87 mmol/L, mean $\pm$ SD, n=5). For both rest-control and exercise-control conditions, the average peak change in glucagon (n=2) was negligible (0.96-fold versus 0.95-fold, respectively). The average peak change in glucagon (n=2) was similar for both the rest-protein and exercise-protein conditions (4.01-fold versus 3.15-fold, respectively).

CONCLUSION: Preliminary data indicates that whey protein promotes glucagon secretion equally at rest and during exercise and does not appear to work synergistically. Importantly, whey protein represents a novel strategy to mitigate dropping glucose during exercise in people with T1D, is readily available and could be easily translated into current exercise guidelines and clinical practice for people with T1D wishing to exercise.

IS THERE A RELATIONSHIP BETWEEN GLYCEMIC CONTROL AND PHYSICAL PERFORMANCE IN ADULTS WITH TYPE 1 DIABETES?

PIRAZZI, A., GATTI, A., GIURIATO, M., CAVALLO, C., CARNEVALE PELLINO, V., DEL BIANCO, M., DANESE, P., CUM, S., BRUNATO, B., ASSALONI, R., VANDONI, M.

UNIVERSITY OF PAVIA

INTRODUCTION: Optimal glycemic control (GC) is essential in people with type 1 diabetes (T1D) for long-term health. In fact, GC is associated with the prevention of diabetes complications. Evidence underlines that health benefits are potentiated by a regular practice of physical exercise (PE). Specifically, PE improves the metabolic profile contributing to blood glucose management and reducing daily insulin requirements. Dealing with daily PE implies for people with T1D several practical issues because of its duration, intensity and typology impact in a different way on the glycemic trend. However, it remains unclear the relationship between a stable GC and physical performance (PP) in this population.

METHODS: 59 adults (24F/35M; aged (95% C.I.; 40.189, 46.794)) with type 1 diabetes participated in the study. The data collection consisted of a series of clinical metrics and PP tests. Performance tests evaluate aerobic, strength and flexibility parameters. They were assessed through the Six-Minute Walking Test (6MWT), Yo-Yo Intermittent Recovery Test (Yo-Yo IR), Standing Broad Jump (SBJ), Handgrip Strength Test (HG) and Sit-and-Reach (SaR). HbA_{1c} values were obtained from medical records while Time in Range (TIR), Time Above Range (TAR), Time Below Range (TBR), Coefficient of Variation (CV) and Glucose Monitor Index (GMI) were tracked by a continuous glucose monitor. A linear regression analyses adjusted by sex, age and insulin therapy was conducted to determine the relationship between clinical and motor variable.

RESULTS: Results indicated that there were no significant association between 6MWT and Yo-Yo IR with HbA_{1c} (6MWT: β = -0.228, p=0.177; Yo-Yo IR: β = -0.223, p=0.460), TIR (6MWT: β = 0.337, p=0.050; Yo-Yo IR: β = -0.012, p=0.968) and CV (6MWT: β = -0.387, p=0.011; Yo-Yo IR: β = 0.017, p=0.948). Similarly, no relationships were observed for the SBJ, SaR and HG tests with these metabolic parameters (all p>0.05). Also TAR and TBR values showed no significant association with all performance tests (all p>0.05).

CONCLUSION: These findings highlighted the concept that better GC is not associated with higher PP levels. Since there is an absence of a significant correlation between PE measure and optimal glycemic management, we can affirm that

multiple factors such as insulin therapy, diet strategies and supplementation influence GC in people with T1D. Therefore, these results indicated that a multidisciplinary approach is necessary in this field.

EFFECTS OF EXERCISE INTERVENTION ON 24-HOUR CONTINUOUS GLUCOSE IN NON-DIABETIC POPULATION: A SYSTEMATIC REVIEW

YANG, B., ZHANG, X.
PEKING UNIVERSITY

INTRODUCTION: Maintaining optimal blood glucose regulation is critical for metabolic health, even in non-diabetes. Recently, more and more studies using continuous glucose monitoring (CGM) have explored diverse exercise modalities—including aerobic, resistance, and high-intensity interval training (HIIT)—on glucose regulation in non-diabetic populations. There have been systematic reviews of CGM to assess the effects of exercise on glycemic variability in diabetic patients, however, a comprehensive analysis of the non-diabetic population is lacking. The objective of this review is to quantify the effects of exercise intervention on 24-hour continuous glucose profiles in non-diabetic individuals.

METHODS: Adhering to PRISMA guidelines, PubMed, Web of Science, Embase, CNKI, and WanFang databases were searched up to January 23, 2024. Following eligibility screening, variables of basic information, population characteristics, intervention, results, and CGM Sensor/System were extracted and processed through qualitative synthesis. The risk of bias was evaluated using the revised Cochrane risk-of-bias tool v2.0 (RoB2).

RESULTS: From 8,356 initially identified articles, 2,134 duplicates and 6,183 irrelevant records were excluded, resulting in the inclusion of 19 interventional trials (312 participants) in the final analysis. Study designs included 6 parallel-group RCTs, 11 crossover RCTs, and 2 non-RCTs. Among the included studies, exercise interventions demonstrated reductions in specific CGM outcomes: 8 out of 9 studies reported decreases in the incremental area under the curve (iAUC), 4 of 10 studies observed reductions in the mean amplitude of glycemic excursions (MAGE), 3 of 10 studies showed lowered standard deviation (SD). Risk of bias ratings indicated 36.8% (7/19) low risk, 47.4% (9/19) some concerns, and 15.8% (3/19) high risk.

CONCLUSION: The systematic review revealed limited and methodologically heterogeneous evidence suggesting that exercise interventions may modestly improve continuous glucose monitoring (CGM)-derived metrics, including reductions in incremental area under the curve (iAUC), mean amplitude of glycemic excursions (MAGE), and standard deviation (SD). These effects were observed across diverse study designs (6 parallel-group RCTs, 11 crossover RCTs, and 2 non-RCTs) but lacked statistical significance in most outcomes ($P > 0.05$). Notably, 80% of trials exhibited uncertain or high risk of bias, underscoring concerns about evidence reliability. Future rigorously designed RCTs with larger cohorts, standardized interventions, and prolonged follow-up are warranted to confirm these trends and elucidate the clinical relevance of exercise-induced glycemic improvements in broader populations.

THE IMPACT OF A MULTIDIMENSIONAL PHYSICAL ACTIVITY INTERVENTION ON GLYCEMIC CONTROL IN TYPE 1 DIABETES

FUSCO, A., PAPALE, O., ZEVOLI, M., FESTINO, E., DI ROCCO, F., FOSTER, C., PRESTANTI, I., SERAFINI, S., IZZICUPO, P., CORTIS, C.

UNIVERSITY "G. D'ANNUNZIO" OF CHIETI-PESCARA

INTRODUCTION: Type 1 diabetes is characterized by hyperglycemic episodes influenced by diet, sleep quality, chronotype and physical activity, among others. While aerobic exercise is known to improve glycemic control, its effect on blood glucose regulation remains underexplored. Thus, this case study aimed to evaluate the effects of a prolonged and differentiated (indoor and outdoor exercise) physical activity intervention on glycemic control in an individual with type 1 diabetes.

METHODS: The participant (age: 23years; weight: 95kg; height: 1.90m; Body Mass Index (BMI): 26.3kg/m²; waist to hip ratio: 0.98; basal metabolic rate: 2015kcal; Heart Rate Maximum (HRmax): 197beats·min⁻¹) completed two outdoor session (~3800m) and two indoor session with self-selected speed, in the initial 2-min stage, at 0% grade slope. The grade increased 2% each stage during the uphill phase until reaching volitional fatigue, followed by a 2% decrease at each stage during the downhill phase until returning to 0% grade. Blood pressure was assessed before and after each session. Daily nutrition intake, insulin intake and blood glucose were continuously monitored. Dietary adherence (PREvenición con Dieta MEDiterránea), sleep quality (Pittsburgh Sleep Quality Index), chronotype (Morningness–Eveningness Questionnaire), and physical activity levels (International Physical Activity Questionnaire) were assessed before each session. Physical Activity Enjoyment Scale was used to measured enjoyment after each session.

RESULTS: The sessions were completed in ~44 and ~39 minutes with the participant achieving the 84% (outdoor) and 96% (indoor) of his theoretical HRmax. The intervention resulted in glycemic improvements, with time spent in hyperglycemia (>250mg/dL) decreasing from 56.46% to 0%, while time in the normal range (70–180mg/dL) increasing to 63.96%. A 47% reduction in insulin units showed that also insulin sensitivity improved.

CONCLUSION: Despite differences in intensity, indoor and outdoor activities yielded comparable benefits, with outdoor activities perceived as more enjoyable, positively impacted glycemic control, advocating for tailored strategies in diabetes care.

OP-MH08 Injury Prevention

DEVELOPMENT OF A PRELIMINARY MULTIVARIABLE MODEL PREDICTING HAMSTRING STRAIN INJURIES DURING PRESEASON SCREENING IN SOCCER PLAYERS: A MULTIDISCIPLINARY APPROACH

PIPONNIER, E., BAIZE, D., MASSAMBA, A., HUREAU, T., RENEAUD, N., GARCIA-GIMENEZ, Y., MARCHAND, F., BONTEMPS, B., CORCELLE, B., MALÉJAC, V., JAAFAR, A., IPPOLITI, E., PAYET, F., AJARAI, I., D'ARRIPE-LONGUEVILLE, F., MÉRIAUX-SCOFFIER, S.

CÔTE D'AZUR UNIVERSITY

INTRODUCTION: Hamstring strain injuries (HSI) remain a major concern in soccer. Yet existing prediction models fail to account for the multifactorial nature of injury risk. Key factors such as sprint kinematics, performance fatigability, and psychological influences have been largely overlooked. The aim of this study was to develop a parsimonious and multidisciplinary model to identify players at risk of HSI using a single preseason screening session. Additionally, we compared this model's predictive accuracy to that of individual predictors.

METHODS: A total of 120 male and female soccer players competing at regional and national levels underwent preseason assessments, including psychological, physiological, biomechanical, and behavioural variables. Injury occurrence was prospectively monitored throughout the competitive season. After variable selection, logistic regression with the Wald backward stepwise method was used to refine the model. The predictive abilities of the final model and individual variables were determined using the area under the receiver operating characteristic curve (AUC).

RESULTS: Twenty-nine players sustained an HSI during the follow-up period. The final model included eight predictors: age, sex, HSI history, knee flexor performance fatigability, sprint performance (best sprint time and maximal theoretical velocity), perceived vulnerability to injury, and subjective norms regarding pain and fatigue in soccer. It demonstrated strong predictive accuracy (AUC = 0.82, sensitivity = 79%). No individual predictor, when considered independently, reached sufficient discriminative power (AUC ≤ 0.65).

CONCLUSION: Assessing single risk predictors does not allow for accurate HSI prediction in soccer players. In contrast, our multidisciplinary model achieved high accuracy in identifying at-risk players. Parsimonious in its design, it highlights the interest of both multifactorial and multidisciplinary approach. Notably, knee flexor performance fatigability following repeated sprints emerged as a key predictor, emphasizing the role of fatigue in HSI occurrence. Additionally, sprint performance and psychological variables significantly contributed to injury prediction, reinforcing the need for an integrated approach to injury prevention. If externally validated, the present model could serve as a valuable tool for injury prevention strategies in soccer teams.

TACKLER AND BALL-CARRIER TECHNICAL PROFICIENCY DURING MODERATE AND SEVERE TACKLE INJURIES IN ELITE RUGBY UNION

HENDRICKS, S., THEUNISSEN, Z., HARE, C., PAUL, L., BEHARDIEN, R., MPAKA, L., LAMBERT, M., VILJOEN, W., READHEAD, C.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Tackle injuries have the highest injury incidence, may cause the greatest number of days lost (severity) and carry a high injury burden. Moderate and severe injuries in particular may have financial, psychological and team performance implications. To develop effective injury prevention strategies, an understanding of how tackle injuries occur in their specific context is required. Video analysis has been shown to be a useful tool to understand injury mechanism during competition. Therefore, the purpose of this study was to analyse tackler and ball-carrier technical proficiency during moderate and severe contact injuries in professional rugby union and compare with non-injury event controls from the same player and from the same team.

METHODS: Injury surveillance was conducted during The Currie Cup (South Africa's annual premier domestic senior male professional level rugby union competition) between 2022 and 2023 as part of the SA Rugby Injury and Illness Surveillance and Prevention Project (SARIISPP). Using the SARIISPP injury surveillance data, video footage of injuries with a 'moderate' and 'severe' severity (≥8days' time loss) were identified. Player-matched and team-matched

non-injury events were also identified as controls. Technical proficiency for 46 (moderate and severe; ≥8 days lost) tackler and ball-carrier injuries and 182 matched non-injury events (90 own controls, 92 team controls) were examined using a standardised list of technical criteria.

RESULTS: Mean technical proficiency scores for tackler front-on injury events was 10 (95% CI 9.2-11), and for side-on/behind injury events was 6.7 (95% CI 5.7-7.7), which was significantly different to their team controls 12 (95% CI 11-12, $p=0.0053$, $ES=0.62$, moderate) and 7.7 (95% CI 7.1-8.2, $p=0.0696$, $ES=0.66$, moderate), respectively. Side-on/behind injury events was also significantly different to their own controls 7.3 (95% CI 6.9-7.7, $p=0.4755$, $ES=0.35$, small). Mean technical proficiency scores for ball-carriers during front-on tackles was 6.7 (95% CI 5.9-7.5), which was significantly different to their team controls 8 (95% CI 7.5-8.4, $p=0.0074$, $ES=0.62$, moderate), and own controls 7.4 (95% CI 6.9-7.9, $p=0.2223$, $ES=0.3$, small).

CONCLUSION: Both tackler front-on and side-on/behind tackler proficiency scores were lower than the team's non-injury tackles. For the ball-carrier, only front-on tackle events had lower proficiency scores than the team's non-injury tackles. By comparing technical proficiencies during injury events and matched controls, technique deficiencies exposing players to injury were highlighted. These highlighted deficiencies may inform injury prevention strategies and assist coaches in optimising training to reduce tackle injury risk.

WHAT DOES SHOE CUSHIONING PERCEPTION TELL US ABOUT INJURY RISK IN RECREATIONAL RUNNERS?

MALISOUX, L., DELATTRE, N., URHAUSEN, A., MORIO, C., THEISEN, D.

LUXEMBOURG INSTITUTE OF HEALTH

INTRODUCTION: The protective effect of shoe cushioning against running-related injuries has recently been demonstrated in a large, randomised trial including 800+ leisure-time runners. The underlying mechanism includes a decrease in loading rate and an increase in time to impact peak of the high-frequency signal in softer shoes. However, runners cannot easily assess these biomechanical factors when testing new running shoes. Alternatively, the comfort filter had previously been suggested as a new paradigm relating running shoes and injury risk, suggesting that runners should select a comfortable product according to this filter to reduce injury risk. Therefore, the objective of this study was to investigate whether the perception of cushioning and the overall appreciation of running shoes were associated with injury risk.

METHODS: This is a secondary analysis of a randomized trial on the effect of shoe cushioning on injury risk. Running exposure and injury data were prospectively collected over 6 months. Healthy recreational runners were asked to fill in a questionnaire on 1) shoe cushioning perception at the heel, 2) ideal shoe cushioning level at the heel, and 3) global appreciation of the study shoe using numerical rating scales (score from min. 1 to max. 9). The difference between shoe cushioning perception and ideal shoe cushioning level was computed to reflect the difference between perceived and ideal cushioning. The variables related to perception were then categorised in tertiles. A Cox proportional hazards model was used to estimate adjusted hazard rate ratios (HR), taking right censoring and competing risks into account, and using hours of running as time scale.

RESULTS: The analysis includes 527 participants (35.3% females, mean age (SD): 41.1 (10.2) years, and body mass index: 24.3 (3.1) kg.m⁻²). The participants ran 172,307 km over the follow-up, and 60 of them (11.4%) reported at least one running-related injury. Compared to the second tertile (ref: >3 to <6), those with low value for cushioning perception (≤ 3) had greater injury risk (HR [95%CI]: 2.51 [1.30; 4.86], while no difference was observed between the second tertile and those with high values (≥ 6 ; HR: 0.77 [0.29; 2.04]). Similarly, compared to the second tertile (ref: >-2 to ≤ 0), those with low values for perceived-ideal difference in cushioning (≤ -2) had greater injury risk (HR [95%CI]: 2.00 [1.12; 3.57], while no difference was observed with those with high values (> 0 ; HR: 0.81 [0.37; 1.79]). No significant association was found between global appreciation of the shoe and injury risk.

CONCLUSION: The present study demonstrates that greater perceived shoe cushioning is associated with lower injury risk. Therefore, the study suggests that cushioning perception, and potentially comfort filter, may be a valuable approach for shoe selection to prevent running-related injuries, although the validity of this paradigm deserves further research and the causal pathway has yet to be explained.

GYROKINESIS® REDUCES PAIN AND RESULTS IN GREATER IMPROVEMENTS IN POSTURAL SWAY WHEN COMPARED TO PILATES IN INDIVIDUALS WITH OSTEOARTHRITIS: A 24-WEEK PILOT STUDY

MAURI, C., STEWARD, C.J., HILL, M., GRAZIOLI, E., PARISI, A.

1 UNIVERSITÀ DEGLI STUDI DI ROMA FORO ITALICO, IT; 2 UNIVERSITY OF NOTTINGHAM, UK; 3 COVENTRY UNIVERSITY, UK

INTRODUCTION: Osteoarthritis (OA) is the most prevalent musculoskeletal disorder, resulting in pain that significantly impacts quality of life. It is frequently associated with impaired balance, highlighting the importance of balance training to reduce pain and fall risk. Gyrokinesis® (GY) is an innovative exercise modality that enhances proprioceptive control and may address OA-related symptoms, including pain and postural stability, more effectively than traditional exercises such as Pilates (PL). This exploratory study examined whether a 24-week GY intervention produces greater improvements in pain and postural control compared to PL in individuals diagnosed with OA.

METHODS: Twenty female participants with OA were enrolled onto the study (age: 60.4 $\pm$ 6.9 years) and non-randomly allocated (based on geographical location) to either 24-weeks of GY (n=12) or PL (n=8). Both modalities comprised a structured training regimen over a duration of 24 weeks, with participants engaging in bi-weekly sessions lasting one hour each. Outcome measures, including perceived pain (Brief Pain Inventory Questionnaire), kinesiophobia (Tampa Scale of Kinesiophobia) and postural sway parameters during left and right single-leg stance tests were assessed at baseline and after the intervention. The amplitude, velocity and mean power frequency were calculated to infer postural performance and strategy.

RESULTS: Statistical analysis was performed using a repeated measures ANCOVA with baseline as the covariate. Both GY and PL significantly reduced pain scores, with greater reductions observed in the GY group ($p < 0.001$; 95% CI -4.21 to -2.34 a.u.) compared to PL ($p = 0.025$; 95% CI -2.48 to -0.19 a.u.). Additionally, both interventions improved postural sway, with significant reductions in right leg anteroposterior velocity (GY: $p < 0.001$, 95% CI -1.61 to -0.96 cm/s; PL: $p = 0.006$, 95% CI -0.99 to -0.19 cm/s). However, GY led to greater improvements than PL in left leg anteroposterior ($p < 0.001$, 95% CI -1.44 to -0.54 cm/s) and mediolateral ($p = 0.025$, 95% CI -1.51 to -0.11 cm/s) velocity and anteroposterior root mean square ($p = 0.038$, 95% CI -1.70 to -0.05 cm). There were no changes in mean frequency.

CONCLUSION: Both Gyrokinesis® and Pilates were effective in alleviating pain however, the GY group demonstrated greater improvements in some measures of static balance when compared to PL in patients with OA. These findings provide promising preliminary evidence that GY may be a more effective intervention for reducing fall risk in this population. Future research should seek to replicate these initial findings with larger samples sizes and across a range of different healthy and clinical populations.

TRANSLATING RESEARCH INTO PRACTICE FOR REDUCING INJURY INCIDENCE IN ATHLETES

RYAN, M., BORGERDING, R.

CONCORDIA UNIVERSITY IRVINE

INTRODUCTION: Reducing injury incidence in athletes poses significant challenges due to the numerous variables involved, many of which are sensitive to temporal changes and difficult to control [1]. For those committed to improving athlete health outcomes, a critical question arises: How can strategies be effectively implemented to achieve measurable reductions in athlete injury incidence? This research attempts to address this question by translating epidemiological research into actionable approaches for secondary school sports programs.

METHODS: This study employed a participatory action research approach over two years within a single secondary school sport program. Participants included student-athletes, coaches, school administrators, and parents. Researchers attended weekly practices and games, collaborating with program stakeholders to implement injury reduction initiatives and observe program operations. A mixed methods design was used, involving quantitative analysis of injury incidence from the school's online surveillance database and qualitative data collection through semi-structured interviews, conversational interviews, researcher field notes, and peer debriefs. Injury incidence within the sports program was compared between the two seasons with active guidance and four previous seasons without such guidance.

RESULTS: The group without guidance ($n = 139$) experienced 12 injuries, resulting in an injury incidence proportion of 0.08. The group with guidance ($n = 65$) experienced one injury, yielding an injury incidence proportion of 0.01. The relative risk of injuries in the guided group was 0.178 (95% CI: 0.024 - 1.342). Thematic analysis of qualitative data revealed six themes: education in action, shared responsibility, resource allocation, incremental progress, commitment to change, and questioning cultural norms.

CONCLUSION: This study highlights the potential of applying epidemiological data to inform injury prevention strategies in secondary school sports. Further research is needed to better understand how these strategies may influence injury outcomes and to explore their applicability across various contexts. We hope this work encourages practitioners and researchers to consider ways to apply epidemiological research to practices that aim to support athlete health.

BEHAVIORAL CHARACTERISTICS AND NEURAL ACTIVATION IN ANTICIPATING DECEPTIVE ACTIONS AMONG BASKETBALL PLAYERS: A TASK-BASED FMRI STUDY

ZHU, R., CAO, C.

TSINGHUA UNIVERSITY

INTRODUCTION: Basketball is a complex open-skill sport where deceptive actions are crucial for misleading opponents. Athletes must quickly anticipate these actions, making it essential to understand the cognitive mechanisms behind this anticipation. Research shows that observing actions activates the Action Observation Network (AON) or the Mirror Neuron System (MNS), aiding in recognizing and mimicking actions. The AON includes key brain regions responsible for processing observed actions and their intentions. Expert athletes exhibit superior visual cognitive abilities and greater activation in AON-related regions compared to novices. This study uses fMRI technology to examine behavioral and neural activation differences in anticipating deceptive actions between expert and novice basketball players.

METHODS: This study investigates predictive behavior and brain activation differences through behavioral experiments and fMRI. Thirteen male experts (CUBA championship level) and 14 male novices (ordinary university students) participated. Stimuli included videos of shooting and breakthrough fake actions, totaling 108 valid segments. Participants judged the authenticity of the shots in a block design. Brain functional images were collected using a Siemens 3.0 T MAGNETOM Prisma MRI scanner, and behavioral data were analyzed using SPSS 27.0 with independent samples t-tests and repeated measures ANOVA.

RESULTS: In the shooting fake action anticipation task, the expert group exhibited an overall accuracy of 89.23 ± 5.94 , significantly higher than the novice group's 64.13 ± 9.46 ($t=7.56$, $p<0.001$). The expert group also demonstrated superior accuracy at all designated breakpoints: first breakpoint (87.69 ± 7.12 vs. 58.10 ± 13.94 , $t=7.15$, $p<0.001$), second breakpoint (91.54 ± 6.47 vs. 65.48 ± 10.18 , $t=7.99$, $p<0.001$), and third breakpoint (88.46 ± 10.24 vs. 68.81 ± 12.78 , $t=4.49$, $p<0.001$). In the

breakthrough fake action anticipation task, the expert group achieved an accuracy of 80.61 ± 10.15 , significantly greater than the novice group's 36.90 ± 15.60 ($t=8.55$, $p<0.001$).

The expert group reported a higher confidence level (83.31 ± 6.68) compared to the novice group (62.50 ± 12.23 , $t=5.43$, $p<0.001$). For fMRI data, both groups activated AON-related brain regions, including the left angular gyrus and left dorso-lateral prefrontal cortex. Experts showed significantly higher activation in the bilateral medial frontal gyrus, right hippocampus, and left anterior cingulate cortex compared to novices.

Discussion: This study highlights significant differences in behavioral performance and neural activation between expert and novice basketball players when anticipating deceptive actions. Experts demonstrated superior accuracy and confidence, particularly in shooting fake actions. The findings underscore the importance of the AON and related brain regions in processing deceptive actions, revealing that experts utilize more efficient cognitive strategies and neural mechanisms.

EXPLORING THE EFFECT OF PHYSICAL EXERCISE ON BODY RECOGNITION NEURAL NETWORKS: EVIDENCE FROM ERPS

TANET, E., BIANCO, V., PIERPALO, I., BERCHICCI, M.

UDA

INTRODUCTION:

The extrastriate body area (EBA), located in the lateral occipitotemporal cortex, responds robustly to human bodies and body parts [1]. Event-related potentials (ERPs) have been used to investigate this response, with studies showing that body perception modulates components like P1 and N1, reflecting early stages of visual processing [2]. Physical exercise has well-documented benefits, promoting neural plasticity and cognition, especially in regions linked to motor control [3]. However, its effect on brain areas involved in body recognition, such as the EBA, remains underexplored. We aim to investigate whether physical exercise influences neural responses in the EBA by examining changes in ERPs related to body perception. We hypothesize that physical exercise modulates electrical activity in response to body stimuli, with these effects reflected in body-related ERPs. Specifically, we expect alterations in the amplitude or latency of body-related components after aerobic exercise, suggesting neural plasticity in response to physical activity.

METHODS:

Young healthy subjects undergo a 64-channel EEG recording while randomly looking at visual stimuli depicting the whole body, arms, and legs, both static and in motion, along with scrambled image of the same stimuli as controls, before and after 20 minutes of aerobic exercise on a cycle ergometer. Habitual physical activity is assessed using the International Physical Activity Questionnaire (IPAQ), and body image is evaluated using the Body Image Coping Strategies Inventory (BICSI). Hand dominance is assessed using the Edinburgh Handedness Inventory. Based on G*Power calculations with a statistical power of 80% and an effect size of 0.27 for a within-between interaction ANOVA, this protocol will be conducted on 30 participants.

RESULTS:

Preliminary data from 7 subjects (6F; 23 ± 0.47 years; BMI: 22.8 ± 2.77) show no clear difference between control and body stimuli but suggest a modulation of the N1, the P2 and the P3 components following physical activity. Further analysis with 30 participants will also explore potential correlations between questionnaire scores and ERP data.

CONCLUSION: Acute aerobic physical exercise appears to influence body-related ERPs, with preliminary data suggesting modulations in early and late components, supporting the hypothesis that physical exercise can impact neural responses related to body perception. However, further analysis of the full sample is required to confirm these effects and explore the underlying mechanisms.

NEURAL CORRELATES OF EXERCISE-INDUCED COGNITIVE GAINS: A META-ANALYSIS OF FMRI STUDIES

LI, G.

SHANGHAI UNIVERSITY OF SPORT

Cognitive function is fundamental to daily life, and its decline often precedes various diseases. While the general-domain cognitive benefits of physical exercise are well-documented, the underlying neural mechanisms remain poorly understood. This meta-analysis, encompassing 52 studies with 1,503 participants, investigates how physical exercise modulates task-related brain activation and its relationship to cognitive improvements. Results indicate that physical exercise significantly enhances cognitive performance (Hedges $g = 0.271$) and increases task-related activation, particularly in the bilateral precuneus. Notably, these activation increases correlate positively with performance gains. Furthermore, factors such as exercise intensity, adherence, and social environment significantly modulate changes in brain activation. These findings provide robust neural evidence for the general cognitive benefits of physical exercise and offer critical insights for designing effective interventions. To examine whether physical exercise also exerts specific-domain effects, a secondary analysis focusing on 23 studies of executive function was conducted. During executive function tasks, physical exercise significantly increased activation in the anterior cingulate cortex (ACC), posterior cingulate cortex (PCC), cuneus, and precuneus, while reducing activation in the superior temporal gyrus, insula, midbrain, and thalamus. These findings suggest that the precuneus plays a central role in mediating exercise-induced general cognitive benefits (general-domain

effect). Additionally, they highlight that the observed improvements in specific domains, such as executive function, may be linked to changes in distinct task-relevant brain regions (specific-domain effect). The underlying mechanisms involve a dual process of neural efficiency and neural compensation. Physical exercise enhances cognitive efficiency by reducing activation in non-task-related regions and supports cognitive compensation by increasing activation in task-relevant and integrative hub regions, such as the precuneus and ACC. This dual mechanism optimizes brain function, providing a comprehensive framework for understanding how physical exercise promotes cognition and informing the development of targeted intervention strategies.

INVESTIGATING THE LINK BETWEEN LIFETIME PHYSICAL ACTIVITIES AND EEG APERIODIC SLOPE IN ADULTS AGED 55+

FREIBERGS, Z., UŠACKA, A., ŠNEIDERE, K., STEPENS, A.

RIGA STRADINS UNIVERSITY

INTRODUCTION: Resting-state EEG (rs-EEG) evaluates spontaneous brain activity, reflecting neural oscillations in different frequencies. Among rs-EEG variables, the aperiodic slope follows a 1/f pattern with higher power at lower frequencies. The steepness of this slope describes the exponential decrease of power across frequencies in the power spectral density. Evidence indicates that a steeper aperiodic slope is associated with better cognitive performance, whereas a flatter slope is linked to poorer performance in healthy individuals. Research also shows that the slope flattens with age. Lifestyle factors, including physical activity, are linked to better cognitive functioning. However, it is unclear whether accumulated lifetime physical activity, defined as motor reserve, affects the aperiodic slope. Therefore, this study aimed to investigate this relationship, given the protective role of physical activity in aging.

METHODS: The study included 33 participants, aged 56-77 years ($M=66.06$, $SD=5.94$, 33.3% male). Rs-EEG was recorded with a 32-channel g.Nautilus headset, using gel electrodes placed according to the 10-20 system, with impedance below 50 k Ω . Data were preprocessed with EEGLAB in MATLAB and downsampled to 256 Hz. Recordings lasted 3 minutes each with eyes open and closed. The median aperiodic slope steepness was computed using the FOOOF algorithm in Python. Physical activity data were collected using the Motor Reserve Index questionnaire (MRIq; Pucci & Mondini, 2020).

RESULTS: Spearman's rank correlation analysis was conducted, and no statistically significant associations were found between the median aperiodic slope and either age or the Motor Reserve Index.

Across the six domains of physical activity, namely, housework, walking, leisure activities, sports, care activities, and workplace activities, a correlation was found only between the median aperiodic slope and housework activities ($r=.432$, $p=.012$).

CONCLUSION: Our results show that within our sample of older adults the aperiodic slope is not correlated with motor reserve; nevertheless, there might be a positive link between lifetime housekeeping activities and the slope steepness.

Housekeeping, as a regular and cognitively engaging physical activity, might play a significant role in cognitive and brain maintenance, thus promoting healthy ageing and contributing to better cognitive performance, as reflected in the aperiodic slope. While our results contribute to the existing understanding of brain maintenance and cognitive reserve, we recognize the limitation of the small sample size and the retrospective nature of the MRI questionnaire, thus further studies in a larger and more varied sample of adults and added objective measures of physical activity are needed.

RESTING-STATE CONNECTIVITY AND ACTIVATION CHANGES REFLECTING ACUTE MENTAL FATIGUE: AN FMRI STUDY

AUDIFFREN, M., ANDRÉ, N., BENRAÏSS, A., ANANDRA, S., ZÉNON, A., SIBON, I., MARQUES, T., DANESHGAR-PIRONNEAU, S., AUGAIS, K., NOËL, S., CHANRAUD, S.

UNIVERSITY OF POITIERS

Introduction: Mental fatigue is a temporary psychophysiological state resulting from prolonged effort engagement in a demanding task and generally associated with a decrease in performance and a decrease in sympathetic activity and/or cognitive control over time. However, the brain mechanisms explaining acute mental fatigue are still debated. The principal aim of this study is to examine a possible mechanism implying the triple-network model (Menon, 2023). This model assumes that the salience network (SN), which is mainly anchored in the anterior cingulate cortex and anterior insula, exerts a form of control over the fronto-parietal network (FPN) and the default-mode network (DMN). During an effortful cognitive task, the SN and the FPN are generally co-activated whereas the DMN is deactivated. Previous brain-imaging studies showed that mental fatigue can be associated with changes in connectivity between task-positive (SN and FPN) and task negative (DMN) large-scale neuronal networks which increase attentional lapses and mind wandering (i.e., higher activation of the DMN). The principal hypothesis that will be tested in this experiment is that the decrease in performance over time observed in a demanding task is associated with a decrease in control of the SN over the DMN. **Methods:** Thirty-eight participants performed a 30-min incongruent Stroop task and a 30-min documentary watching task in two different counterbalanced sessions. Two types of trials were distinguished: 'reading' trials for which participants had to read the word and 'naming' trials for which they had to name the color of the ink. 'Naming' trials require more inhibitory control than 'reading' trials. The functional MRI acquisition was performed on a Siemens 3T MRI scanner. Resting-state sessions were acquired before and after each cognitive task and activation was measured while participants were performing on the Stroop task. Functional connectivity was represented by transformed bivariate correlation coefficients between regions of interest (ROI) involved in the SN, FPN and DMN. Levels of BOLD-response at the end of the task was compared to the beginning of the same task in the same ROI than previously. **Results:** The larger the effect of time-on-task on reaction time (RT) for 'naming trials' during the Stroop task, the larger the decrease in connectivity between the SN and the

DMN over time. Complementary analyses on the activation of brain ROI should confirm the hypothesis of a decrease of control of the SN over the DMN. Discussion: According to our results, acute mental fatigue will be characterized by a failure of the salience network to exert a control over the DMN. This will result in a higher difficulty for the participant to maintain constantly their concentration on the task, a decrease in the capacity to inhibit effectively the 'reading' responses and a lengthening of the RT for the 'naming' trials in which participants have to inhibit the 'reading' response.

OP-MH17 Post-surgical Recovery

EFFICACY, SATISFACTION AND FUNCTIONAL RECOVERY OF TELEREHABILITATION VS. TRADITIONAL REHABILITATION IN PATIENTS AFTER KNEE SURGERY: A SYSTEMATIC REVIEW AND META-ANALYSIS

WANG, Y., LIU, X., ZHANG, M.

BEIJING SPORT UNIVERSITY

INTRODUCTION: With the advancement of medical technology and sports science, postoperative rehabilitation options for patients are diversifying. After knee surgery, rehabilitation not only restores joint function but also athletic performance and daily activity. For active individuals or athletes, satisfaction with the rehabilitation process plays a crucial role, as it influences engagement and adherence to rehabilitation programs. This study aims to evaluate the efficacy and satisfaction of telerehabilitation for knee surgery patients (including knee arthroplasty, meniscectomy, and ACL reconstruction) and compare telerehabilitation with traditional outpatient and face-to-face rehabilitation in terms of motor function restoration and athletic performance improvement.

METHODS: We conducted electronic searches in six major databases (Web of Science, PubMed, MEDLINE, ScienceDirect, EMBASE, and Cochrane Library) and manually reviewed references in relevant journals to identify randomized controlled trials (RCTs) on telerehabilitation's impact on motor function recovery and satisfaction for knee surgery patients. Data extraction and quality evaluation were performed by two independent evaluators. Data were analyzed using RevMan 5.4 software.

RESULTS: Twenty RCTs involving 2242 patients were included. The primary endpoint was patient satisfaction, with secondary endpoints including KOOS, WOMAC, TUG, and ROM. Telerehabilitation showed no significant difference in overall patient satisfaction compared to traditional rehabilitation (mean difference = 0.15; 95% CI = -0.23 to 0.53; $p = 0.44$). However, satisfaction was significantly higher for interventions using software or web-based platforms (mean difference = 0.56; 95% CI = 0.08 to 1.03; $p = 0.02$), while videoconferencing and telephone interventions showed lower satisfaction (mean difference = -0.52; 95% CI = -1.02 to -0.02; $p = 0.04$). Telerehabilitation also outperformed traditional rehabilitation in motor function recovery, especially in knee extension ($p = 0.003$) and motor performance ($p = 0.02$), as measured by the TUG test. It also significantly improved WOMAC and KOOS scores ($p=0.007$ and $p=0.01$), but the improvement in knee flexion was not significant ($p=0.47$).

CONCLUSION: Telerehabilitation is superior to traditional rehabilitation in improving motor function and performance after knee surgery, both in objective metrics (TUG, ROM) and subjective scores (WOMAC, KOOS). Using web-based platforms for telerehabilitation not only enhances motor recovery but also increases patient satisfaction. For active individuals or athletes seeking rapid recovery of motor abilities, telerehabilitation using web-based platforms shows great potential as an effective alternative to traditional rehabilitation, especially in improving athletic performance and enhancing motor ability.

LONG-TERM LOWER EXTREMITY RANGE OF MOTION DISPARITIES FOLLOWING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION IN FORMER SECONDARY SCHOOL ATHLETES USING TRAZER MOTION CAPTURE

MORAN, R., GROOMS, D.R., CRISAFULLI, G.

THE UNIVERSITY OF ALABAMA

INTRODUCTION: Knee extension deficits are common following anterior cruciate ligament tear and reconstruction (ACLR) and may remain for multiple years [1]. However, limited literature exists on other knee and lower extremity motions, such as knee flexion and valgus/varus following ACLR. While range of motion (ROM) is commonly recorded in clinical practice statically, using handheld goniometers, recent advancements in technology enable clinicians to analyze ROM and screen for imbalances during dynamic movements. The purpose of this project was to compare long-term knee and lower extremity ROM between ACLR and non-ACLR limbs during an air squat in former secondary school athletes using motion capture technology. We hypothesized that ACLR limbs would have deficits in knee, tibial, and ankle ROM when compared to the non-ACLR limb.

METHODS: Twenty (18 female, 2 male) former secondary school athletes (age=20.2±1.6 years) who had prior ACLR during sport and were medically cleared for unrestricted activity/return-to-sport (range=1-5 years post), completed a 5-repetition, double leg, air squat while being recorded using the TRAZER motion capture system [2]. Measures consisted of average degrees (°) of ROM across the 5 repetitions for knee flexion, knee valgus/varus, tibial angle, and ankle dorsiflexion between the ACLR and non-ACLR limbs. A series of Wilcoxon Signed Rank Tests were used to compare ROM between limbs.

RESULTS: Significant deficits were observed on knee flexion with decreased ROM in the ACLR limb ($108.0 \pm 9.8^\circ$) as compared to the non-ACLR limb ($109.7 \pm 10.3^\circ$; $p=0.03$). No ROM differences were observed between limbs on knee valgus/varus (ACLR= $1.3 \pm 4.0^\circ$ vs. non-ACLR= $2.8 \pm 4.6^\circ$; $p=0.10$), tibial angle (ACLR= $26.1 \pm 4.4^\circ$ vs. non-ACLR= $27.0 \pm 4.2^\circ$; $p=0.09$), or ankle dorsiflexion (ACLR= $10.3 \pm 5.5^\circ$ vs. non-ACLR= $11.3 \pm 5.3^\circ$; $p=0.023$).

CONCLUSION: Long-term ROM deficits were observed in knee flexion only with less ROM in the ACLR limb. It is possible that these knee flexion deficits mirror knee extension lag, however it is unclear whether these limb disparities become apparent in years following medical clearance or persisted throughout the ACLR rehabilitation. Additionally, knee flexion limb disparities may also only exist in more dynamic tasks and therefore, future research is needed to compare motion capture and goniometer measures.

DISTAL-TO-PROXIMAL PROGRESSION OF GROWTH-RELATED INJURIES IN MALE YOUTH ACADEMY FOOTBALLERS: A TWO-SEASON PROSPECTIVE COHORT STUDY OF 16,024 PLAYER-SEASONS

OXENDALE, C., GREEN, M., STOKES, K., CUMMING, S., PARRY, G., WILLIAMS, S.
LIVERPOOL JOHN MOORES UNIVERSITY, UNIVERSITY OF BATH, THE PREMIER LEAGUE

INTRODUCTION: Youth football players are particularly vulnerable to apophyseal injuries, which can have long-term consequences for health and performance. The objective was to assess the incidence, severity, and burden of apophyseal injuries among U9–U21 academy football players over two seasons.

METHODS: Time-loss injuries and match and training exposure minutes were tracked in male academy football players (U9–U21) from Premier League and Category One Academies (29 academies in the 2021-22 season and 31 in the 2022/23 season). Apophyseal injuries were identified using OSICS codes, and their incidence, severity, and burden were analysed.

RESULTS: A total of 10,589 injuries were reported, including 603 apophyseal injuries. These injuries followed a distal-to-proximal progression with age, occurring most frequently in the ankle (U9–U11), followed by the knee (U12) and hip/groin (U15–U18). The incidence (~ 0.4 injuries/1000 h) and burden (~ 20 days/1000 h) of apophyseal injuries during match and training sessions were highest in the U12–U16 group. A statistically significant trend of increasing injury severity was observed with age: U9–U11 (median: 20 days), U12–U14 (median: 29 days), U15–U16 (median: 38 days), and U18–U21 (median: 35 days). Ankle and knee apophyseal injuries resulted in the second highest injury burden, compared with all musculoskeletal injuries sustained in the U9–U11 and U12–U14 groups, respectively.

CONCLUSION: Apophyseal injuries exhibit a distal-to-proximal progression with age, with the highest injury burden observed in the U12–U16 groups. These findings can help inform injury mitigation strategies adopted in youth academy football.

INVESTIGATING THE ASSOCIATION OF INTERACTION OF VARIANTS WITHIN THE TYPE I COLLAGEN GENES AND MEASURES OF KNEE JOINT LAXITY

COLLINS, M., PHIPSON, C., LAGUETTE, M.J., FIRFIREY, F., BECKLEY, S., STINTON, S., BRANCH, T., SEPTEMBER, A.V.
UNIVERSITY OF CAPE TOWN

INTRODUCTION: Joint laxity is a multifactorial phenotype with a genetic component. Type I collagen (COL1A1) gene variants, rs1107946 (G/T) and rs1800012 (G/T), have been associated with inter-individual variation in knee joint laxity measurements. Specifically, the rs1107946 GG genotype was independently associated with larger external and internal tibial rotation of the non-dominant leg, while the GG genotype occurring at both COL1A1 variants was associated with larger internal, but not external, tibial rotation of the dominant leg. Although not independently associated, a GG genotype occurring at both COL1A1 variants was associated with increased active and maximum tibial displacement of the non-dominant leg. Type I collagen alpha-chains are encoded by COL1A1 and COL1A2. As joint laxity is a polygenic trait, genotype-genotype interactions of variants within functional related genes should be investigated. However, the association of COL1A2 variants, or COL1A1-COL1A2 variant interactions, with knee joint laxity measurements have yet to be investigated. Thus, the aim of this study was to investigate the association of the COL1A2 rs42524 (G/C) variant with measures of knee laxity, both independently and via interactions with COL1A1 variants.

METHODS: 123 participants who had previously been genotyped for rs1107946 and rs1800012 were genotyped for rs42524. Genotype scores were calculated as a proxy for genotype-genotype interactions with rs1107946 GG, rs1800012 GG and rs42524 GG each given a score of 2, such that participants could have a score of 0, 2, 4 or 6. External-internal tibial rotation, anterior-posterior tibial translation, as well as maximal and active tibial displacement were measured in both the dominant and non-dominant legs of each participant.

RESULTS: No significant independent associations between COL1A2 rs42524 and measures of knee laxity were reported. However, there was a significant decrease in external (linear trend $p=0.042$) and internal (linear trend $p=0.025$) rotation of

the non-dominant leg, as well as internal rotation of the dominant leg ($p=0.029$) from the group with a genotype score of 6, a score of 4, a score of 2, to a genotype score of 0. Similarly, the active displacement of the non-dominant leg was significantly greater ($p=0.026$) when the group with a genotype score of 6 [6.3 mm (3.1; 7.9)] was compared to the groups with scores of 0 or 2 [3.0 mm (1.4; 7.0)]. The anterior tibial translation of the dominant leg was significantly higher ($p=0.039$) in the group with a score of 6 [7.5 mm (5.5; 9.5)] compared to the group with a score of 0 [4.5 mm (3.1; 7.1)].

CONCLUSION: The combined type I collagen genotype effect was associated with measures of tibial rotation, active tibial displacement and anterior tibial displacement. These findings highlight the importance of investigating genotype-genotype interactions within functional related genes with multifactorial traits.

OP-SH24 Children and Body Image

"SHUT UP! DON'T LOOK AT ME!": A QUALITATIVE DESCRIPTION OF BODY IMAGE AND ATTENTION AMONG ELITE ATHLETES

THIBODEAU, D., SABISTON, C., ATKINSON, M.
UNIVERSITY OF TORONTO

Elite athletes face numerous, pervasive, and ongoing pressures regarding their bodies' weight, shape, and performance. Due to the body-focused, judgement-based, and highly critical nature of sport cultures, body surveillance and dissatisfaction, disordered eating, and associated negative body emotions (e.g., shame, guilt) are common among elite athletes in a variety of sports. Negative body image, in particular, poses risks to athletes' abilities to focus on competition and perform to the best of their abilities. When attention is biased towards the body, athlete focus is diverted away from sport performance. Given the prevalence of negative thoughts, perceptions, behaviors, and emotions about the body in sport, it is important to understand the ways in which body image affects athletes' attention. Eight elite athletes (Mage = 26.25 years, $n = 2$ cisgender men, $n = 6$ cisgender women) were interviewed for this qualitative description study to describe the perceived association between body image and attention. Following an inductive qualitative content analysis, three dominant themes were explored. Theme 1, "Who's the leanest person here?": the pressures of how athletes feel they ought to appear, reflects the effect of incessant body comparisons among other athlete bodies, the intense vulnerability felt in uniforms which distracts from sport, and the effects on athletes' attention from being watched, photographed, and recorded. Theme 2, "It's not only a safety hazard, but you're not going to perform your best": athletes focus on sport not their bodies, refers to the participants taking control of their attention through body image and sport where they can, as well as the consequences to attention from pressures related to eating and weight. Theme 3, "I just flung that over my head, that's incredible!": the supports of body image and attention, is comprised of the strategies utilized by participants to improve their body image and attention in sport, as well as the value of having positive experiences with coaches on their abilities to focus. The findings of this research provide a detailed description of the perceived association between body image and elite athletes' control of attention in sport. In addition to discussion of the detrimental effects of negative body image on attention in the context of sport, participants also described strategies undertaken to manage their attention and body image to deter performance detriments. This research contributes to the literature concerned with maximizing sport performance and the attentional repercussions of well-established body image concerns which are pervasive in elite athletics.

ACUTE AEROBIC AND COORDINATIVE INTERVENTIONS - EFFECT ON COGNITIVE PERFORMANCE IN PRE- ADOLESCENT CHILDREN

PILZ-BURSTEIN, R., MALKA SALIS, N., MORAN, D.S.
THE GIVAT- WASHINGTON ACADEMIC COLLEGE OF EDUCATION

Acute Aerobic and Coordinative Interventions - Effect on Cognitive Performance in Pre- Adolescent Children

Pilz-Burstein, R., Malka Salis, N., Moran D.S.

The Givat- Washington Academic College of Education

INTRODUCTION: The relation between physical fitness, acute exercise and cognitive performance has drawn significant attention in recent years. The cognitive response to an exercise intervention varies between age groups and is affected, among else, by the intensity, duration and type of exercise. The aim of the present study was to investigate the effect of a single aerobic workout versus a coordinative intervention on cognitive performance in pre-adolescent children.

Method:

Eighty-six boys and girls ages 8-9 years participated in the study. The children were randomly divided into two groups: a. The experimental group (group A) performed acute aerobic exercise by skipping rope jumping for 25 minutes continuously: two legs front, two legs back, right and left leg alternately. b. The control group (group B) performed coordinative activity by spinning a dreidel from a sitting position for 25 minutes continuously. Heart rate (HR) was monitored continuously by a POLAR heart rate watch in both groups to evaluate the effect of the exercise vs. the coordinative activity. The Stroop test stages 1-2-3 was applied to assess executive function (EF) as reflecting cognitive function. Tests were performed twice by

each child: once prior to the activity intervention and again within 5 minutes of the activity termination. The number of correct responses was recorded in each of the Stroop test stages.

Results:

Mean HR of group A, the skipping rope group changed from 91 ± 12 prior to the exercise to 193 ± 16 beats/minutes upon termination; mean HR of group B, the coordinative group changed from 88 ± 10 to 113 ± 10 beats/minutes. The skipping group achieved higher scores on the Stroop tests after exercise compared to scores prior to the activity in all three stages ($p < 0.001$). A positive effect was observed also in the coordinative group with higher scoring upon termination compared to that prior to the spinning dreidel activity ($p < 0.05$). However, the post-exercise outcomes of the skipping group were better compared to those of the coordinative activity group. Interaction between measurement time and type of intervention was found significant for Stroop 1 ($p < 0.02$) and Stroop 3 ($p = 0.00$).

Discussion:

The results of the present study demonstrate a positive effect of acute, moderate-intensive aerobic exercise on some of EF abilities in pre-adolescent children. Yet, coordinative tasks that involve only very light activity as shown by the HR response, also revealed a beneficial effect on the EF performance. Based on these results it may be suggested that for the benefit of cognitive performance of school age children, acute, short activity interventions, whether aerobic or coordinative, should be part of the daily schedule and integrated routinely in between class hours.

TACKLING INEQUALITIES AND INCREASING UNDERPRIVILEGE CHILDREN WELLBEING: PRELIMINARY RESULTS FROM THE "TALENT GARDEN" PROJECT

SMARGIASSI, M.1, SARTOR, F.1,3, GIOVANNELLI, I.1, ROVIGATTI, P.1, RICCIARDI, C.2, BARDARO, N.2, ROBAZZA, C.1, BERTOLLO, M.1, MARINI, S.1

1 "G. D'ANNUNZIO" UNIVERSITY OF CHIETI-PESCARA; 2 PROSSIMITÀ ALLE ISTITUZIONI O.N.I.U.S.; 3 BANGOR UNIVERSITY

INTRODUCTION: Childhood physical activity is essential for the development of motor skills, cognition, and overall health. Children from low-income backgrounds often face obstacles in accessing structured training programs, which can impact their physical and psychological well-being. The purpose of this study is to investigate the effects of a structured physical training program on children from low-income neighbourhoods in Pescara, Italy.

METHODS: A convenience sample of 28 children from underprivileged neighbourhoods between the ages of 6 and 10 ($M = 8.57$, $SD = 1.26$) was recruited through the ONLUS association which provides the intervention and other support services in this area. A cross-sectional analysis was performed to explore the levels of psychomotor performance, psycho-physical wellbeing and sports gratification. Children underwent the Movement Assessment Battery of Children (M-ABC-2) to examine their fine and gross motor skills, agility, coordination, proprioception, balance, and posture. An ad hoc cognitive test was also implemented to evaluate the overall well-being of each child in relation to their sports participation. The assessment was conducted by kinesiologists in small groups before practice sessions. Data were analyzed by R-4.4. One sample t-test, and Pearson correlation were applied; p-value < 0.05 taken statistically significant.

RESULTS: The 28.6% of children present a deficit (i.e. Attention Deficit Hyperactivity Disorder), significantly more males ($n=7$) than females ($n=1$), $p < 0.04$. There was no difference in terms of M-ABC-2 psychomotor tests except for static balance skill in which children with deficits scored 8 seconds compared to 17sec, $p < 0.01$. No difference in levels of psycho-physical wellbeing and sports gratification (overall $M = 73.5$, $SD = 12.0$) was detected. Statistically significant correlation was found for coordination and walking ($r = 0.71$; $p < 0.001$), strength and walking ($r = 0.62$; $p < 0.001$), agility and ball catch ($r = 0.61$; $p < 0.001$) and finally coordination and strength ($r = 0.54$; $p < 0.001$).

CONCLUSION: This project is ongoing, and after 23 weeks of intervention, we will do the follow up to evaluate the program's impact. Preliminary results indicate that the psycho-physical background of this sample is in line with the normative trends. The use of sport-specific drills, combined with general movement activities, is finalized to maximize neuromuscular adaptation and overall athletic performance. In addition, the program aims to foster structured socialization, teamwork, and cognitive function, which contributes to the ultimate goal of enhancing psychological well-being. These findings could provide valuable insights into the role of accessible sports programs in promoting overall child development living in disadvantages area.

EFFECTS OF PHYSICAL ACTIVITIES AND SPORTS ON THE EXECUTIVE FUNCTIONS OF CHILDREN AND ADOLESCENTS WITH AUTISM SPECTRUM DISORDER: SYSTEMATIC REVIEW AND META-ANALYSIS

LAMAS, L., GOMES, A., DI MARTINO, G., COSTA, R.R.

UNIVERSITY OF BRASILIA

INTRODUCTION: Autism spectrum disorder (ASD) is characterized by impaired socialization, interaction deficits, and repetitive behaviors [1]. The development of executive functions (EFs) –working memory, inhibitory control, cognitive flexibility – may contribute to the life quality of these children [2]. Structured sports and physical activities (PA) interventions may improve EFs [3] although effects on children with autism are not well-established. This systematic review and meta-analysis aimed to assess the effects of chronic PA and sports interventions on executive functions and social-emotional skills in children with ASD.

METHODS: This systematic review was reported according to PRISMA guidelines (PROSPERO CRD42024558078). Web of Science, Scopus, Cochrane, PubMed, PsycINFO, and Embase were searched in December 2024. The search strategy

terms and the eligibility criteria were determined using the PICOT method, considering: Participant - children and adolescents with ASD aged between 5-13 years old; Intervention - physical activity or sports (duration >2 weeks); Comparison group - children and adolescents with ASD not engaged in physical activity or sports; Outcome - executive functions (working memory, inhibitory control, and cognitive flexibility) and social-emotional skills (communication, socialization, social skills, repetitive behaviors); Type of study - randomized clinical trials, non-randomized trials, and longitudinal intervention studies. The selection of studies and data extraction were independently evaluated by two investigators. The meta-analyses were performed using a between-group, pre- to post-intervention meta-analytic design based on standardized mean differences (Hedges' g) with a random-effect model.

RESULTS: Of 7,630 articles identified, fourteen studies were included. In general, the interventions proposed were effective in improving communication ($g = 0.79$; $p = 0.039$), Social Responsive Scale - 2 score total ($g = 1.24$; $p = 0.003$), socialization ($g = 1.13$; $p = 0.025$), inhibition ($g = 1.63$; $p < 0.001$), and working memory ($g = 1.27$; $p = 0.001$) in comparison to the control groups without interventions. On the other hand, stereotyped behavior ($g = 0.59$; $p = 0.209$), attention performance ($g = 1.95$; $p = 0.533$), cognitive flexibility ($g = 0.49$; $p = 0.116$), and planning ($g = 0.33$; $p = 0.646$) were not affected by the interventions with physical activity or sports in comparison to the control groups.

CONCLUSION: Findings offer insights into how PA and sports contribute to the cognitive development of children with autism, and how teachers and coaches can support their growth by promoting physical and emotional well-being through regular and cognitively engaging activities.

MUSCLE STRENGTH AND RANGE OF MOTION IN YOUTH FEMALE OVERHEAD ATHLETES: IMPLICATIONS FOR INJURY PREVENTION

DOMBROVSKA, L.1, KLAVINA, A.1,2, VARPA, N.3, REIHMANE, D.1

1 RIGAS STRADINS UNIVERSITY 2 LITHUANIAN SPORTS UNIVERSITY 3 RIGAS TECHNICAL UNIVERSITY

INTRODUCTION: Youth participation in sports is beneficial for physical and mental health, however early specialization and repetitive movements, can cause overuse injuries and imbalances in the body. One of such groups are overhead athletes where most strain is on the upper extremities (ex: volleyball, basketball, handball and others)[1]. The restricted range of motion and weakness in rotator cuff muscles are the modifiable injury risk factors, that can be caused by muscle imbalances, excessive training loads and poor biomechanics [1,2]. Some studies of overhead athletes show higher shoulder injury rates specifically in 15-18 years old comparing to male athletes [2]. Aim of this research was to present comparison of shoulder range of motion and isometric strength in overhead youth female athletes.

METHODS: Fifty seven youth female overhead athletes participated in pre-season testing representing overhead athletes group basketball ($n=9$), volleyball ($n=19$), handball ($n=16$), tennis ($n=4$), swimming ($n=4$), rock climbing ($n=5$), and non-overhead athletes group $n=30$, participating in sports: track and field ($n=6$), gymnastics ($n=12$), skeleton ($n=4$) luge($n=8$). Bilateral AROM for external rotation (ER) and internal rotation (IR) in the shoulder was measured with EasyAngle goniometer (Sweden). Isometric strength (IS) was measured for ER and IR with EasyForce dynamometer (Sweden). Parameters of AROM shoulder were calculated glenohumeral IR deficit (GRID), glenohumeral ER gain, (GER Gain), total arc of motion (TAM) and total range of motion deficit (TRMD).

RESULTS: Results presented significant differences for overhead athletes have significantly greater AROM comparing to non-overhead athletes with differences IR of shoulder dominant side 7.69 $p<.05$, non-dominant 6.56 $p<.05$ and shoulder ER in dominant side 21.3 $p<.001$ and 13 $p<.001$ in non-dominant side. Significant differences were found in TAM for both dominant 29.0 $p<.001$ and non-dominant side 19.5 $p<.001$. Even with GER gain of 8.31 $p<.001$ for overhead athletes TRMD comes negative -9.44 $p<.01$ for overhead female athletes comparing to non-overhead athletes

CONCLUSION: The results of this study showed the differences in shoulder AROM and strength imbalances in overhead female athletes during preseason testing. Professionals working with female youth overhead athletes should address significant AROM and strength deficiencies to reduce injury risks.

COMBINATORY EFFECTS OF ESTRADIOL AND PROGESTERONE ON PROTEIN SYNTHESIS IN C2 C12 SKELETAL MUSCLE CELLS AND THE TRAINING RESPONSE OF YOUNG FEMALE ATHLETES DURING THE MENSTRUAL CYCLE.

DIEL, P., CHEN, S., ULLRICH, F., SIEGERT, F., HELD, S., ISENMANN, E.

DEUTSCHE SPORHOCHSCHULE KÖLN

INTRODUCTION: During the menstrual cycle (MC), the fluctuation of 17- β estradiol (E2) and progesterone (P4), may affect protein metabolism and training adaptations. This study assessed the effects of E2 and P4 and their combinations A.) on myotube diameter and total protein metabolism and molecular mechanisms in differentiated C2C12 myotubes, and B.) through a human intervention study, which analyzed how young women respond to high-volume weight training performed either in the follicular or luteal phase of the MC.

METHODS: A.) Differentiated C2C12 cells were treated with different doses and combinations of E2 and P4. After 3 days of treatment cells were fixed and protein and RNA were extracted. Myotube diameter, protein synthesis rate and the expression of genes of mechanistical interest was analyzed. B.) 12 young women ($31,8 \pm 3$ years, $64,4 \pm 10$ kg, $171,2 \pm 7$ cm) were randomly assigned to high-volume training in the follicular phase (HVF) or luteal phase (HVL). The HVF group trained four days a week until ovulation occurred, and their volume was reduced to two training sessions a week till menstruation. The HVL group trained in the opposite direction. The MC was monitored via cycle diary, ovulation test and of E2 and P4 saliva concentrations. The training program included squats, deadlifts, bench presses and rows. Every four weeks, strength performance (1RM) was assessed and body composition was evaluated. Nutrition was standardized and monitored via FDDB Explorer.

RESULTS: A.) E2 treatment, in contrast to P4, led to a significant increase in myotube diameter ($+40\%$ E2: 1.26 ± 0.11 vs P4: 0.86 ± 0.06 ; $p < .05$) and total protein content ($+11\%$, E2: 1.13 ± 0.04 vs P4: 1.02 ± 0.09 ; $p = 0.2$). These effects could be counteracted by P4. E2, but not P4 treatment, results in an increase of the expression of myosin heavy chain and insulin-like growth factor-1 protein expression. Also, these effects were antagonized by P4. The expression of relevant genes show a comparable regulation. B.): So far, 5 female athletes completed the study. Initial results show significant increases in squat ($+15,4 \pm 7,7$ kg) and bench press ($7,0 \pm 2,9$ kg) performance as well as an increase in fat-free mass ($\Delta +1.4 \pm 1.8$ kg; $p = 0,07$), muscle mass ($\Delta +1.8 \pm 1.1$ kg; $p < .01$) and thigh circumference (right: $\Delta +2.4 \pm 1.2$ cm; $p < .05$; left: $\Delta +2.1 \pm 1.1$; $p = .09$). The available data show no differences between the training response in the follicular phase (HVF) or luteal phase (HVL). Study is ongoing.

CONCLUSION: Our in vitro data demonstrate an anabolic effect of E2 in C2C12 myotubes, which is counteracted by P4. This finding provides mechanistic evidence that hypertrophy training may be more effective during the follicular phase compared to the luteal phase, where progesterone levels increase significantly. Preliminary results from our training study in female athletes align with strength performance data; however, due to the low number of participants who completed the study, show no significant differences between the HVF and HVL groups thus far.

EFFECTS OF DIFFERENT ARTERIAL OCCLUSION PRESSURES DURING BLOOD FLOW RESTRICTION TRAINING ON MUSCLE DAMAGE: A DOUBLE-BLIND RANDOMIZED CONTROLLED TRIAL

HAPP, K., BARAWI, S., NIEDERER, D., SCHWIETE, C., HEINRICH, C., FRANZ, A., WAHL, P., BEHRINGER, M.

GOETHE UNIVERSITY FRANKFURT

INTRODUCTION: Blood flow restriction (BFR) training usually combines low-load (LL) resistance exercise with vascular occlusion, leading to strength and hypertrophy adaptations similar to or even exceeding those of conventional strength training [2]. However, despite its benefits, concerns remain about exercise-induced muscle damage (EIMD) from BFR training due to mixed findings [2]. The potential for increased EIMD is plausible, as metabolic stress can trigger various interlinked mechanisms leading to muscle cell damage or amplify mechanically induced muscle damage [1]. The applied arterial occlusion pressure (AOP) is a key factor influencing metabolic stress and therefore potentially EIMD. However, its relationship with EIMD near muscle failure remains unexplored. This study investigates how different occlusion pressures affect EIMD compared to free-flow training

METHODS: This double-blind, randomized controlled trial examined EIMD across different AOPs in 40 participants, divided into 4 groups: no pressure (NP), low pressure (LP; 50% AOP), medium pressure (MP; 75% AOP), and high pressure (HP; 100% AOP). Participants performed unilateral knee extensions at 30% 1RM up to a maximum of 4 sets of 20 repetitions or until failure. Oxygen saturation (SmO₂), respiratory exchange ratio (RER), lactate concentration, perceived exertion, and thermographic images were assessed. EIMD was primarily evaluated by isokinetic peak torque change 24h post-exercise ($\Delta 24h$), with secondary markers including pain (VAS), blood markers (CK, MB), swelling, stiffness, contractility, and skin temperature. Measurements were taken before, and at 1h, 24h, 48h, and 72h post-exercise. A one-way ANOVA analyzed strength changes ($\Delta 24h$ -baseline) and acute exercise responses. Repeated measures ANCOVAs examined secondary markers over time.

RESULTS: NP (74 ± 9) and LP (67 ± 15) groups completed more repetitions than MP (42 ± 7) and HP (39 ± 2). HP showed greater Δ SmO₂ decrease ($-55 \pm 24\%$) and higher Δ RER ($64 \pm 20\%$) than NP ($-19 \pm 22\%$). Perceived exertion was higher in MP (18 ± 1) and HP (19 ± 1) compared to NP (16 ± 2), but lactate and skin temperature did not differ. NP had greater strength reduction than MP (MD = -9.95 , $p = 0.045$, 95%CI [-19.7 , -0.2]) and HP (MD = -10.51 , $p = 0.038$, 95%CI [-20.5 , -0.5]). NP had higher VAS scores than MP and HP over time (F(6.29, 71.34) = 2.24, $p = .046$).

CONCLUSION: Our findings support the safety of BFR training, as EIMD did not exceed levels observed in conventional training. LP BFR resulted in similar EIMD to unrestricted training, while MP and HP led to even lower strength loss and

DOMS. However, AOPs above 75% reduced mechanical load, potentially limiting long-term adaptations. LP preserved mechanical load while reducing training duration, making it a safe and time-efficient option.

THE EFFECT OF WHOLE-BODY CRYOTHERAPY ON MUSCLE INJURY: A MORPHOLOGICAL STUDY IN RATS

NUKADA, H., HOTTA, R.1, KAMIMURA, T.2, GOTO, K.3

1 TOHO UNIVERSITY, FACULTY OF MEDICINE, 2 MAYEKAWA MFG, CO., LTD. 3 RITSUMEIKAN UNIVERSITY,

INTRODUCTION: Whole-body cryotherapy (WBC) is widely used in sport medicine as a therapeutic method for acute muscle injury and to promote faster recovery after intense physical activity. WBC has been shown to decrease levels of inflammatory markers, suggesting its potential role in managing systemic inflammation. However, the morphological investigation of the effects of WBC has not been conducted. We assessed the histological effect of WBC on acute muscle injury induced by bupivacaine (BPVC) using rats.

METHODS: BPVC (0.5% BPVC hydrochloride 0.5ml) (Marcain, Aspen Japan) was injected into the middle portion of the left tibialis anterior muscle in Sprague-Dawley rats (male, 300-350g). One session of WBC involves the following procedure: under anesthesia, the rat is placed in a cryochamber (approximately -100°C) designed by Mayekawa MFG, Co., Ltd. for 60 seconds. This procedure is repeated three times with a 3-minute interval between each session. Rats treated with WBC were divided into two groups: 1) those that received WBC immediately (0), 2 and 4 hours after BPVC injection (BPVC+WBC 0h group), and 2) those that received WBC 24, 26, and 28 hours after BPVC injection (BPVC+WBC 24h group).

The tibialis anterior muscle was then collected 24 hours after the WBC treatment for morphological assessment. The area of intramuscular edema was evaluated using binary image analysis in ImageJ. Edema was identified as expanded interstitial spaces filled with black pixels, in contrast to the white areas representing muscle fibers. Artifact regions were similarly identified and excluded from the analysis. The area of cellular infiltration was also analyzed using binary imaging. The control groups included rats with BPVC injection only (BPVC group), saline injection and sham surgery.

RESULTS: Muscle edema and cellular infiltration were significantly less in the BPVC+WBC 0h group compared to the BPVC group. The severity of cellular infiltration was more pronounced in the BPVC+WBC 24h group than in the BPVC+WBC 0h group. Morphometrically, the area of edema was significantly smaller in the BPVC+WBC 0h group compared to the BPVC group: $0.06 \pm 0.02\%$ vs. $0.13 \pm 0.02\%$ (as a percentage of the whole muscle area), $p=0.02$, respectively. The transverse area of the whole muscle was not significantly different between BPVC+WBC and BPVC rats.

CONCLUSION: When WBC was performed immediately after acute muscle injury, muscle edema and cellular infiltration were significantly inhibited. However, when WBC treatment was delayed after injury, the effect was limited. Since a notable decrease in pro-inflammatory cytokines with WBC has been reported, these results suggest that WBC performed immediately after injury suppresses the release of inflammatory cytokines during the acute phase of injury. In conclusion, WBC suppresses the acute inflammatory response after muscle injury and is more effective when performed immediately after the injury.

EVALUATING LOWER LIMB ASYMMETRIES THROUGH STRENGTH, RATE OF FORCE DEVELOPMENT AND FORCE CONTROL ASSESSMENT: A MULTI-METRIC APPROACH ACROSS HOMOLOGOUS AND HETEROLOGOUS MUSCLES

DEMANUELE, S., BOCCIA, G., MARCANTONIO, A., MASSAGRANDE, C., GHIOTTO, L., SCHENA, F., TAPERI, C.

UNIVERSITY OF VERONA

INTRODUCTION: Asymmetries are a constantly debated topic with often conflicting results due to different outcome measures. A multi-metric approach is becoming increasingly crucial for the need for an individual approach to data analysis and the need to perform multiple different tests. Among the various parameters that can be taken into consideration, maximum voluntary force (MVf) is the most common, but other parameters, such as the rate of force development (RFD) or motor control metrics evaluated through linear or non-linear approaches, are continuously growing and can provide different points of view[1].

This study, through a multi-metric approach, has several objectives: 1) to quantify the prevalence of asymmetries; 2) to determine whether dominance influences muscle function; 3) to examine whether asymmetries in muscle function are specific to certain muscles or whether one side consistently outperforms the other regardless of muscle group; 4) to assess whether the direction of asymmetry within each muscle group is consistent across different muscular-strength and motor control performance metrics.

METHODS: 71 participants (30F, 31 M; 23 ± 2 years) visited the laboratory once to undergo assessments for knee extensors (KE) and flexors (KF) in both limbs, including MVf, rapid ballistic contraction at the submaximal level to evaluate the RFD at peak (RFDpeak) and time-locked intervals (RFD50,100,150), scaling factor (RFD-SF), and assessments of approximate entropy (ApEn), coefficient of variation, and Detrended Fluctuation Analysis (DFA α) during sustained contractions (50% of MVf). Bilateral Strength Asymmetry (BSA) was used to calculate the level of asymmetry. Repeated measures within- and between-factor ANOVAs assessed differences in each metric between muscle groups and limbs. Kappa coefficients (K) were calculated to determine the level of agreement for the direction of asymmetry.

RESULTS: Except for MVF ($d = 0.113$), RFD150 ($d = 0.156$) and RFD-SF ($d = 0.409$) for KF and RFD50 ($d = 0.426$) for KE, no differences were achieved for the other metrics showing no clear superiority of one limb over the other, with asymmetries dependent on muscle group and performance metric. All K values were null, slight or fair (all $K \leq 0.23$). No significant gender differences in asymmetry were found (all $p \geq .123$).

Based on the Smallest Worthwhile Change, 75 – 78 % of participants can be considered asymmetrical. On average, the absolute values of BSA ranged between 14 and 18%, considering both muscular-strength and motor control performance metrics.

CONCLUSION: These results showed that asymmetry should be considered the norm, not the exception. From a practical point of view, these results highlight the importance of comprehensive assessment across multiple metrics to identify imbalances rather than relying on a single test and, consequently, the need to structure personalized programs to correctly address performance or motor control asymmetries by trainers.

Invited Symposium

IS-AP05 Investigating the Causes of Fatigue in Endurance Activities: Societal Benefits, Physiological Markers, and Interdisciplinary Approaches

SOCIETAL BENEFITS OF INVESTIGATING FATIGUE

MEIJEN, C.

ST MARYS UNIVERSITY

The first presentation explores how investigating fatigue contributes to societal well-being. Fatigue affects millions, impacting productivity, health, and quality of life. By comprehensively understanding mental and physical fatigue, we can devise targeted interventions that enhance performance in sports, workplaces, and education. For example, in sports, recognizing the signs of fatigue allows athletes and coaches to adjust training loads, thereby reducing injury risks and improving performance outcomes. Understanding fatigue can lead to advancements in occupational health, as workers suffering from fatigue are more prone to accidents and lower productivity levels. By identifying the causes of fatigue, organizations can implement preventive measures, such as optimizing work schedules and promoting health and wellness programs. In educational settings, students often grapple with fatigue that hinders their academic performance. Understanding the psychological and physiological contributors to student fatigue can lead to more effective learning strategies and improved mental health support, fostering an environment where students can thrive. Fatigue often combines with negative mood states, and understanding and addressing fatigue can alleviate negative mood, thereby reducing stress and the likelihood of intense emotional reactions.

CONCEPTUAL AND HEURISTIC CHALLENGES IN DEFINING AND MEASURING FATIGUE

DOMINIC, M.

UNIVERSITY OF ESSEX

The second presentation will explore the challenges we face in finding a universally agreeable definition of fatigue, given the prevalent use of this term in such a wide array of everyday, academic and clinical domains. Previous propositions about antecedent factors and mechanisms, both interoceptive and exteroceptive, that lead to subjective experience of fatigue are now so numerous and context specific that the prospect of theoretical parsimony seems, for now at least, beyond reach. Nevertheless, the subjective feeling of fatigue can be measured, and this has great practical utility in understanding the conditions that lead to fatigue and what can be done to prevent its occurrence or ameliorate its impact.

PSYCHOLOGICAL INTERVENTIONS AND THE NEED FOR INTERDISCIPLINARY APPROACHES

LANE, A.

UNIVERSITY OF WOLVERHAMPTON

The third presentation explores the psychological aspects of fatigue in endurance activities and the necessity for interdisciplinary interventions. Psychological fatigue often manifests as mental exhaustion, characterized by decreased motivation, impaired cognitive function, and negative emotional states. Interventions focusing solely on psychological factors may overlook the underlying physiological contributors, leading to incomplete solutions. Research by Meijen et al. (2023) emphasizes the importance of psychological strategies, such as goal setting, motivational self-talk, and distraction techniques, in managing fatigue during endurance activities. However, these strategies should be complemented by physiological assessments to ensure a comprehensive approach to fatigue management. An interdisciplinary framework that integrates psychological and physiological insights can enhance the effectiveness of fatigue interventions. For instance,

athletes could benefit from tailored psychological strategies that account for their physiological state, leading to improved performance outcomes. This holistic approach not only addresses fatigue more effectively but also promotes overall well-being, recognizing the interplay between mind and body. Conclusion In summary, understanding the physiological markers of fatigue and their relationship to performance is essential for developing effective interventions. Psychological strategies are vital, yet they must be integrated with physiological assessments for a comprehensive integrated approach. Equally, understanding that physiological driven strategies can alleviate fatigue and repair negative mood. By fostering interdisciplinary collaboration, we can enhance our understanding of fatigue in endurance activities and develop more effective strategies for individuals in various contexts. OP-AP37 Blood Flow Restrictions

THE EFFECT OF BLOOD FLOW RESTRICTED, HEAVY, AND DE-LOADED RESISTANCE TRAINING ON PERCEPTUAL AND PHYSIOLOGICAL RESPONSES DURING EXERCISE AND RECOVERY

DE MARCO, K., GOODS, P.S.R., BALDWIN, K.M., HISCOCK, D.J., SCOTT, B.R.

MURDOCH UNIVERSITY

INTRODUCTION: Athletes often incorporate resistance training (RT) to enhance strength and performance, however during certain training phases, RT is de-loaded (DLRT), possibly limiting its effectiveness. Blood flow restricted RT (BFRRT) can elicit muscular adaptations similar to heavy load RT (HLRT), while only requiring low loads, making it a potential solution during de-loading periods. However, differences between these RT strategies in the acute physiological responses and any subsequent fatigue remains unclear. Therefore, this study aimed to compare the physiological, perceptual, and performance effects of BFRRT, HLRT, and DLRT acutely and for 48-h post-training.

METHODS: Eighteen resistance-trained females completed half squat (1RM = 96.2 ± 18.0 kg) and split squat (1RM = 72.4 ± 14.6 kg) under 3 exercise conditions: 1) BFRRT (half squat = 1 set: 30 repetitions, 3 sets: 15 repetitions; split squat = 4 sets: 15 repetitions on each leg; 30%1RM, 30 s inter-set rest, 60% arterial occlusion pressure), 2) HLRT (5 sets: 5 repetitions, 80%1RM, 3 min inter-set rest), 3) DLRT (3 sets: 3 repetitions, 75%1RM, 45 s inter-set rest). Follow-up testing was conducted 24- and 48-h after each condition. Blood lactate was recorded pre- and 2 min post-exercise. Session rating of perceived exertion (sRPE) was recorded 20 min post-session. Maximal voluntary contraction (MVC), countermovement jump (CMJ) height, and muscle soreness were measured before and after experimental sessions, and at all follow-up sessions. Data were log10 transformed and analysed using a linear mixed model with Bonferroni post-hoc comparisons.

RESULTS: Blood lactate increased post-exercise for all conditions, with BFRRT (+90.0%, $d_z = 2.2$) and HLRT (+71.4%, $d_z = 1.7$) significantly higher than DLRT, and BFRRT also higher than HLRT (+22.1%, $d_z = 0.6$). sRPE was significantly higher in BFRRT (+54.6%, $d_z = 1.6$) and HLRT (+41.7%, $d_z = 1.2$) compared to DLRT; but were not different from each other. MVC significantly decreased from pre- to post-exercise (-11.8%, $d_z = 0.6$), but with no between-condition differences. Muscle soreness in BFRRT (+84.1%, $d_z = 1.2$) and HLRT (+93.2%, $d_z = 1.5$) were significantly higher than DLRT at all time points. Within-condition analysis showed increased soreness 48-h post-exercise in BFRRT (+80.9%, $d_z = 0.7$) and HLRT (+137.85%, $d_z = 1.3$) compared to pre-exercise. Muscle soreness at 48-h post-exercise was significantly lower in BFRRT than HLRT (-63.9%, $d_z = -0.6$); however, BFRRT was higher than DLRT (+88.2%, $d_z = 0.6$). There were no significant effects for time or condition for CMJ.

CONCLUSION: BFRRT elicits similar acute physiological and perceptual responses to HLRT, with reduced post-exercise muscle soreness and no difference in performance during the recovery period. Therefore, BFRRT may be a viable alternative to HLRT when muscle soreness is contraindicated, but the long-term efficacy of this approach requires further investigation.

EFFECTS OF BLOOD FLOW RESTRICTION ON MUSCLE STRENGTH THICKNESS AND SPORTIVE MOTIVATION IN ELITE CANOE ATHLETES

UGUR TOSUN, B., ANGIN, E., KIRMIZIGIL, B.

EASTERN MEDITERRANEAN UNIVERSITY

INTRODUCTION: Canoeing requires coordination, core stability, and strength, engaging both aerobic and anaerobic energy systems [1]. While upper extremity strength is often emphasized, lower extremity strength is equally important for optimal performance. Strength training enhances both performance and endurance, with resistance exercises at $\geq 65\%$ one-

repetition maximum (1 RM) promoting muscle hypertrophy [2, 3]. Blood Flow Restriction (BFR) training provides a low-intensity (20-30% 1 RM) alternative, simulating the effects of high-intensity exercise through hypoxia [4]. Research shows that BFR training improves muscle size, strength, and psychological motivation [5], a key factor in athletic success [6]. This study investigates the effects of BFR training on lower extremity strength, muscle thickness, and sportive motivation in elite male canoe athletes.

METHODS: Seventeen male national team canoe athletes (aged 18-25) participated in this study. Muscle thickness and cross-sectional area (CSA) of lower extremity muscles were measured using ultrasound, while isokinetic strength was assessed at 60°/s with a Biodex System. Motivation was evaluated using the Sport-Specific Achievement Motivation Scale (SSAMS). The 8-week BFR training program utilized KAATSU C3 cuffs at 30% of 1 RM for Quadriceps, Hamstrings, and Leg Press exercises, with progressive pressure increases. Training sessions included warm-up, three to four sets of exercises, and cool-down. Measurements were taken pre- and post-training to assess outcomes.

RESULTS: The participants included in the study had an average age of 18.59 ± 0.71 years, an average sports age of 6.88 ± 1.17 years, an average weekly training frequency of 7.24 ± 1.64 days, an average height of 177.28 ± 7.27 cm, and an average body weight of 74.74 ± 11.19 kg. Muscle measurements showed notable bilateral increases, including Rectus Femoris Thickness (RFT) rising from 1.74 ± 0.24 cm to 1.91 ± 0.22 cm ($p < 0.001$) on the right and from 1.56 ± 0.26 cm to 1.79 ± 0.29 cm ($p < 0.001$) on the left. Cross-sectional area (CSA) of the Rectus Femoris (RF) and Hamstrings also significantly increased. Isokinetic strength tests demonstrated enhanced Quadriceps Femoris (QF) peak torque (PT), with right QF PT increasing from 198.16 ± 36.58 Nm to 227.12 ± 46.91 Nm ($p = 0.002$) and left QF PT from 191.52 ± 27.33 Nm to 224.45 ± 42.51 Nm ($p = 0.001$). Motivation scores also improved, particularly in the "Motivation to Approach Success" and "Avoiding Failure" subscales ($p < 0.001$).

CONCLUSION: BFR training effectively enhances muscle performance and psychological factors in elite athletes [1]. The findings highlight the unique benefits of BFR training, which enhances hypertrophy through hypoxic conditions and recruits fast-twitch muscle fibers without requiring high-intensity loading, significantly reducing the risk of injury [2].

EXAMINING SEX DIFFERENCES IN NEUROMUSCULAR AND HYPERTROPHIC ADAPTATIONS TO SEQUENTIAL LOW-LOAD BLOOD-FLOW-RESTRICTION AND HIGH-LOAD RESISTANCE TRAINING

LEDERGERBER, R., RITSCHKE, P., LICHTENSTEIN, E., KELLER, M.

UNIVERSITY OF BASEL

INTRODUCTION: Low-load Blood Flow Restriction training (BFR) is a viable alternative to high-load resistance training (HL), due to its lower mechanical tension, where still comparable or slightly lower gains in muscle hypertrophy and strength are seen (1). However, neural adaptations remain poorly understood and are hypothesized to be less pronounced, while sex differences have hardly been studied at all (2). Thus, this study aimed to investigate the sequential application of HL following BFR on neuromuscular and hypertrophic adaptation and compare its sex-dependent effects (3).

METHODS: In this 10-week randomized controlled trial, 37 healthy male and female adults (35-60 years) completed progressive resistance training for knee extensors either 8 weeks with low-load BFR followed by 2 weeks of HL, or exclusively HL training. Measurements at baseline including familiarization (PRE1 and PRE2), 8 weeks (MID) and 10 weeks (POST) included maximal voluntary contraction of knee extensors (MVC), voluntary activation (VA, via electrical muscle stimulation) and vastus lateralis and rectus femoris muscle volume (VL_RF, via ultrasound at 30-70% femur length). Linear mixed models were used to analyze group differences over time and between sex, reporting Cohen's d effect sizes.

RESULTS: The HL group showed greater increase in MVC at MID and POST ($d = 0.49^*[-0.01; 0.99]$) compared to the BFR group, with females benefiting slightly more at MID ($d = 0.15[-0.47; 0.78]$) but not at POST ($d = -0.15[-0.78; 0.47]$). VA changes at MID and POST were slightly negative for HL ($d = -0.25[-1.54; 1.03]$), however, females demonstrated larger improvements at MID ($d = 0.62[-0.97; 2.22]$) and POST ($d = 0.77[-0.83; 2.36]$). While the BFR group showed greater improvements in VL_RF at MID ($d = 0.25[-0.29; 0.80]$), HL was more beneficial for females ($d = 0.48[-0.24; 1.20]$).

CONCLUSION: Our findings suggest that HL is more effective for neuromuscular adaptations, whereas BFR may offer short-term hypertrophic benefits. However, as the differences were small on a group level and large variability was present, it seems that not just mechanical tension, but also metabolic stress is a driver of neuromuscular adaption (3). Notably, HL was particularly beneficial for females, leading to greater increases in muscle size and neuromuscular function. Future research should further deepen sex-specific responses to optimize resistance training protocols.

EFFECT OF BLOOD FLOW RESTRICTION TRAINING ON ACUTE AND LONGITUDINAL OUTCOMES IN EARLY POSTOPERATIVE ACL REHABILITATION: A RANDOMISED CONTROLLED TRIAL

BARZYK, P., FIEDLER, C., KUCH, J., HEITNER, A., BENDER, J., PAUL, J.

PRAXISKLINIK RENNBAHN AG

INTRODUCTION: Anterior cruciate ligament (ACL) injuries represent the most prevalent type of knee injury, with surgical reconstruction being the prevailing treatment modality. However, postoperative pain and muscle weakness are common occurrences. Blood flow restriction (BFR) training has demonstrated potential in enhancing muscle adaptation and reducing pain; nevertheless, its efficacy in the early postoperative period following ACL reconstruction remains to be determined. The present study investigates whether the incorporation of BFR into low-load strength training confers additional clinical benefits in comparison to low-load exercise alone.

METHODS: 30 participants (6 females; age 32.3 years) who had undergone primary ACL reconstruction were randomised to receive either low-load strength training with (LL-BFR) or without (LL) BFR. The interventions consisted of four sets of leg press exercises (30 repetitions for the first set, 15 for subsequent sets) performed twice a week for four weeks, as an adjunct to standard rehabilitation protocols. The primary outcome measure was pain perception, assessed by pressure pain thresholds (PPT) at four sites (quadriceps femoris affected/ un-affected, biceps brachii and trapezius on the dominant side) and a visual analogue scale (VAS) for knee pain at rest and during a stair climb. Secondary outcomes included knee joint ROM, rectus femoris thickness, maximum strength and knee joint effusion. Exertion levels during the exercise were measured using the BORG scale, and knee function was assessed using the IKDC questionnaire.

RESULTS: Mixed linear models were employed for the statistical analysis. Participants in the LL-BFR group reported significantly greater perceived exertion during training ($p=0.01$). However, no statistically significant between-group differences were observed for primary or secondary outcome measures for acute effects. Similarly, no group-time interactions were identified for longitudinal results. However, significant time effects were observed for muscle thickness ($p=0.014$); maximum strength ($p=0.002$); knee joint effusion (affected $p=0.004$, unaffected $p=0.007$); active (ext. $p=0.035$, flex. $p<0.001$) and passive ROM (ext. $p=0.029$, flex. $p<0.001$) on the affected side; VAS scores (rest $p<0.001$, stairs $p=0.003$) and IKDC scores ($p<0.001$).

CONCLUSION: The present study shows that a combination of BFR and low-load strength training does not provide additional clinical benefits to low-load training alone in the early postoperative phase, following ACL reconstruction. The study's limitations encompass imbalances in sex distribution, minimal baseline pain levels, and inherent variability in subjective pain reporting. Conversely, the study's strengths encompass high study adherence and a homogenous patient population characterised by standardised surgical and rehabilitation protocols. Further research is required to explore the potential of BFR in specific patient subpopulations, with different training loads or at later stages of rehabilitation.

EFFECTS OF WHOLE-BODY VIBRATION WARM-UP TO ACHIEVING THE BEST SPORTS SKILL-RELATED PERFORMANCE: A RANDOMIZED CONTROLLED TRIAL

AMATO, A., PETRIGNA, L., AMORIM, P.R.S., MUSUMECI, G.

UNIVERSITY OF CATANIA, ; FEDERAL UNIVERSITY OF VIÇOSA,

INTRODUCTION: Several studies focused on the long-term effects of whole-body vibration (WBV) training on health. However, to date, conflicting results are on its acute use to optimize performance, and no one has tested the effect of a warm-up with WBV on team sports-related skills like power, reaction, flexibility, and reactive strength of leg muscles simultaneously. No standardized warm-up protocols have been tested to verify the effectiveness of WBV on sports skills. This study aims to evaluate the effects of a 5-minute, single-bout WBV protocol on team sports-related performance to understand if WBV is a possible faster, space-saving warm-up before competition or used by the bench players waiting to perform.

METHODS: We included 93 volunteer participants (age: 23.48 ± 5.1 y; BMI: 24.03 ± 3.3 kg/m²) in data analysis. All participants were assessed before (T0) and after (T1) the experimental protocols through the following tests: lower limb reaction time test (RTT), countermovement jump test (CMJ), sit and reach test (SR), and the Reactive Strength Index (RSI) to evaluate the reactive strength of leg muscles skill. The s-EMG signal for the tibialis anterior and gastrocnemius lateralis muscles was monitored during the tests to investigate the mechanisms of action through which the WBV could influence performance. After the T0 assessment, participants were randomized into three groups: the WBV group (WBVg), which did a 5-minute WBV warm-up; the free body group (FBg), which did the same but with the WBV turned off; and the control group (CONg), which performed no protocol between T0 and T1. After the 5-minute WBV intervention, all tests were repeated. Mixed ANOVA was performed to check between and within-group effects. Bonferroni correction was used to investigate the differences between conditions. The association between variables was examined.

RESULTS: After a 5-min WBV warm-up, the WBVg significantly improved the performances of the CMJ (cm) (T0: 36.69 ± 10.9 , T1: 38.37 ± 8.9 ; $p<0.01$), SR (cm) (T0: 27.27 ± 9 , T1: 29.26 ± 9.1 ; $p<0.01$), and RTT (s) (T0: 0.52 ± 0.1 , T1: 0.49 ± 0.1 ; $p<0.01$). No significant change was found in CONg for CMJ(cm) (T0: 34.58 ± 10.9 , T1: 35.37 ± 10.5 ; $p>0.05$), RTT (s) (T0: 0.52 ± 0.09 , T1: 0.51 ± 0.1 ; $p>0.05$); RSI (m/s) showed a significant decrease (T0: 0.62 ± 0.3 , T1: 0.56 ± 0.3 ; $p<0.05$). FBg improved test scores between T0 and T1 for the CMJ (cm) (T0: 37.22 ± 8.2 , T1: 39.01 ± 9.1 ; $p<0.01$), SR(cm) (T0: 24.54 ± 7.8 , T1: 27.22 ± 7.4 ; $p<0.01$) and RTT (s) (T0: 0.52 ± 0.1 , T1: 0.48 ± 0.1 ; $p<0.01$). Although the decreasing trend agrees with the literature, no statistical difference was found in EMG activation post-warm-up in both muscles indexing, and no fatigue occurred.

CONCLUSION: Our 5-minute WBV warm-up was adequate to optimize performance. This warm-up before performances needing flexibility, power, reactive strength of leg muscles, and quick reaction time has no adverse event like fatigue or

performance decrease. Future studies could test the effectiveness of the same protocol before and during real sports competitions

JGU MAINZ

INTRODUCTION: Heat strain is a significant external factor that should not be underestimated when it comes to optimizing physical performance in sports. Studies have shown that better acclimatization, along with improved thermoregulation, is positively correlated with enhanced performance [1]. In monitoring core body temperature, telemetric ingestible pills represent the gold standard of measurement systems. However, the expenses and limited reusability are major drawbacks. New measurement methods, such as wearable sensors, offer a non-invasive, and cost-effective alternative. Nevertheless, the accuracy of these sensors requires further investigation in different exercise settings.

METHODS: Twelve endurance-trained participants [6=male; 6=female; age=24.83J (± 2.17); bodyweight=67.87kg (± 8.01); height=173.75cm (± 6.06); maximal oxygen uptake: 52.1 mL/min/kg (± 7.45)] were enrolled in the study. Each participant performed two running bouts on a treadmill (46 min; at 85% of the individual anaerobic threshold) on a treadmill (Saturn, h/p/cosmos, Germany). The external load was determined by percentage of individual anaerobic threshold (IAT) via cardiopulmonary exercise testing. Core temperature ($^{\circ}\text{C}$) was measured continuously with the wearable CORE sensor (green-TEG AG, Switzerland) and the telemetric pills eCelsius-Performance (BodyCAP, France). The tests were conducted in a thermally controlled environment ($24.03^{\circ}\text{C} \pm 1.28$). For statistical analysis, we performed spearman correlation analysis to detect the agreement between both measurement systems. Significance level was set to $p < 0.05$.

RESULTS: A strong correlation was found between pill and CORE sensor in both protocols (T1: $r = 0.86$, $p < 0.001$; T2: $r = 0.79$, $p < 0.001$). In later stages of both protocols, the sensor slightly overestimated the core body temperature compared to the pill ($+0.3^{\circ}\text{C}$).

CONCLUSION: The wearable sensor seems to be a cost-effective alternative to the ingestible pill when operating in a thermally controlled environment. Due to the slight overestimation of temperature in the later stages of the investigation, the risk of overheating seems to be minimized when relying on the sensor data. However, field studies involving additional stress conditions and different thermal environments will be necessary to further assess the reliability of the sensors in the future.

CONTINUOUS MONITORING OF HEART RATE, CORE BODY TEMPERATURE, AND SLEEP IN REAL-LIFE SETTINGS: A PROOF-OF-CONCEPT

SCHWEIZER, T., SIEBOLD, E., LIZARRIBAR CARRILLO, Y., GILGEN-AMMANN, R.

SWISS FEDERAL INSTITUTE OF SPORT MAGGIEN

INTRODUCTION: Sleep deprivation and heat stress impair human performance and may disrupt thermoregulation, leading to increased physiological strain. As both conditions are prevalent in basic military training, this underscores the need for continuous, real-life monitoring. Wearable technologies provide a non-invasive solution, with upper-arm wearables offering a well-tolerated option. However, their validity across various activity intensities and environmental conditions remains underexplored. This research aimed to (1) validate the upper-arm-worn devices, the Calera Research for core body temperature (CBT) and the Polar Verity Sense for heart rate (HR), as HR is integral to both the CBT estimation and sleep detection algorithms, and (2) evaluate the performance of a self-developed sleep detection algorithm using acceleration (ACC) and HR data from the upper-arm.

METHODS: In a semi-controlled validation study, 16 healthy participants (age 27.4 ± 5.8 years; height 173.5 ± 9.2 cm; weight 69.9 ± 9.4 kg) completed two test sessions under two heat stress conditions, performing nine activities from rest to vigorous intensity. HR and CBT were validated against reference measures (Polar H10 for HR, rectal sensor for CBT) using mean absolute error (MAE) and agreement analysis. In a 15-week military field study, continuous HR (1 Hz) and ACC (52Hz) data from 46 participants (age 19.8 ± 1.4 years; height 177.5 ± 6.9 cm; weight 73.9 ± 10.8 kg) were collected to develop an upper-arm-based sleep detection algorithm. Adapted from the Hypnospy framework [1], the algorithm integrates a customized cleaning process, physiological and movement-based thresholds, smoothing, and volatility analysis. Daily self-reported sleep windows served as a reference for comparison.

RESULTS: The Polar Verity Sense demonstrated strong accuracy across most activities (bias -0.05 bpm; MAE 1.43 bpm). The Calera Research showed moderate accuracy, with a systematic overestimation and temporal shift (bias 0.21°C ; MAE 0.39°C). The sleep detection algorithm provided estimations comparable to self-reports for each participant.

CONCLUSION: These findings highlight the performance of the Polar Verity Sense and Calera Research for continuous monitoring across rest and various activity intensities, providing reliable and actionable data. The sleep detection algo-

rhythm provided reasonable estimates but showed some discrepancies compared to self-reports, likely due to inaccuracies in participant responses rather than algorithmic limitations. While these findings indicate potential for automated sleep and physiological monitoring in real-world conditions, further validation against objective sleep measures is needed. Overall, this research supports the potential applicability of upper-arm-worn wearables for 24-hour monitoring.

VALIDATION OF WEARABLE DEVICE ALGORITHMS FOR PERSONALISED PHYSIOLOGICAL STRAIN MONITORING DURING REAL-WORLD OCCUPATIONAL TRAINING.

TAN, S., LOW, S.L.H., TRAN, T.C.K., CHEN, C.T.Y., NISHA, V., CHONG, L.J.Y., LOW, I.C.C., LEE, J.K.W.

NATIONAL UNIVERSITY OF SINGAPORE

INTRODUCTION: Real-time heart rate (HR) and body core temperature (T_c) monitoring is key for mitigating heat-related injury risk and optimising training in hot and/or humid environments. However, validated methods for monitoring T_c are impractical for use in the field due to their invasiveness (e.g. rectal probes) and prohibitive cost (e.g. telemetric capsules). Wearable technology enables non-invasive estimation of HR and T_c to facilitate real-time physiological strain monitoring. Yet, their validity for personalised physiological monitoring during field training is unclear. Hence, we selected and validated consumer wearable devices for physiological strain monitoring during real-world occupational training.

METHODS: We reviewed the existing literature and selected four wearables for an initial laboratory validation based on four criteria: safety, suitability, accuracy, and data accessibility. Fitbit Sense (FB, Coolbit T_c algorithm) CALERAresearch (CA, CALERAresearch arm T_c algorithm) and Equivital Lifemonitor (EQ, ECTemp) were selected for further validation in the field. Eighty healthy firefighters (age = 30 ± 5 years, female = 5) completed up to three firefighting training activities based on their individual training requirements. All training activities, namely breathing apparatus proficiency test (BAPT), confined space rescue (CSR), and marine firefighting scenario (MFS), were conducted in warm and humid conditions (T_{db} = 29.5 ± 1.2°C, RH = 78 ± 10%). Criterion for HR validity was set at a mean absolute percentage error (MAPE) <10% and Intraclass Correlation Coefficient (ICC) ≥0.9. Validity criterion for prediction of group and individual T_c responses were set at a mean bias error (MBE) <±0.27°C and 95% prediction errors within ±0.40°C (PTA ± 0.40°C) respectively.

RESULTS: HR and T_{gi} ranged between 41 to 203bpm (6359 data points) and 36.5 to 40.6°C (6341 data points) respectively. EQ displayed excellent HR accuracy across all training activities (MAPE = 5 ± 14%, ICC = 0.900 to 0.956). FB exhibited poor-to-moderate accuracy (ICC = 0.215 to 0.559) with larger underestimations at higher HR values. Group prediction errors were acceptable (MBE <±0.27°C) in FB (-0.07 ± 0.68°C) and CA (-0.25 ± 0.35°C) during BAPT. While FB and CA had a similar MBE and PTA ± 0.40°C (all p > 0.05), FB exhibited larger 95% CIs across all training activities (FB = ±2.45°C, CA = ±0.86°C). Percentage of individual T_c prediction errors within ±0.40°C was poor in all devices (FB = 41%, CA = 55%, EQ = 18%).

CONCLUSION: The EQ had the highest accuracy for HR monitoring. While FB and CA were valid for estimating group-based T_c responses during BAPT, both devices failed to meet our validity criterion in other firefighting training activities. All wearable T_c algorithms displayed individual prediction errors that were too large for personalised physiological strain monitoring during field training. Further refinement of selected consumer wearables is necessary to enable their deployment in real-world physiological strain monitoring.

PROPOSAL OF A METHOD BASED ON THE USE OF A DRONE TO MEASURE INSTANTANEOUS SPEED DURING NONLINEAR SPRINTS OVER OUTDOOR AREAS

WANG, F., ZHANG, Q., GLAISE, P., HAUTIER, C.

UNIVERSITE CLAUDE BERNARD LYON 1

INTRODUCTION: Current approaches for assessing Change-of-Direction (COD) performance, COD deficit, and asymmetries predominantly rely on photocell systems that measure total task time, yet fail to capture critical kinetic details during COD phases (e.g., peak velocity before turning). Although lab-grade systems (e.g., Vicon) provide 3D kinematic precision, their spatial constraints limit field applications. This study develops a non-contact motion capture system integrating drone aerial imaging with deep learning algorithms to enable precise 2D kinematic analysis of COD maneuvers.

METHODS: Sixteen male collegiate soccer players (age: 19.7 ± 1.3 yr; body mass: 70.2 ± 8.9 kg; height: 176.3 ± 7.8 cm) certified as National First-Class Athletes by Chinas General Administration of Sport performed COD in 90° trials on artificial turf. DJI Air 3 drone equipped with real-time kinematic positioning maintained stable aerial surveillance (60Hz) at 34m altitude. The homography matrix algorithm converted video trajectories to georeferenced coordinates using four ground markers, with a YOLOv8s model trained on 2,000 annotated frames achieving 99.3% mAP@0.5 tracking accuracy. Based on the georeferenced coordinate data, key parameters were subsequently derived from velocity-time profiles: peak velocity, minimum velocity, deceleration duration, deceleration distance, mean deceleration, and maximum deceleration.

RESULTS: The proposed method demonstrated parameter-dependent reliability, with speed-related metrics exhibiting superior consistency. Peak velocity during right-direction COD (90°R) showed the highest reliability (ICC(3,1)=0.818 [95%CI:0.560-0.930], CV=3.4%), followed by right-direction deceleration duration (ICC=0.797 [0.510-0.920], CV=13.3%). Bilateral comparisons revealed stable measurement of key parameters: left-right differences in peak velocity were clinically negligible (Delta=0.06 m/s, SEM=0.10-0.13) with 72% of spatiotemporal metrics exceeding the ICC≥0.70 threshold.

While maximum deceleration parameters showed moderate variability (ICC=0.470-0.640, CV=23.4-24.5%), speed metrics maintained CV<10% across both directions, confirming the systems robustness for dynamic velocity profiling in field settings.

CONCLUSION: This method overcomes the spatial and ecological constraints of conventional timing systems by enabling detailed 2D kinematic analysis of outdoor COD maneuvers, particularly excelling in capturing critical speed parameters (ICC=0.72-0.90, CV=3.4-10.2%) and deceleration phase kinetics. The validated capacity to quantify COD deficit through peak-to-minimum velocity differentials (Delta=2.26-2.35 m/s) and detect bilateral asymmetries (Delta=0.06 m/s in peak velocity) establishes its utility for precision training program design. While maximum deceleration metrics require further refinement (ICC=0.47-0.64), the systems sport-specific validity in measuring COD components-particularly acceleration-deceleration transitions-positions it as a viable method for field-based testing.

CAN TRAINING WITH A HARNESS-SYSTEM IMPROVE PERFORMANCE FOR YOUNG FIGURE SKATERS?

MYKLEBUST, H., PANFILOV, V.

UNIVERSITY OF STAVANGER

INTRODUCTION: Figure skating is a sport in which athletes are judged on technical perfection, gaining the most points for mastering the most difficult technical elements. Jumps are particularly complex, and the development of new training methods for figure skaters has aimed at improving performance through enhanced technical jump execution, increasing the number of rotations, and mastering multi-revolution jumps in the shortest possible time. Different types of harness and rotator systems have become popular in the figure skating community, but controlled studies examining their training effects are lacking [1]. This study aims to examine kinematic effects of using the 'Pro-Motion Off Ice Harness System' in the training of young developing figure skaters.

METHODS: An experimental, randomized, controlled, cross-over study design was used with 23 female figure skaters (age: 10-15 years, height: 156.8 ± 7.5 cm, body mass: 47.1 ± 9.3 kg), all of whom completed a four-week training intervention with the harness system. The skaters were tested pre-intervention and after 4 and 8 weeks. The intervention consisted of 10 minutes of harness training followed by jumping, 3 times a week for 4 weeks. Skaters were randomly divided into an intervention group and a control group, switching groups after 4 weeks. The tests consisted of two countermovement jumps (CMJ) with free use of arms, and three maximal rotation jumps (RJ). Flight times (FT) and total degrees of rotation were recorded using video and analyzed by a single scientist. The maximum value among jumps was used for analysis. Typical error (TE) for test-retest variability of flight times among these skaters using this analyst was < 2 % [2].

RESULTS: The main findings showed that there were no statistically significant effects on the kinematic variables in RJ after four weeks of training with the harness system. Pre-intervention, the skaters rotated 598 ± 91 degrees within a FT of 418 ± 42 ms in RJ, which corresponded to 87 ± 6 % of FT in CMJ.

Post-intervention results showed a small, non-significant increase in rotated degrees (M = 12.4, SD = 42.6, 95% CI [-6.0, 30.8], t(22) = 1.401, p = 0.175, d = 0.29) but only trivial changes for FT (M = 3.5, SD = 24.2, 95% CI [-6.9, 13.9], t(22) = 0.691, p = 0.497, d = 0.14). In contrast, four weeks without harness training showed no systematic changes in rotated degrees (M = 0.7, SD = 22.8, 95% CI [-10.0, 11.4], t(19) = 0.137, p = 0.892, d = 0.03) with a TE of 2.2 % for rotated degrees and TE of 2.3 % for FT in RJ.

CONCLUSION: Four weeks of 3 x 10 minutes harness training per week was not enough to achieve significant improvements for the group of 23 figure skaters. A larger sample size and a larger or longer training dose with the harness system might yield significant effects.

EFFECT OF INTERSET INTERVAL DURATION ON NEUROMUSCULAR RESPONSES TO HIGH-LOAD RESISTANCE TRAINING

GAMERO DEL CASTILLO, D., BAUDRY, S.

UNIVERSITÉ LIBRE DE BRUXELLES - FSM

INTRODUCTION: The interset rest period in resistance training is crucial in determining the total work that can be performed during a training session. When using maximal loads (>85% of one repetition maximum (1RM)), rest intervals ranging from 3 to 7 minutes are commonly recommended^{1,2}. However, scientific evidence supporting these durations is limited although the muscular and neural mechanisms responsible for decreased performance (fatigability) can be influenced by rest duration. This study investigated the effects of rest intervals on fatigability in response to a strength training session with heavy loads.

METHODS: Twenty-two resistance-trained males (mean $\pm$ SD: age 23 $\pm$ 2 years, body mass 74 $\pm$ 7 kg, height 180 $\pm$ 6 cm) participated in three sessions performed in a counterbalanced order. The protocol consisted of 4 sets of 3 repetitions at 90% of 1RM on a horizontal leg press machine, with rest intervals of 3 (S3), 5 (S5), or 7 min. (S7). Procedures included: isometric maximal voluntary contraction (MVC) of the lower limb, tetanic contraction of the quadriceps (50 pulses at 50 Hz), and triplets (3 pulses at 100 Hz) evoked by femoral nerve stimulation. Electromyographic (EMG) activity of the vastus lateralis (VL), and rectus femoris (RF), tissue oxygenation index (TOI) of the VL, and the rate of perceived exertion (RPE) were also measured.

RESULTS: MVC force decreased more in S3 and S5 compared with S7 ($p<0.001$). The central activation ratio did not show any significant difference in any interset duration ($p<0.05$) while EMG during MVC declined in VL and RF in S3 and S5 ($p<0.05$), but not in S7. The tetanic force declined significantly post-session ($p<0.001$) with greater reductions in shorter interset intervals (34 $\pm$ 28% S3; 22 $\pm$ 16% S5; 21 $\pm$ 17% S7). Triplet force decreased significantly for S3-S5 and S3-S7 ($p<0.05$). TOI decreased more in S3 and S5 compared with S7 ($p<0.001$) thus RPE increased more in S3 and S5 compared with S7 (5 $\pm$ 1% S3; 3 $\pm$ 1% S5; 2 $\pm$ 1% S7, $p<0.001$).

CONCLUSION: Our findings indicate that shorter rest intervals (S3, S5) amplify neuromuscular fatigue. The absence of central activation ratio failure suggests peripheral mechanisms as key factors in reduced performance. Accordingly, the force developed during electrically-evoked contraction decreased to a greater extent for short interset rest duration (S3 and S5). Likely due to increased metabolic stress as suggested by TOI. Additionally, higher RPE scores with shorter rests highlight increased psychophysiological strain which could reflect metabolic changes.

Overall results suggest a 7-minute interset rest as more optimal for reducing neuromuscular fatigability under high-load conditions.

EFFECT OF DIFFERENT TRAINING PROTOCOLS ON MAXIMUM VOLUNTARY ISOMETRIC AND ECCENTRIC TORQUE IN THE ELDERLY

MICHELE, T., MONTE, A., D'EMANUELE, S., GHIOTTO, L., BOCHICCHIO, G., TARPERI, C., POGLIAGHI, S., ZAMPARO, P.
UNIVERSITY OF VERONA

INTRODUCTION: Muscle strength is an essential functional parameter during daily life activities. Muscle force typically decreases with age (Bemben et al., 1991), affecting the quality of life (Trombetti et al., 2016). Therefore, training strategies that can improve muscle strength in the elderly are of scientific and practical interest. Several training protocols in this population have been shown to improve cardiovascular function (Craighead et al., 2019), but their role in eliciting improvements in muscle force is still not completely understood. Therefore, this study aimed to compare the effects of different endurance training modalities on maximum isometric and eccentric muscle strength (torque).

METHODS: Thirty-two healthy elderly participated in the study. They were divided into four work-matched training groups: moderate-intensity continuous training (concentric, 4M/4F), heavy-intensity continuous training (concentric, 4M/4F), heavy-intensity continuous training (eccentric, 4M/4F), high-intensity interval training (concentric, 4M/4F). Training modalities were carried out at the cycle ergometer (Lode for the concentric and Cyclus 2 for the eccentric modalities). The participants were tested at baseline and after 4 and 8 weeks of training. Knee extensor torque was measured using an isokinetic dynamometer (Cybex Norm); subjects were seated with the back supported and the hip joint flexed at 70°. They were requested to perform two maximal voluntary isometric contractions at a 90° knee angle and two maximal eccentric isokinetic contractions at five different angular speeds [45, 90, 150, 210, 250 °/s]. The mean torque value during the steady state of the isometric contractions and the maximum torque value during the isokinetic phase (at each angular speed) were calculated.

RESULTS: The four groups were matched for age (66.5 $\pm$ 5.2 years), stature (1.7 $\pm$ 0.8 m) and body mass (69.2 $\pm$ 11.2 kg). Maximum eccentric torque was unaffected by training modality in all groups. Maximum isometric (concentric) torque increased from 130.7 $\pm$ 70.8 Nm to 142.3 $\pm$ 78.7 Nm ($p=0.041$) in the high-intensity continuous training group after 4 weeks of training; no further improvements were observed after 8 weeks. No significant differences were observed (either after 4 or 8 weeks) in the other training groups in concentric torque.

CONCLUSION: Our data indicate that these training protocols have trivial or no effect on maximum isometric and eccentric torque in an elderly population. Only in the high-intensity continuous training group did torque significantly improve after 4 weeks, indicating a positive impact of training intensity on muscle force capacity. The eccentric training protocol did not affect eccentric torque. Although endurance training improves cardiovascular function in older adults (Craighead et al., 2019), this is not the case for muscle force.

ARE CHANGES IN MAXIMUM ANATOMICAL CROSS-SECTIONAL AREA ACROSS THE LOWER BODY RELATED TO CHANGES IN MUSCLE VOLUME FOLLOWING 15 WEEKS OF RESISTANCE TRAINING?

BALSHAW, T., FUNNELL, M., MCDERMOTT, E., MADEN-WILKINSON, T., JAMES, L., FOLLAND, J.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Quantifying lower body muscle volume (VOL) with magnetic resonance (MR) imaging requires segmentation of a relatively large number of axial images along the length of the muscle (1). In contrast, maximum anatomical cross-sectional area (ACSAmx), can be derived more efficiently as only a small number of images around ACSAmx need to be segmented. Currently the extent to which changes in ACSAmx across individual muscles of the lower body are associated with changes in VOL following resistance training (RT) has received little attention, with prior work only focusing on the relationship between RT-induced changes ACSAmx and VOL for the overall quadriceps femoris (QF; 2). The purpose of this study was to determine the relationship between RT-induced changes in ACSAmx and changes in VOL across individual muscles of the QF, hamstrings (HAMS), and also the gluteus maximus (Gmax).

METHODS: Thirty-nine healthy young men participated in the study. Before and after 15 wk of lower body RT (knee extension, knee flexion, leg press; x3/wk) dominant limb axial MR images between the anterior superior iliac spine and lateral tibial condyle were acquired. Scans were segmented to quantify ACSAmx and VOL of the Gmax, the constituent muscles of the QF and HAMS. Pearson's product moment bivariate correlations were performed between pre to post RT percentage changes in ACSAmx and VOL for each muscle/muscle group.

RESULTS: Percentage changes in ACSAmx and VOL following RT were correlated for the overall QF ($r=0.874$, $p<0.001$) and HAMS ($r=0.966$, $p<0.001$) muscle groups as well as all individual muscles (vastus lateralis $r=0.699$, vastus intermedius $r=0.646$, vastus medialis $r=0.894$, rectus femoris $r=0.897$, biceps femoris short head $r=0.923$, biceps femoris long head $r=0.880$, semitendinosus $r=0.834$, semimembranosus $r=0.890$, Gmax $r=0.820$, [all] $p<0.001$).

CONCLUSION: Overall RT-induced changes in QF (76%) and HAMS (93%) ACSAmx explained moderate to high amounts of variance in corresponding changes in VOL. Following RT, the extent that percentage changes in ACSAmx explained variance in changes in VOL across individual muscles differed markedly (42% vastus intermedius to 85% biceps femoris short head). In conclusion, the extent to which RT-induced changes in ACSAmx are related to changes in VOL varied notably across key individual lower body muscles and should not uniformly be accepted as a substitute for or alternative to directly assessing changes in muscle volume.

THE EFFECT OF 4 WEEKS HIGH VS. LOW LOAD ISOMETRIC UNILATERAL ELBOW FLEXION RESISTANCE TRAINING ON THE MAGNITUDE OF INTER-LIMB STRENGTH TRANSFER AND RETICULOSPINAL TRACT PROPERTIES

ABU-TALIP, N., ŠKARABOT, J., BALSHAW, T.G.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Bilateral increases in strength after unilateral resistance training (ULRT) have long been observed but few studies have directly compared the extent that interlimb strength transfer differs when manipulating ULRT prescription. Whilst high load (HL) has been identified as a key ULRT loading parameter, it is currently unclear if low load (LL) ULRT can induce comparable interlimb strength transfer (1,2). The purpose of this study was to compare the effect of 4 wk of HL vs. LL elbow flexion (EF) ULRT on the magnitude of interlimb strength transfer and explore the changes in reticulospinal tract (RST) properties as a potential substrate of adaptations.

METHODS: Over a 4 wk intervention period thirty young, healthy adults (male, $n=19$; female, $n=11$) completed 15 sessions of isometric EF ULRT with the dominant arm following randomisation to volume-matched HL (70% of maximum voluntary force [MVF], $n=15$) or LL (35% MVF, $n=15$) conditions. Non-dominant arm EF MVF and RST properties (assessed via: (i) the StartReact paradigm [RST gain ratio] and (ii) the ratio of motor evoked potential [MEP; transcranial magnetic stimulation of the primary motor cortex] and cervicomedullary MEP [CMEP; electrical stimulation of the cervicomedullary junction] conditioned by startling stimuli compared to unconditioned responses during submaximal contractions) were assessed pre and post intervention.

RESULTS: Non-dominant arm MVF increased in both HL (+10.6%; $p=0.006$; Pre: 197 ± 73 N; Post: 213 ± 73 N) and LL (+12.5%; $p<0.001$; Pre: 208 ± 82 N; Post: 232 ± 85 N) but did not differ between groups (group x time effect, $p=0.298$). The groups also responded similarly to the interventions for all RST property measures (group x time effect, $0.402 \leq p \leq 0.756$). The RST gain ratio did not change following HL ($p=0.629$; Pre: 1.17 ± 0.18 ; Post: 1.14 ± 0.14) or LL ($p=0.447$; Pre: 1.12 ± 0.14 ; Post: 1.15 ± 0.15), nor did the MEP ratio in either condition (HL, $p=0.426$; Pre: 1.04 ± 0.47 ; Post: 0.98 ± 0.33 ; LL, $p=0.995$; Pre: 0.96 ± 0.23 ; Post: 0.96 ± 0.25). However, the CMEP ratio increased (+24.4%, time effect, $p=0.003$) after both LL (Pre: 1.26 ± 0.49 ; Post: 1.51 ± 0.47) and HL (Pre: 1.33 ± 0.46 ; Post: 1.53 ± 0.35).

CONCLUSION: Volume-matched HL and LL ULRT both improved isometric strength of the untrained arm. However, the extent of interlimb strength transfer did not differ between conditions indicating accumulated ULRT volume might be a more critical loading parameter than intensity when aiming to maximise interlimb strength transfer. Though the RST gain and the MEP conditioned by the startling stimulus were unaffected by the intervention, the ratio of conditioned to uncondi-

tioned CMEP increased after training, suggesting the possibility that some of the interlimb strength transfer observed was mediated by adaptations within the reticulospinal tract.

ACUTE EXCITABILITY CHANGES OF THE RETICULOSPINAL TRACT DURING A SINGLE BOUT OF RESISTANCE EXERCISE IN HEALTHY HUMANS

ZHOU, J., WALKER, S., PIIRAINEN, J.M., KIDGELL, D., AVELA, J., AHTIAINEN, J.
UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: The reticulospinal tract is a key neural pathway implicated in adaptation to resistance training (1). Strength-trained individuals demonstrate greater reticulospinal excitability compared to untrained controls (2); however, its acute response to resistance exercise in humans remains largely unexplored. Ipsilateral motor-evoked potentials (iMEPs) have been proposed as a reliable measure of reticulospinal function, given the RSTs bilateral descent with an ipsilateral predominance (3). This study examined acute changes in reticulospinal excitability due to resistance exercise.

METHODS: 29 untrained healthy adults (9 males, 20 females) participated in this study. Electromyography electrodes recorded contralateral motor-evoked potentials (MEP) from the dominant arm (m. biceps brachii) and iMEPs from the non-dominant arm. MEPs and iMEPs were elicited using transcranial magnetic stimulation (TMS) at 100% stimulator output when participants reached an elbow flexion angle of 110° during bilateral biceps curls with 30% of their one-repetition maximum load, a method previously validated for iMEP elicitation (4). The protocol included one set of 40 repetitions with 20 TMS pulses (administered in cycles of 5 stimulations followed by 5 pauses, until all 40 repetitions were completed). The ipsilateral to contralateral amplitude ratio (ICAR) was calculated to assess the relative importance of the two tracts (i.e., reticulospinal and corticospinal tracts) (5). The Rating-of-Fatigue scale (ROF, 0-10) and velocity loss (%) of maximal concentric contraction speed assessments were performed pre- and immediately post-loading to measure fatigue.

RESULTS: Clear iMEPs were observed in 27 subjects. Immediately after the biceps curl exercise, a significant change in the velocity loss ($12 \pm 7\%$, $p < 0.001$) and ROF were observed (1.7 ± 1.1 to 5.1 ± 2.0 , $p < 0.001$). Both iMEP ($r = 0.166$, $p < 0.001$) and ICAR ($r = 0.161$, $p < 0.001$) rather than MEP ($r = 0.067$, $p = 0.117$) correlated with repetitions during 40 repetitions. Furthermore, comparing the median responses of the first 5 with the last 5 of 40 repetition set revealed significant increases in iMEP ($37 \pm 39\%$, $p < 0.001$), MEP ($5 \pm 13\%$, $p = 0.023$), and ICAR ($33 \pm 49\%$, $p = 0.004$).

CONCLUSION: The observed increases in iMEP and ICAR with increasing repetitions may suggest a potential involvement of the reticulospinal tract during resistance exercise and provide targets for future research on neural responses to resistance exercise. Further research is needed to determine whether these changes represent a compensatory mechanism for neuromuscular fatigue or are influenced by other factors.

Invited Symposium

IS-PN08 Unraveling Dietary Protein Sources for Skeletal Muscle Health and Performance: 'From Workouts to Wellness

CONSIDERING THE SOURCE OF DIETARY PROTEIN FOR SKELETAL MUSCLE ADAPTATION IN EXERCISING INDIVIDUALS

WALL, B.
UNIVERSITY OF EXETER

Dietary protein ingestion to support skeletal muscle recovery, remodelling and adaptation to exercise training represents a cornerstone within modern sports nutrition. Physiologically, this is due to the exercise induced stimulation of muscle protein synthesis rates being augmented by the ingestion of each protein containing meal over days and weeks. Experimental research into the regulation of muscle protein turnover via exercise and protein has developed well-defined, generally agreed upon sports nutrition guidelines around protein intake for training individuals; most notably, that intakes in excess of currently accepted RDA/Is are more optimal. Recent work has now applied more focus to the adjacent question of what types of protein may be more or less optimal, and to what extent the choice of protein may influence sports nutrition recommendations. This question was traditionally viewed more through the lens of optimising protein supplementation/isolates. However, media (e.g. 'GameChangers' documentary) and societal (e.g. concerns over environmental sustainability) priorities advocating for (more) plant-based diets have encouraged this work to refocus on a broad range of

protein-rich, animal- and non-animal derived food sources. Such research has begun to accumulate data on measurements of daily or weekly whole-sale dietary change, as opposed to a per meal basis, and therefore begins to represent dietary patterns more reminiscent of how protein is habitually consumed in individuals selecting different diets but seeking similar benefits during prolonged training. This presentation will review the growing literature base surrounding the regulation of muscle protein turnover via diverse dietary protein sources. Further, research examining the translation of these mechanistic approaches to protein-rich food choices during longer term, whole-sale dietary changes (e.g. omnivorous vs vegan diets) to more prolonged measures of muscle protein metabolism and adaptive responses to training will be considered. The extent to which we can offer practical recommendations on protein type, in combination with protein amount, will be discussed. The presentation therefore aims to provide content of interest to researchers in the field as well as those wanting a more applied contemporary perspective regarding protein nutrition guidelines for exercisers giving more consideration to from where their protein is obtained.

CAN THE SOURCE OF DIETARY PROTEIN OPTIMIZE MUSCLE HEALTH WITH ADVANCING AGE?

BREEN, L.

UNIVERSITY OF BIRMINGHAM

The loss of muscle mass, strength and function with advancing age (termed 'sarcopenia') is associated with heightened risk of disease comorbidity, loss of independence and poorer quality of life. Estimates suggest that this condition affects >10% of those aged 65 and over and is more prevalent with advancing age. In line with global population ageing sarcopenia diagnoses are increasing at an unprecedented rate, placing a strain on healthcare resources and economies. Dietary protein is essential for muscle maintenance and health across the life-course, primarily through the stimulation of postprandial muscle anabolic processes. Congruent with data demonstrating that postprandial muscle anabolism is compromised in older age, mounting evidence shows that dietary protein intakes for age-related muscle health should exceed current population-wide recommendations. However, achieving higher levels of dietary protein intake in older age can be challenging for numerous reasons. These include alterations in the regulation of appetite and digestion, sensory issues including smell and taste, chewing efficiency and swallowing function. Beyond protein quantity, dietary protein quality (determined by the metabolic availability of [essential] amino acids) may be important stimulus for skeletal muscle anabolism and maintenance in older age, particularly in the context of lower protein-containing diets. In this regard, animal-derived proteins are typically touted as 'higher quality' than plant-derived proteins based on their EAA profile, superior rate of digestibility, and overall bioavailability for anabolic processes in peripheral tissues such as skeletal muscle. However, the superior muscle anabolic properties of animal over plant-derived proteins in older adults have commonly been demonstrated with single servings of isolated supplemental sources in acute, tightly controlled experimental conditions. In contrast, dietary protein is typically consumed within a whole-food matrix as part of a mixed meal, delivering multiple nutrients in complex structures that alters protein digestibility and the capacity for postprandial muscle anabolism. Recent studies have employed innovative methodologies over longer-term free-living periods to provide fresh insight on the role of dietary protein source and quality for muscle mass regulation in older adults. This talk will provide a detailed overview of the mechanisms through which dietary protein source and quality may influence muscle anabolism and maintenance in older adults, drawing on historic and contemporary research findings. Future directions to determine source-specific protein requirements to promote muscle health in older adults will also be presented. This talk holds relevance for researchers interested in understanding the dysregulated nutrient sensing in ageing muscle and practitioners using diet/nutrition approaches to promote health and general wellbeing in older adults.

DIETARY PROTEIN SOURCE TO PREVENT MUSCLE DECONDITIONING IN CLINICAL SETTINGS

WEIJZEN, M.

MAASTRICHT UNIVERSITY

Hospitalization or recovery from illness often necessitate a period of physical inactivity which is accompanied by an accelerated loss of muscle mass and muscle strength. This accelerated muscle loss during hospitalization can have particularly detrimental consequences on muscle strength and function in the older population, as many older adults do not recover fully from this catabolic event. Additionally, in hospitalized patients, significant alterations in dietary intake—primarily reduced energy and protein consumption—further complicate recovery. Insufficient protein intake has been shown to accelerate muscle loss, prolong hospital stays, elevate the risk of complications, increase morbidity and mortality, heighten readmission rates, and impair functional recovery. Food intake is typically reduced due to a variety of factors, such as restricted timing of food provision, adverse effects of medication, reduced appetite, and prescribed periods of fasting. It has been recommended that older individuals or individuals with acute or chronic illness should consume 1.2-1.5 g protein/kg/d. However, achieving these intake levels in a clinical setting is challenging. Although protein provision might theoretically meet these guidelines, actual protein consumption often falls short, resulting in protein intake levels far below recommendations. A growing shift toward plant-based proteins in clinical settings adds an additional layer of complexity, as these protein sources often have lower digestibility and an incomplete amino acid profile compared to animal proteins, potentially further compromising protein quality and bioavailability in patients with elevated protein needs. This talk will provide a comprehensive overview of dietary protein consumption in clinical settings. It will highlight research on muscle loss during hospitalization and anabolic resistance associated with (critical) illness, while presenting practical nutritional approaches to optimize protein intake. Special emphasis will be given to future directions and considerations related to dietary protein sources in clinical care. This talk will appeal to researchers in the field, as well as practitioners working with

clinical populations, offering valuable insights into the caution required for implementing the upcoming protein transition in clinical practice.

OP-BM12 Balance

SENSORY REWEIGHTING AFTER VIRTUAL REALITY-AUGMENTED BALANCE TRAINING IN YOUNG ADULTS

KETTERER, J., GOLLHOFFER, A.1, ASSLÄNDER, L.2, GRANACHER, U.1, GEHRING, D.1

1UNIVERSITY OF FREIBURG; 2UNIVERSITY OF KONSTANZ

INTRODUCTION: Maintaining balance in an upright stance is a fundamental movement skill. Balance control relies on sensory feedback from visual, vestibular, and proprioceptive systems [1]. Previous research has shown that the relative contribution of each sensory system changes depending on environmental conditions, a process referred to as sensory reweighting [2]. However, the effects of balance training (BT) on sensory integration are currently unresolved. This study aimed to investigate the effects of virtual reality-based BT (BT+VR) versus conventional BT on sensory integration during bipedal stance in young adults.

METHODS: Twenty-two participants aged 22.9 ± 1.1 years were randomly allocated to a BT or a BT+VR group. BT participants received conventional BT, while BT+VR participants additionally received visual input manipulations in the form of a tilting visual scene during the performance of BT exercises. Both training protocols were conducted for four weeks with two weekly sessions. To investigate the visual sensory contribution, participants were exposed to two stimulus conditions. The visual scene tilted in pseudo random sequences with peak-to-peak amplitudes of 1° or 4° (pp1 and pp4) while postural sway was recorded in bipedal stance using a force plate. The independent-channel model was applied to estimate the visual contribution to balance [3], i.e., the visual weight (Wv), together with parameters characterizing the dynamics of the feedback system. Specifically, the proportional and derivative feedback-loop gains represent the strength of muscle contraction relative to the deviation from the desired upright position and postural sway velocity. Three-way rmANOVAs were performed with the factors group (BT vs BT+VR), time (pre vs post), and stimulus condition (pp1 vs pp4).

RESULTS: Results revealed a significant main effect of condition ($p < 0.001$, part. eta squared effect size [ES]=0.97), with higher Wv observed in pp1 compared to pp4. A significant condition-by-time interaction ($p = 0.003$, ES=0.38) was found, with a 15% pre to post decrease in Wv in pp1. However, no significant group-by-time interactions were found. For the proportional and derivative feedback-loop gains, significant main effects of time were observed ($p = 0.004$, ES=0.28; $p = 0.044$, ES=0.35, respectively).

CONCLUSION: This study demonstrates that both BT and BT+VR can induce adaptations in sensory reweighting by reducing the visual contribution to balance. While neural adaptations following BT have been extensively studied, this study provides novel evidence of adaptations in the feedback system of balance control after BT and BT+VR in healthy young adults. These findings may have clinical implications for patients (e.g., with Parkinson disease) or older adults who often have increased visual dependence during balance control.

COMPARISON OF FOUR INTERVENTIONS AIMED AT IMPROVING BALANCE IN OLDER ADULTS

THEODOSIADOU, A., FABRE, M., SAHINIS, C., PAPAVASILEIOU, A., PATIKAS, D.A., AMIRIDIS, I.G., LAPOLE, T., BAUDRY, S.

UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: Aging results in a progressive decline of motor control, affecting static and dynamic balance [1]. Balance training programs for elderly individuals typically involve exercises targeting various factors, such as visual input, surface type, or foot positioning [2], but rarely incorporate specific stimulation of the neuromuscular system to enhance the training effects. While previous studies have focused on techniques like vibration or electrical stimulation [3,4], the combination of both remains largely unexplored. This study aims to investigate the effects of four balance training interventions that integrate balance exercises and neuromuscular stimulation.

METHODS: Seventy-four healthy older adults (75-87 years old) completed a 6-month protocol that included 8 weeks of tailored balance training consisting of either 40-min session of balance exercises alone (CON group) or combined with concurrent application of electrical stimulation (TENS group), vibration (LV group) or both (LV+TENS group). Four evaluations were conducted: 8 weeks before the training (T1), 1-7 days before the training (T2), 1-7 days after the training period (T3), and after an 8-week retention period with no training (T4). The assessment included the 10-Meter Walking Test (10MWT), 6-Minute Walking Test (6MWT), Timed Up and Go (TUG), Berg Balance Scale (BBS), and Short Physical Performance Battery (SPPB). Linear mixed model (fixed effect: evaluation and group, random effect: participants) were used for analysis.

RESULTS: No significant differences were found between T1 and T2 for any test ($p>0.05$), without group differences either. No significant effects of training ($p=0.138$) or group ($p=0.525$) were observed for the 6mWT. However, an improvement in 10mWT ($p=0.004$), TUG ($p<0.001$), SPPB ($p<0.001$) and BBS ($p<0.001$) was observed from T2 to T3, without differences between groups. After the retention period, the scores returned to their initial values (as in T2) for the TUG, SPPB and BBS ($p=0.002$; $p=0.049$; $p<0.001$, respectively) without differences between groups ($p>0.05$).

CONCLUSION: These findings suggest that tailored balance training significantly enhances clinical balance performance, underscoring its importance as a non-pharmacological intervention to combat age-related decline in balance capacity. However, the addition of LV and TENS did not give additional benefits compared to exercises alone. This suggests that while these modalities are often posited to enhance neuromuscular activation and proprioceptive feedback, their contribution to balance improvement may be limited, at least in the context of this study. One possible explanation could be that the balance exercises provided sufficient stimulus for adaptation, leaving little range for additional gains from LV or TENS.

HEALTHY YOUNG AND MIDDLE-AGED ADULTS WITH LOW FALL-RESISTING SKILLS IMPROVE BALANCE RECOVERY DURING SIMULATED REAL-WORLD BALANCE DISTURBANCES AFTER PERTURBATION-BASED GAIT TRAINING

WEBER, A., HARTMANN, U., WERTH, J., EPRO, G., KAUFMANN, M., KLUGE, A., ELLEGAST, R., KARAMANIDIS, K.
UNIVERSITY OF KOBLENZ

INTRODUCTION: Perturbation-based balance training during locomotion is recognized as an effective physical intervention to enhance fall-resisting skills across diverse populations [1]. However, its transfer to real-world scenarios remains insufficiently investigated. Given that the generalization of adaptive locomotor stability responses is essential for fall prevention, this study examined whether balance recovery improvements gained either through mechanically or visually induced gait perturbations translate to real-world balance disturbances in high fall risk individuals.

METHODS: 110 healthy young and middle-aged participants (aged 18–63 years, male and female) were randomly assigned to a control group ($n=30$, no perturbation training) or one of two perturbation training groups: mechanically induced (MEC, $n=40$) or visually induced (VR, $n=40$). All participants walked on a treadmill during training. The MEC group experienced posterior and medio-lateral gait perturbations via ankle and waist pulls using a pneumatically operated brake-and-release system. The VR group encountered visually induced perturbations through virtual environment rotations displayed in VR glasses. To assess potential transfer effects to real-world perturbation scenarios, participants completed walkway negotiation tasks before and after treadmill training, encountering tripping, slipping, and misstep elements. Based on pre-training anterior margin of stability (MoS) during trip, slip, and misstep perturbations, participants were classified as high (HIGH) or low performers (LOW) using a median split with a minimum 20% separation threshold. Balance improvements in simulated real-world scenarios were evaluated by analysing MoS pre- and post-training.

RESULTS: For each perturbation type our analysis revealed a similar number of LOW and HIGH performer independent of the analyzed exercise groups. LOW showed an increase in MoS during tripping and slipping in both intervention groups (mean increment in MoS: VR-trip: +8.65 cm, VR-slip: +4.18 cm; MEC-trip: +9.71 cm, MEC-slip: +7.95 cm; $p<0.05$). In the misstep transfer task, a significant MoS increase was observed only in the MEC group (+3.88 cm; $p<0.05$). In contrast, HIGH and the control group showed no increase in MoS or any components of dynamic stability from pre- to post-testing during tripping, slipping, or missteps.

CONCLUSION: Our findings show that healthy young and middle-aged adults with low fall-resisting skills can benefit from repeated exposure to unpredictable visual and mechanical induced gait perturbations enhancing their fall resilience during simulated real-world balance disturbances. Thus, implementing such perturbation-based exercise interventions in occupational and clinical settings might be an effective tool to decrease fall risk in various population groups.

CHANGES IN BALANCE PERFORMANCE IN ADOLESCENT FOOTBALL PLAYERS AT THE BEGINNING OF COMPETITION PERIOD

PONTAGA, I., SINULINGGA, A.R., LIEPA, A., SLAIDINS, K., SALAJEVA, A.
RIGA STRADIŅŠ UNIVERSITY, LATVIAN ACADEMY OF SPORTS EDUCATION

INTRODUCTION: Balance performance, particularly in a one-leg stance, is critical for enhancing a football player's ability to perform high-intensity and explosive actions such as sprints, jumps, accelerations, and decelerations during changes of direction - key physical capacities required for success in competition (Chtara et al., 2018; Rouissi et al., 2018). Kim & Kim (2018), Chtara et al. (2018) proved that shin muscle strength growth causes balance improvement. Lower ankle joint stiffness is associated with a larger range of movement (ROM) in plantar flexion and worse static balance (Loram & Lakie, 2002). Our study aims to assess static and dynamic balance, ankle plantar (PF) and dorsal (DF) flexor muscle strength, and ankle ROM changes in adolescent football players in the competition period's first 8 weeks.

METHODS: Nineteen 15.3 ± 0.9 years old male football players (mean training experience: 8.1 ± 2.6 years, training volume: 8.4 ± 2.1 h/week at the end of the preparation period, and 9.8 ± 2.0 h/week in the competition period, $p < 0.012$) participated. The static and dynamic balance were evaluated using the stabilimeter platform. The ankle PF and DF muscle isometric peak forces were measured using a handheld dynamometer. The torques were calculated by multiplying the peak force with the lever arm length. The ankle PF and DF active and passive ROMs were tested using a goniometer.

RESULTS: The 8 weeks of the competition period led to: One leg stance static balance side-asymmetry appearance standing on the dominant (D) and non-dominant (N) legs ($p \leq 0.037$), and improvement solely in the N leg: the ellipse area of the centre of pressure (COP) movements, its perimeter, COP sway distance in the medial-lateral direction, the mean anterior-posterior and medial-lateral sway speed reduced ($p \leq 0.041$). Dynamic balance improved: the trunk total deviation angle reduced standing on the D and N legs ($p \leq 0.041$). The total stability index transited from the category "poor" (3.2 ± 1.7) to "normal" (2.3 ± 0.91) standing on the N leg. The isometric peak torques of ankle PF and DF muscles were stronger in the D leg than in the N ($p \leq 0.021$). After 8 weeks, the ankle DF peak isometric torques increased in both legs ($p \leq 0.0012$). The passive PF ROM was reduced in both ankles ($p = 0.0002$), and the active PF ROM increased in the D limb ($p = 0.033$).

CONCLUSION: In sum, in the 8 weeks of the competition period dynamic balance performance improved standing on the D and N legs, but static balance performance enhanced only in the N one-leg stance. The ankle DF muscle became stronger to provide better motor skills in the D leg and larger DF active ROM and stability during landing tasks in the N leg. The ankle passive PF ROM was reduced in both legs due to ankle stiffness growth that improves balance performance.

NEUROMUSCULAR ADAPTATIONS TO UNEXPECTED POSTURAL PERTURBATIONS IN HANDBALL ATHLETES.

PAPAVASILEIOU, A.1,2, XENOFONDOS, A.2, BASSA, E.1, ENGLISH, L.T.2, PATIKAS, D.A.1

1 SCHOOL OF PHYSICAL EDUCATION AND SPORT SCIENCE AT SERRES, ARISTOTLE UNIVERSITY OF THESSALONIKI, GREECE 2 DEPARTMENT OF LIFE AND HEALTH SCIENCES, FREDERICK UNIVERSITY, LIMASSOL, CYPRUS

INTRODUCTION: Adapting to unpredictable postural perturbations is essential for handball athletes, where rapid movements and direction changes are common [1]. Vibration-induced sensory perturbations challenge proprioception, requiring quick adjustments to maintain balance. Understanding how athletes respond, provides insights into long-term neuromuscular adaptations from specialized training, crucial for injury prevention [2]. This study examined differences in activation patterns of the soleus and tibialis anterior muscles during and after vibration-induced perturbations.

METHODS: 13 handball athletes (7 females, age: 24.25 ± 2.10 years, BMI: 22.83 ± 1.68 kg/m², training experience: 9.98 ± 2.46 years) and 12 non-athletes (4 females, age: 28.11 ± 4.83 years, BMI: 23.02 ± 4.19 kg/m²) participated in the study. Participants were exposed to unexpected 12-15 s bilateral vibration on the Achilles tendons while standing on a force plate with eyes blindfolded. Centre of Pressure (CoP) displacement and activation of the tibialis anterior (TA) and soleus (SOL) muscles were recorded and analysed for 8 s after vibration onset and offset. Repeated measures ANOVA identified significant differences in CoP displacement and muscle activation ($p < 0.05$).

RESULTS: Both groups exhibited a significant backward CoP shift (TIME: $F(16, 368) = 27.5$, $p < 0.0001$), starting 1.5 s after the vibration onset (post hoc: $p < 0.05$), while after the perturbation (post-offset), showed a further backward shift (TIME: $F(16, 368) = 19.2$, $p < 0.0001$), followed by a forward displacement within the first 1.5 s (post hoc: $p < 0.05$). SOL activation began 0.5 s after onset in both groups (TIME: $F(16, 368) = 6.3$, $p < 0.0001$). However, post-offset, handball athletes demonstrated stronger activation (TIME*GROUP: $F(16, 368) = 1.8$, $p = 0.03$) from 1.0 to 1.5 s (post hoc: $p < 0.001$), while non-athletes showed a significant weaker response at 0.5 s ($p < 0.001$). TA activation displayed similar patterns in both groups during the onset of vibration (TIME: $F(16, 368) = 3.0$, $p < 0.0001$), but after the offset, non-athletes exhibited a stronger TA response (TIME*GROUP: $F(16, 368) = 2.4$, $p < 0.01$) to anticipate the forward CoP displacement.

CONCLUSION: Although both handball players and non-athletes compensated similarly for the unexpected vibration-induced perturbation, their neuromuscular strategies differed. Handball players relied more on enhancing agonist (SOL) activation during standing, while non-athletes showed greater antagonist (TA) activation. The reduced involvement of the antagonist muscle in handball players may suggest more efficient recovery mechanisms, highlighting neuromuscular adaptations from training that contribute to better balance control.

OP-AP39 Swimming III - Performance Testing

KEY PERFORMANCE INDICATORS IN FREESTYLE SWIMMING: COMPARING START, TURN, AND SWIMMING VELOCITY IN TOP-ELITE FEMALE JUNIOR AND ADULT SWIMMERS

WIDMER, C., HERNANDEZ, J.1,2, ROMANN, M.1,2, TAUBE, W.2, BORN, D.P.1,3

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN UNIVERSITY OF FRIBOURG, FACULTY OF SCIENCE AND MEDICINE, SWITZERLAND; SWISS AQUATICS – NATIONAL SWIMMING FEDERATION, SWITZERLAND

INTRODUCTION: Due to the increasing importance of start and turn performance in swim races throughout the recent years, the aim of the study was to compare the effect of start performance, turn performance, and swimming velocity on the race result between top-elite female junior and adult swimmers across all distances of freestyle pool races (50 m to 1500 m) and to provide a software tool to predict race outcomes based on the various key performance indicators.

METHODS: In the present study, a total of 289 individual freestyle races from female participants at the European long-course championship, as well as 391 freestyle races at the Junior European long-course championship were analysed. All heats, semi-finals, and finals across all freestyle distances (50 m to 1500 m) were included. Linear regression analyses were used to assess the relationship between overall race time and three independent variables: start performance, turn performance, and swimming velocity. Regression equations were used to develop the predictor software tool.

RESULTS: Start times showed the greatest effect on sprint distances, i.e. 50 m and 100 m. However, the effect diminished towards longer race distances. While swimming velocity had the largest effect on the race results across all distances for both junior and adult swimmers, the effect of turn times increased from 100 m to 400 m for both, junior and adult swimmers. Interestingly, the effect of turn times decreased again for 800 m and 1500 m races. Generally, there was a trend towards a greater effect of turn times in adult swimmers. The regression model explained 98-99% of the variance in race performance ($r^2 = 0.98-0.99$). Based on the regression equations a software tool (potential predictor) was created to allow coaches and federation officials to identify individual swimmers' potentials and create benchmarks for future development.

CONCLUSION: For both junior and adult swimmers, swimming velocity had the greatest effect on race results. While the effect of start performance decreased from short to long race distances, turn performances showed a U-shaped, hence largest effect on middle-distance races, i.e. 200 m and 400 m. The prediction tool that was developed from the regression model allows the prediction of individual performance progressions and rankings at international swimming competitions by combining isolated performance analysis with race analysis data.

ANAEROBIC SPEED RESERVE AND CRITICAL SPEED AS PREDICTORS OF 200 M FREESTYLE PERFORMANCE: A PRACTICAL ALTERNATIVE TO PHYSIOLOGICAL TESTING IN TRAINED SWIMMERSLANIGAN, B., BINNIE, M., PEELING, P., SCOTT, B., PEIFFER, J., WALL, B., TRIHY, E., MITCHELL, L., PYNE, D., GOODS, P.
MURDOCH UNIVERSITY

INTRODUCTION: The ability to predict performance potential in racing sport events lasting from ~1 to 3 min is complex due to a heavy reliance on both aerobic and anaerobic energy systems. In swimming, this is made more difficult by the practical inaccessibility presented by the aquatic nature of the sport, which interferes with the collection of physiological measures that are commonplace in sports more suited to laboratory testing. Anaerobic speed reserve (ASR) and critical speed (CS) are mathematical models which can be calculated based solely on performance data in both predominantly aerobic (providing an estimate of maximal aerobic speed: MAS) and predominantly anaerobic events (providing an estimate of maximal sprint speed: MSS). However this approach has received limited attention in swimming cohorts, and therefore, the aim of this research was to determine the association between ASR and CS with a mixed energy system performance (200 m freestyle) in trained swimmers. We further examined whether these associations could be strengthened with the addition of physiological markers of aerobic and anaerobic capacity.

METHODS: Trained male ($n=8$) and female ($n=9$) swimmers completed three maximal freestyle swims (50, 200, and 400 m) on separate days, with the 50 m (MSS) and 400 m (MAS) speeds used for the determination of ASR and CS. Arterial oxygen saturation, blood lactate concentration, peak oxygen consumption (VO_{2peak}), blood bicarbonate concentration, and blood pH were measured pre- and post-trial. Linear regression models were adopted to assess the best predictors of 200 m freestyle performance, with multivariate analysis of variance used to assess the impact of distance on all variables.

RESULTS: MSS was the strongest predictor of 200 m performance ($R^2 = 0.83$), followed by CS ($R^2 = 0.69$), whilst ASR could only provide moderate predictive capabilities ($R^2 = 0.36$). However, the addition of CS, ASR and ΔpH to MSS in our optimal

regression model accounted for 95% of variance in 200 m freestyle performance, decreasing mean absolute error from 2.41 s to 1.46 s. The removal of physiological data (ΔpH) from the model had only a trivial impact on predictive capabilities ($R^2 = 0.94$). There was a large and significant effect ($\eta^2 > 0.14$) of trial distance on all physiological and performance variables; however, post hoc analysis revealed no significant difference for VO_{2peak} .

CONCLUSION: In this investigation, MSS provided the strongest single predictor of 200 m freestyle performance, while the addition of ASR and CS substantially improved the model. Markers of aerobic and anaerobic capacity did not meaningfully improve the model. Modelling of ASR and CS provides a practical alternative to the collection of physiological variables in swimming cohorts for identifying performance potential in this mixed energy system event.

THE RELIABILITY AND SENSITIVITY OF A 25-M MAXIMAL SWIM TO ESTIMATE VLAMAX

BULTE, K., MITCHELL, L., HOFFMANN, S., SIEGEL, R., WARMINGTON, S.
DEAKIN UNIVERSITY

INTRODUCTION: The physiological assessment of swimmers has been widely examined, however there is no consensus on the best methodologies to assess fundamental physiological characteristics. For example, whilst it has been proposed that maximal blood lactate accumulation rate (VLamax) is a useful index of glycolytic power, literature investigating methodologies to estimate VLamax is limited. In swimming specifically, currently only four academic articles examine VLamax, each presenting their own novel methodology. Recently, it was found that a 25-m maximal swim effort presented the highest VLamax compared to 35 and 50-m distances (1). This finding aligns with the initial proposed duration of approximately 10-seconds of maximal effort for a VLamax estimation, and validates a 25-m distance for VLamax assessment in swimmers (1). The reliability and sensitivity to training of VLamax derived from the 25-m test however, has not been established.

METHODS: Nineteen state-to-national level swimmers completed a 25-m VLamax test on three consecutive mornings across three consecutive weeks. The first test of each week was conducted following 48-hours of rest to investigate reliability. The test was also conducted 12- and 36-hours post an anaerobic training set to determine the sensitivity of VLamax to anaerobic stimuli. On all occasions, resting blood lactate was measured immediately prior to entering the pool. Swimmers commenced from a push start and were asked to produce their fastest possible velocity across a 25-m distance. Blood lactate was measured 30-s post-test and then every minute until the concentration reached a plateau or decreased. VLamax was calculated as the difference between maximal and resting blood lactate concentrations, divided by the difference between the test duration and the duration during which it is assumed that lactate production has not yet begun (1). Reliability of VLamax was assessed by typical error (TE), coefficient of variation (CV) and intra-class correlation coefficients (ICC). Generalised linear mixed modelling was conducted to understand the sensitivity of VLamax to anaerobic training stimuli.

RESULTS: The VLamax TE was 0.072 mmol·L⁻¹·s⁻¹ (95% CI: 0.051-0.118 mmol·L⁻¹·s⁻¹) with a CV of 19.9% (95% CI: 14.8-30.2%) and ICC of 0.847 (95% CI: 0.609-0.936). VLamax was significantly reduced at 12- ($\beta = -0.216$, $p = 0.016$) and 36-hours ($\beta = -0.216$, $p = 0.014$) post anaerobic training compared to baseline.

CONCLUSION: VLamax derived from a 25-m maximal swim is sensitive to changes in glycolytic power within a training cycle. The reliability of the VLamax swim test is deemed 'good', however interpretations on anaerobic readiness within a training cycle or glycolytic power profile should be made with respect to the TE and CV. Future investigations into the magnitude of change in VLamax between different physiological profiles are encouraged.

OXIDATIVE AND O₂ DIFFUSIVE FUNCTION IN TRICEPS BRACHII OF SWIMMERS FROM RECREATIONAL TO WORLD CLASS LEVELS

VILLANOVA, S., PASTORIO, E., PILOTTO, A.M., MARCIANO, A., QUARESIMA, V., ADAMI, A., ROSSITER, H.B., CARDINALE, D.A., PORCELLI, S.
UNIVERSITY OF ROME "FORO ITALICO"

INTRODUCTION: Success in swimming is influenced by several physiological, morphological, neuromuscular, biomechanical and technical factors[1]. Although a small share of the energy during sprint events (50-100m) is provided through the oxidative system, swimmers specializing in this event combine power and endurance training with a greater training volume than other sprint sports[2]. Skeletal muscles engaged in swimming strokes (e.g., deltoid and triceps brachii) express high oxidative enzyme activity[3] and abundant capillaries[4]. However, swimmers incorporate heavy strength training or sprint drills with resistance tools in their weekly routine[5]. This can lead hypertrophy of type II muscle fibers, reducing capillary density and potentially impairing skeletal muscle O₂ diffusion[6]. The impact of these muscular adaptations on swimming performance at different competitive levels is unclear. This study aimed to evaluate oxidative and O₂ diffusive function measured by near-infrared spectroscopy (NIRS) of triceps brachii muscles of recreational to Olympic level swimmers and explore their relationships with swimming performance.

METHODS: Twenty-eight swimmers were enrolled and assigned into three groups according to their level: "Recreational/Trained" (Tier 1/2;n=8), "National" (Tier 3;n=12), and "International/World class" (Tier 4/5;n=8). Performance was evaluated by 100 metre freestyle trials. Training volume was measured by self-reported distance. The muscle O₂ consumption

(mVO₂) recovery rate constant (k) of m. triceps brachii was non-invasively estimated by NIRS (Train. Red Plus) through repeated intermittent occlusions under two conditions: well oxygenated (kHIGH) and low O₂ availability (kLOW). kHIGH is proportional to muscle oxidative capacity and the difference between kHIGH and kLOW (Δk) is proportional to the relative resistance to diffusive O₂ flux.

RESULTS: FINA points and 100m performance differed among groups. Training volume was greater in Tier 4/5 (34.0 ± 5.5 km/week) and Tier 3 (35.5 ± 11.6 km/week) than in Tier 1/2 (6.4 ± 1.8 km/week). kHIGH was greater in Tier 4/5 and Tier 3 (3.18 ± 0.41 and 2.79 ± 0.40 min⁻¹) vs. Tier 1/2 (2.10 ± 0.36 min⁻¹; all $p < 0.002$). kHIGH correlated with FINA points, 100m performance and training volume. Δk was not different among Tiers and not correlated with training volume or performance.

CONCLUSION: M. triceps brachii oxidative capacity was positively associated with performance and training volume in swimmers. However, Δk , which reflects the relative resistance to muscle O₂ diffusive flow, was not different from recreational to world class athletes. These data suggest that m. triceps brachii oxidative capacity is closely associated with swimming performance, and that capacity for O₂ diffusion is increased in approximate proportion to muscle oxidative capacity across swimmers ranging widely in ability.

SUPPORTING SELF-REGULATED LEARNING IN SPORTS SETTING: SWIMMING

LETNAR, B., KLOSTERMANN, A., SCHMIDT, M.

UNIVERSITY OF BERN

INTRODUCTION: The influence of various performance indicators – such as anthropometrical, physiological and biomechanical data – on freestyle swimming performance, has been a common focus in previous research on both elite and young athletes (Lätt et al., 2010; Nasirzade et al., 2015). Apart from such homogenous groups, performance improvement in freestyle swimming also represents a common goal in more heterogeneous groups, such as university students in sports programs, where research remains scarce. To bridge this gap and identify how student's skill acquisition can be best supported, despite their various physical characteristics and training backgrounds, our ongoing research aims to track student's learning process and identify key performance indicators influencing final outcomes in freestyle swimming performance.

METHODS: 77 students attending swimming lessons at University of Bern are participating in the study. Student's performance in 200m freestyle swimming (time and technique) is assessed at three time points during the semester using qualitative and quantitative assessments. Anthropometrical characteristics, psychological characteristics (motivation, mindset about self-regulated learning), theoretical subject knowledge and use of digital tools are monitored throughout the study to determine their correlation with and predictive value for students' swimming performance.

Special emphasis is placed on digital tools as a means of supporting students' learning. Students participating in the study have access to a multimedia database that offers differentiated motor learning support for independent use, learning diaries, and various theoretical and self-assessment resources. Engagement with these resources varies, as some are mandatory course components while others are optional and available at students' discretion. Throughout the study, we monitor students' engagement with non-mandatory digital materials as well as their progression in mandatory digital assignments.

RESULTS: Results of this study will allow us to assess both the effectiveness and utilization of digital resources in sports skill learning within tertiary education.

CONCLUSION: Findings of this study will furthermore help with the identification of key performance indicators in freestyle swimming lessons that extend beyond predisposed physical characteristics of the students, contributing to the knowledge in the field.

DOSE-RESPONSE RELATIONSHIP BETWEEN STATIC BALANCE AND SPATIO-TEMPORAL GAIT PARAMETERS IN SINGLE- AND DUAL-TASK CONDITIONS AMONG ADULTS AGED 40-79 YEARS

CHENGLONG, W., WANG, J., NIE, M., XIAO, C.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Gait performance is a critical indicator of physical function and activity of daily living in later life. Extensive research has established that gait parameters are strongly associated with falls, all-cause mortality and other adverse health outcomes. However, the relationship between balance and gait, particularly the dose-response relationship, remains unclear in middle-aged and older adults. Therefore, this study aims to investigate the association between static balance ability and spatio-temporal gait parameters during single-task and dual-task conditions among Chinese adults aged 40 to 79 years.

METHODS: This study involved 297 adults aged 40 to 79 years from Tongzhou District in Beijing and Taiyuan City in Shanxi Province. Static balance was assessed using a one-legged stance test with eyes closed (performed on either the left or right foot), measured by the duration participants could maintain the position. Spatio-temporal gait parameters, including step time, step length, gait speed and cadence, were collected using an accelerometer (Xsense Dot, Netherlands) under two conditions: single-task (walking 20 meters in a straight line on flat ground) and dual-task (walking while performing a random subtraction of three-digit numbers). Restricted cubic splines (RCS) were applied to explore potential dose-response relationships between static balance and gait performance.

RESULTS: The average age of the participants was 53.6 ± 11.0 years. Under the single-task condition, the step time was 0.48 ± 0.09 s, step length was 0.66 ± 0.11 m, gait speed was 1.12 ± 0.18 m/s, and cadence was 124.0 ± 17.7 counts/min. Under the dual-task condition, the step time was 0.49 ± 0.08 s, step length was 0.63 ± 0.09 m, gait speed was 1.03 ± 0.19 m/s, and cadence was 119.5 ± 16.9 counts/min. Significant differences were observed in gait parameters between single-task and dual-task conditions ($P < 0.05$). After adjusting for covariates, no significant linear trends were found between one-legged stance duration with eyes closed and any gait parameters under the single-task condition ($P > 0.05$). For the dual-task condition, linear regression analysis revealed that, compared to the lowest quartile of standing time (Q1) of standing time, there was a significant positive correlation between standing time in Q2 ($P = 0.039$) and Q3 ($P < 0.001$) with step time. Additionally, a positive association was observed between standing time in Q3 ($P = 0.027$) and step length. However, no significant linear relationship was found between standing duration and gait speed or cadence ($P > 0.05$). RCS analysis indicated a nonlinear relationship between one-legged stance duration and dual-task step time (P for nonlinear = 0.029). Specifically, a standing time of less than 12.4s was negatively correlated with step time, while a standing time greater than 12.4s was positively correlated with step time. This suggests that 12.4s may represent a minimum threshold for improved dual-task step time performance.

CONCLUSION: Static balance ability was associated with gait parameters under dual-task conditions in adults aged 40-79 years. A dose-response relationship was identified between one-legged standing duration and step time, particularly during dual-task conditions. To mitigate age-related declines in gait parameters, middle-aged and older adults should prioritize improving static balance ability, as it plays a critical role in maintaining walking capacity and overall mobility.

CLINICAL RELEVANCE OF AGE- AND SEX-SPECIFIC CHANGES IN ISOKINETIC TORQUE-VELOCITY PROFILES IN FRENCH OLDER ADULTS (65–99 YEARS)

DA SILVA, F., CHORIN, F., GUÉRIN, O., JAAFAR, A., PICHE, E., RENAUD, N., ZORY, R.

UNIVERSITÉ CÔTE D'AZUR - LAMHESS - CHU DE NICE / NÎMES UNIVERSITÉ - UPR APSY-V

INTRODUCTION: The use of force-velocity profiling to assess individual physical capacities has gained considerable interest in geriatric screenings over the past few years (e.g., Alcazar et al., 2023). Recent studies have applied this approach to knee extensor muscles using isokinetic devices (e.g., Piche et al., 2021). However, interpreting isokinetic torque-velocity profiles in older adults remains challenging due to the lack of reference values for key parameters (e.g., theoretical maximal torque [T0] and velocity [V0]). Moreover, the functional significance of these parameters is still unclear.

METHODS: A cross-sectional study was conducted on 959 French older adults (272 men, 687 women) aged 65–99 years. Relative knee extensor peak torque was measured at six isokinetic angular velocities (30°/s, 60°/s, 90°/s, 120°/s, 150°/s, 180°/s). Absolute torque data were expressed relative to participants' body mass, allowing for the identification of isokinetic torque-velocity profiles and extraction of key parameters (e.g., T0, V0). In addition, comfortable walking speed was assessed using a 10m OptoGait walkway, and frailty status was determined.

Participants were stratified by sex and age in 5-year increments, except for the 90–100 age group. Age-related differences in isokinetic parameters were analyzed using one-way ANOVAs separately for men and women. Furthermore, Pearson correlations were performed between walking speed and parameters derived from isokinetic torque-velocity profiles to explore their functional relevance.

RESULTS: Statistical analyses revealed a progressive $\approx 50\%$ decline in absolute and relative isokinetic torque values in both men and women, starting at 75 years of age. Normalizing torque to body mass reduced disparities between adjacent age groups. While force-related parameters (e.g., T0) showed a significant decline with age, velocity-related parameters (e.g., V0) remained statistically unchanged. Thus, aging, irrespective of sex, altered the force-velocity profile by flattening its shape and reducing force-related values. Additionally, moderate but significant correlations were found between comfortable gait speed and force-related derived from torque-velocity profiles.

CONCLUSION: This study provides updated sex- and age-specific reference values for key isokinetic knee extensor torque-velocity parameters in older adults. Our findings suggest that force-related parameters derived from isokinetic torque-velocity profiles are functionally relevant, whereas velocity-derived parameters might not correspond to physiological indices.

ACCELEROMETER-DETERMINED PHYSICAL ACTIVITY, SARCOPENIA AND SARCOPENIC OBESITY IN COMMUNITY-DWELLING OLDER ADULTS

WIEDMAIER, J., DUARTE, M., PINTOS-CARRILLO, S., RODRÍGUEZ-ARTALEJO, F., ORTOLÁ, R., SOTOS-PIETO, M., CABANAS-SÁNCHEZ, V., MARTÍNEZ-GÓMEZ, D.

AUTONOMOUS UNIVERSITY OF MADRID

INTRODUCTION: Sarcopenia (i.e., the age-related muscle mass and muscle strength loss) can lead to disabling consequences in older adults [5] as well as sarcopenic obesity (i.e., when increased adipose tissue accompanies sarcopenia) that is considered a strong and independent risk factor for frailty, diverse comorbidities and mortality [2, 3]. Evidence suggests that exercise reduces body fat and improve muscle strength and mass in older people in community dwelling settings [1]; however, it is not completely clear if daily physical activity (PA) is beneficial enough to prevent sarcopenia and sarcopenic obesity in this population [4]. The aim of this study was to analyse the cross-sectional associations of daily accelerometer-measured PA with sarcopenia, sarcopenic obesity and their components in older adults.

METHODS: We analysed data from 2628 older adults (65-94 years) from the Seniors-ENRICA-2 cohort study collected from 2015 to 2017. Participants wore the Actigraph GT9X Link accelerometer on their non-dominant wrist for seven consecutive days, removing it only for water-based activities. The average daily acceleration and steps were used as reliable proxies of daily PA. Muscle strength was evaluated using a hand grip dynamometer (HGS) and the sit-to-stand test (StoS). Fat mass (FM%) and skeletal muscle mass adjusted by height (SMM/height) and weight (SMM/weight) to characterize sarcopenia and sarcopenic obesity respectively, were estimated by bioelectrical impedance analysis. Sarcopenia and sarcopenic obesity were treated as continuous variables, standardized to Z-scores. Associations between the study variables were examined using linear regression models adjusted for main covariates.

RESULTS: Daily acceleration in mg and a 1000-step increase showed an inverse association with StoS (s) [unstandardized β (95%CI): -0.05 (-0.07, -0.03) and -0.08 (-0.11, -0.04) respectively]. Inverse associations were observed between daily acceleration and FM% [unstandardized β (95%CI) -0.04 (-0.08, -0.00)] and between daily steps and SMM/height (kg/m²) [unstandardized β (95%CI) -0.03 (-0.06, -0.01)]. No significant associations were observed between PA and HGS, SMM/weight or the sarcopenia and sarcopenic obesity scores.

CONCLUSION: Daily PA, as assessed by accelerometer, was directly associated with muscle strength and inversely with fat mass in older adults. Although PA does not seem to be directly related to sarcopenia and sarcopenic obesity in this population, it is related to some of their components.

EXERCISE INTERVENTION ALLEVIATES SARCOPENIA THROUGH OPTIMIZING FUNCTIONAL STATUS OF AUTOPHAGY MEDIATED BY THE MIR-34A/SIRT1/FOXO3A SIGNALING AXIS

CHEN, N.

WUHAN SPORTS UNIVERSITY

INTRODUCTION: Sarcopenia significantly compromises the health and quality of life of elderly individuals, while exercise intervention is recognized as an effective approach for the prevention, therapy and rehabilitation of sarcopenia. However, the precision molecular mechanisms for the rehabilitation of sarcopenia upon exercise intervention remain unclear.

METHODS: In the present study, aging population and 24-month-old naturally aging mice subjected to exercise intervention were utilized to systematically explore the role and molecular mechanisms of miR-34a-mediated functional status autophagy in mitigating sarcopenia through RNA-Seq and microRNA screening. Histological analysis, RT-PCR and Western blot were conducted to evaluate atrophic rate of skeletal muscle and corresponding signal pathways associated with

sarcopenia. Moreover, the skeletal muscle-specific miR-34a gene knockout and Atg7 gene knockout mouse models were used to validate the determinant role of miR-34a-mediated functional status of autophagy for sarcopenia upon exercise intervention.

RESULTS: Exercise intervention can effectively delay atrophy of skeletal muscle from both elderly individuals and aged mice, and improve their movement capacity, as shown in the suppression of declined cross-sectional area and strength of skeletal muscle. Meanwhile, miRNA screening revealed miR-34a as the critical miRNA and its corresponding hub gene Sirt1. Moreover, the skeletal muscle-specific miR-34a gene knockout mice revealed similar atrophic rate with the normal mice subjected to exercise intervention, when compared with aged mice with obvious skeletal muscle atrophy without exercise intervention, suggesting that miR-34a suppression exhibited exercise mimetic function. Furthermore, the skeletal muscle-specific Atg7 gene knockout mice upon exercise intervention resulted in the aggravation of skeletal muscle atrophy, suggesting that the functional status of autophagy is the determinant role in aging-induced atrophy of skeletal muscle.

CONCLUSION: Exercise intervention can delay sarcopenia through rescuing aging-induced abnormal miR-34a-mediated autophagy functional status of autophagy. The suppression of miR-34a has the potential to be exercise mimetics. This study may provide a novel research idea and direction for precision and targeted prediction, diagnosis, treatment, and rehabilitation of sarcopenia; evaluation and monitoring of exercise interventions for sarcopenia; the design of precision and targeted interventional strategies for sarcopenia; as well as the development of exercise mimetics for sarcopenia. Furthermore, this study also provides a reference for precision and targeted research on active health strategies or the development of exercise mimetics to cope other chronic diseases in the future.

HANDGRIP STRENGTH HAS DECLINED AMONG PEOPLE FROM MACAO SPECIAL ADMINISTRATIVE REGION: A TEMPORAL TREND ANALYSIS FROM 2001 TO 2020

CHOI, S., TOMKINSON, G., LANG, J., CADENAS-SANCHEZ, C., DONG, H., LEI, S., POON, E.
UNIVERSITY MACAU

INTRODUCTION: Handgrip strength is a key indicator of overall muscular strength and health, with strong associations with morbidity and mortality (1, 2). While global trends in handgrip strength have been extensively studied, limited research exists on temporal trends within specific populations, particularly in Asian regions. This study examined temporal trends in handgrip strength among individual aged 6 to 69 years in the Macao Special Administrative Region between 2001 and 2020.

METHODS: Repeated cross-sectional data were obtained from a nationally representative sample of 41,685 participants (48% male, 52% female) across five survey years: 2001, 2005, 2010, 2015, and 2020. Temporal trends in means were analysed using general linear models, adjusted for sex, age, height, and weight. Trends in distributional characteristics were described visually and quantified as the ratio of coefficients of variation.

RESULTS: Over the 20-year period, handgrip strength declined significantly by 4.5 kg [effect size (ES) = -0.82], with males (6.0 kg; ES = -0.91) experiencing a larger decline than females (2.2 kg; ES = -0.49). The greatest declines were observed in children (ES = -0.20), adolescents (ES = -0.55), and young adults (ES = -0.52). Middle-aged adults showed a small improvement (ES = 0.20), while older adults displayed no significant change. Trends in distributional characteristics were negligible.

CONCLUSION: The findings highlight a concerning decline in muscular strength among Macao residents, particularly the younger demographic. These trends are concerning for population health, as low handgrip strength is linked to chronic diseases and mortality. Continuous surveillance and interventions are essential to enhance muscular strength and public health.

OP-AP40 Mixed Session - From Powerlifting to HRV

OPTIMIZING POWERLIFTING PERFORMANCE THROUGH CONTEXTUAL INTERFERENCE TASK CHOICE

MONTENEGRO, S., PRESTANTI, I., SERAFINI, S., IZZICUPO, P., SARTOR, F.
UNIVERSITY OF CHIETI; UNIVERSITY OF VERONA

INTRODUCTION: Contextual interference (CI) refers to the alteration of a training pattern structure by disrupting practice continuum throughout unrelated tasks (1). The interference effect has been shown to enhance motor skill learning by challenging the ability to integrate various motor patterns. A previous study in powerlifters found that the CI group had a greater improvement in 1RM execution technique than control (2). However, in that study CI was generated by dart-

throwing, and the authors explained that using such unrelated task could have been a limit of their CI intervention. For this reason, we decided to address this concern and use a distinct yet pertinent CI secondary task. Our hypothesis was that high CI training would further improve technical execution.

METHODS: Fifteen amateur powerlifters were randomly assigned into two groups (high and low CI) for a six-week powerlifting training program, using the seal row exercise between bench press sets to create interference. Performance was tested as 1RM bench press and max velocity lift (MVL) at baseline (t0 by 1RM test), week two (t1 by MVL), week four (t2 by MVL), week six (t3 by MVL) and week eight (t4 by MVL). Technical execution was evaluated at the same timepoint by means of 13 technical items Likert Scale (used in powerlifting competition).

RESULTS: Two-way repeated measure (TWRM) ANOVA was performed to test whether CI affected two groups' strength at a different rate over time. There was no group x time interaction ($F(3.48, 45.28) = [1.407]$, $p = 0.250$), nor main effect of group in strength capacity ($F(1,13) = [0.057]$, $p = 0.816$), but a statistically significant main effect of time ($F(3.48, 45.28) = [9.397]$, $p < 0.001$). Wilcoxon Test with Bonferroni corrections showed significant comparisons respectively at: t0 – t3 ($p = 0.025$), t0- t4 ($p = 0.047$), t1-t3 ($p = 0.015$), t1-t4 ($p = 0.035$). Technical execution was also tested using TWRM ANOVA. Global technique entailed analyzing all 13 items and resulted in a main effect of time ($F(64.832) = [3.045]$, $p < 0.001$), with no interaction nor main effect of group. Whereas an item-by-item analysis showed: an effect of group ($F(1,13) = [4.675]$, $p = 0.050$) for item 1 (dorsal arch); an interaction group x time ($F(2.98, 38.76) = [4.118]$, $p = 0.013$) for item 2 (scapula adduction).

CONCLUSION: Both groups of powerlifters significantly improved their strength. However, our more pertinent CI task did not induce a greater strength improvement. Our CI task did show some effects on bench-press technical execution, in particular scapula adduction. Further studies should focus on the appropriate choice of CI tasks.

DELAYED RECOVERY OF LINEAR AND NON-LINEAR HEART RATE VARIABILITY METRICS AFTER VIGOROUS INTENSITY EXERCISE: A CROSS-SECTIONAL RANDOMIZED CROSS-OVER STUDY

GRONWALD, T., KOCK, H.2, RÖGLIN, L.3, MÖHLE, M.3, KIRCHER, E.4, HOOS, O.5, KETELHUT, S.6

1 MSH MEDICAL SCHOOL HAMBURG, 2 INSTITUTE FOR APPLIED TRAINING SCIENCE, 3 MARTIN LUTHER UNIVERSITY HALLE-WITTENBERG, 4 SRH BERLIN, 5 JULIUS-MAXIMILIANS-UNIVERSITY WUERZBURG, 6 UNIVERSITY OF BERN

INTRODUCTION: The present study explored acute responses of heart rate (HR) variability (HRV) metrics and selected hemodynamic parameters during the recovery phase following two exercise bouts of different intensity. The main focus was to advance current research by incorporating the non-linear index alpha 1 of detrended fluctuation analysis (DFAa1), providing additional qualitative information about autonomic nervous system regulation and reorganization during passive recovery.

METHODS: Recreationally active female (n=13) and male (n=13) participants (age: 24.8 ± 4.0 years, body mass: 68.3 ± 10.8 kg, height: 171.2 ± 9.6 cm, habitual physical activity: 7.3 ± 3.5 h/week) were included in the study. In a first session a graded exercise test was conducted to determine peak HR (HRPEAK) and peak oxygen consumption (VO2PEAK) for exercise intensity prescription. In a second and third session, participants completed an endurance training with moderate intensity (MOD) on a treadmill and an exergaming training with vigorous intensity (VIG) in a randomized and counterbalanced order. Before and up to 45 minutes after the respective exercise sessions, RR-interval and hemodynamic measurements (peripheral systolic, SBP; diastolic blood pressure, DBP; pulse wave velocity, PWV) were conducted (supine body position). Blood lactate concentration (BLC) was measured before and immediately after the exercise bouts.

RESULTS: Internal load analysis of MOD vs. VIG revealed significant differences and appropriate prescription of intensity domains for mean %HRPEAK (~66% vs 86%), %VO2PEAK (~48% vs. 66%), as well as for blood lactate concentration (~1 mmol/l vs. 5 mmol/l). The present data showed significant main effects of time, intensity, and their interaction for all RR-interval outcomes, PWV, and SBP. Higher exercise intensity resulted in greater perturbations during recovery, delayed reorganization, and decreased values of linear HRV metrics. DFAa1 demonstrated a stronger correlated reorganization and overcompensation after VIG, with higher values throughout the evaluated recovery process.

CONCLUSION: The present data suggests that VIG transiently delays the recovery of cardiac parasympathetic activity and the normalization of correlation properties of HR time series. Regarding acute early and delayed recovery processes, higher correlation properties may reflect more order (less complexity) and interaction of involved physiological subsystems, supporting the assumption of increased systemic control to process the demands of higher exercise intensity. The assessment of standardized post-exercise (e.g., submaximal test procedures, benchmark workouts) linear and non-linear HRV metrics could serve as a valuable tool for fine-tuning monitoring processes in endurance athletes. By evaluating recovery states, acute fatigue, and overreaching phenomena it can complement resting physiology analysis. This could potentially help to guide structuring micro-cycle programming tailored to individual cardiac reactivation patterns.

ASSOCIATION BETWEEN INCREMENTAL AND SUPRAMAXIMAL TEST PERFORMANCE

MURASAKI, J., CONCEIÇÃO-SANTOS, D.F., DA COSTA, L.R., SAUNDERS, B.
UNIVERSITY OF SÃO PAULO

INTRODUCTION: Incremental tests to determine maximal power output and maximal oxygen uptake ($\text{VO}_{2\text{max}}$) are often conducted as a prior parameter to determine resistance parameters for subsequent submaximal, maximal and supra-maximal exercise tests. Incremental tests rely heavily on aerobic metabolism while supramaximal tests rely heavily on anaerobic metabolism [1,2]. Since oxidative capacity is associated with a predominance of slow-twitch muscle fibers, this may suggest that anaerobic capacity in those with high oxidative capacity might be reduced compared to those with lower aerobic capacity. This study aimed to determine the association between incremental and supramaximal exercise capacity.

METHODS: Seventy-one physically active males (age 26 ± 5 y, body mass 77.9 ± 11.2 kg) performed an incremental cycling test to determine Powermax (W_{max}) prior to a familiarization and main visit to perform a cycling capacity test at 110% of W_{max} (CCT110%). All cycling was performed on a cycle ergometer (Lode Excalibur, The Netherlands). The incremental test started at a power output of 100 W and increased by 6 W until exhaustion. The last completed stage plus the fraction of time spent in the final non-completed stage multiplied by 6 W was defined as a participant's W_{max} . The CCT110% started with a 10-min warm-up at 100 W, followed by 15 s at 80% of individual W_{max} , 15 s at 95% W_{max} followed by 110% W_{max} until exhaustion. Time to exhaustion (TTE) and total work done (TWD) were recorded as the outcome measures. Pearson correlations were performed to evaluate the correlations between W_{max} (absolute [a W_{max}] and relative [r W_{max}] to body mass) and CCT110% performance (TTE and the TWD). The significance level was set at $p < 0.05$.

RESULTS: There was a positive association between r W_{max} and TWD ($r = 0.290$: $0.06 < 95\% \text{CI} < 0.49$; $p = 0.014$), and between a W_{max} and TWD ($r = 0.734$: $0.60 < 95\% \text{CI} < 0.82$; $p < 0.001$) indicating that a higher W_{max} is associated with a greater TWD. However, no significant correlation was found between r W_{max} and TTE ($r = -0.076$: $-0.30 < 95\% \text{CI} < 0.16$; $p = 0.529$), and between a W_{max} and TTE ($r = 0.220$: $-0.01 < 95\% \text{CI} < 0.43$; $p = 0.065$).

CONCLUSION: These data highlight a significant relationship between W_{max} and TWD during the CCT110%. This is likely a reflection of the higher power output during the test. However, the absence of a correlation between W_{max} and TTE suggests that an individual's ability to sustain effort at 110% W_{max} is not reflective of their incremental test performance and challenges the notion that a higher oxidative capacity is inherently linked to reduced anaerobic performance. Future studies should investigate additional metabolic and neuromuscular factors influencing performance at supramaximal intensities.

EXPLORING INTER-LIMB ASYMMETRIES RELATIONSHIPS USING ISOKINETIC, JUMP AND CHANGE OF DIRECTION TESTS

DONGHI, F., FRIGERIO, M., BOSIO, A., SCALISE, G., POLLINI, M., MARTIN, M., RAMPININI, E.
MAPEI SPORT RESEARCH CENTRE

INTRODUCTION: Inter-limb isokinetic (ISOK) strength asymmetries (ASYM) are commonly used to monitor return to sport process and to prescribe specific training interventions, since ASYM has been suggested to be a risk factor for non-contact related injuries (1). Furthermore, ASYM can also be measured in a more sport specific task, characterized by closed-chain movements and fast muscle action with stretch-shortening cycle such as vertical jump (CMJ). However, little is known about the relationships between ISOK and CMJ ASYM with imbalances measured using a repeated CODs test with different degrees of ASYM in evoked knee extension (KE) strength.

METHODS: A total of 464 young (age: 17 ± 1 yrs; weight: 74 ± 6 kg; height: 180 ± 5 cm) and 563 adult professional soccer players (age: 25 ± 5 yrs; weight: 78 ± 6 kg; height: 182 ± 6 cm) were involved in the analysis that included 3216 observations of both CMJ and CODs and 177 observations of ISOK. ISOK KE strength ASYM were evaluated at $60^\circ/\text{s}$ and $240^\circ/\text{s}$, while peak force (PF) ASYM was retained for CMJ. In the CODs test, four intensity levels of continuous shuttle-run over 8m, lasting approximately 30-s each, were performed. Immediately after each level, right and left KE were electrically stimulated in resting isometric conditions to evoke a twitch response, from which peak twitch (PT) torque after the first (PT1) and fourth (PT4) levels as well as the highest absolute PT value (PTmax) were recorded for both sides to evaluate ASYM. All the ASYM were calculated as (stronger-weaker)/stronger*100, with positive (+) or negative sign (-) arbitrarily assigned to indicate respectively when right side or left side were stronger.

Linear Mixed Models were used to investigate the relationships between ISOK and CMJ ASYM with ASYM measured during CODs test. Effect Size was reported as Cohen's d. Significance was set at $p < 0.05$.

RESULTS: No significant correlations were found between ASYM in ISOK and CODs both at $60^\circ/\text{s}$ (PT1: $p = 0.985$; $d < 0.01$; PTmax: $p = 0.560$; $d = -0.06$; PT4: $p = 0.223$; $d = -0.13$), and $240^\circ/\text{s}$ (PT1: $p = 0.886$; $d = 0.02$; PTmax: $p = 0.237$; $d = -0.13$; PT4: $p = 0.069$; $d = -0.19$). No significant correlation was found between ASYM in CMJ and CODs at PT1 ($p = 0.837$; $d = 0.01$), while trivial negative correlations were found between ASYM in CMJ and CODs at PTmax ($p = 0.001$; $d = -0.08$) and PT4 ($p = 0.002$; $d = -0.08$).

CONCLUSION: As previously reported in literature (2), the lack of association in the ASYM measured in different tests confirmed the independent nature of imbalances quantified in specific tasks. Namely, the differences might be explained using open vs closed-chain movements, concentric only vs stretch-shortening cycle, low vs high speed motion and simple vs complex multiplanar exercise. Although weak, the inverse relationship between ASYM in the CMJ and CODs suggest a higher level of fatigue of the CMJ's stronger limb during CODs. This may be due to a higher degree of involvement during the CODs. In conclusion, practitioners are encouraged to use multiple tests to detect existing ASYM.

AN EVALUATION OF THE ACUTE EFFECTS OF DIFFERENT TRAINING LOADS ON NIGHTTIME SLEEP PATTERNS AND AUTONOMIC NERVOUS ACTIVITY IN MILITARY PERSONNEL

LI, Q., LIU, H.C., NEVILL, A.M., DOHERTY, R., MADIGAN, S., HUANG, S., XING, H., HONG, Y., HE, J., BAO, D., LIU, H.Y., WARRINGTON, G.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Sleep is the primary means for the body to recover from fatigue associated with physical training. Insufficient sleep not only impacts the effectiveness of training adaptation but also increases the risk of training injuries and more severe issues such as cardiovascular disease, metabolic disorders, and impaired immune function. Although evidence exists that individuals who regularly engage in high-intensity training often suffer from sleep problems, a definitive causal relationship between training load and insufficient sleep has yet to be established. The aim of this study is to investigate the impact of low, medium, and high training loads on sleep patterns and autonomic nervous activity in military personnel.

METHODS: Sixty healthy, trained military personnel were recruited, all of whom had no significant sleep disorders in the past six months (PSQI ≤ 5 points). Participants followed a fixed daily routine throughout the study period. This study monitored training load over 12 consecutive days. Training days were categorized into three groups based on the intensity of training load: Low ($<50\%$ HRmax); Medium (50-70% HRmax); High ($>70\%$ HRmax). During the training period, daily training loads were monitored using the Firstbeat SPORTS system and session-RPE, recorded using a modified CR-10 scale, after each training session. These values were used for subsequent classification of the participants into different training load groups. Participants were required to wear the GT3X+ accelerometer and the Firstbeat Bodyguard 2 chest strap to monitor their sleep patterns and autonomic nervous system activity during sleep. The sleep patterns and autonomic nervous system activity were then compared between the groups based on the collected data. Data were presented as mean $\pm$ standard deviation (Mean $\pm$ SD). One-way ANOVA was used to analyze basic participant characteristics and sleep-related indicators. A two-way ANOVA with repeated measures was employed to analyze session-RPE data.

RESULTS: Time in Bed was found to be significantly increased on high training load days when compared to medium training days ($P = 0.002$). When compared to low training load days, Sleep Efficiency significantly decreased after medium and high training load days, with Total Wake After Sleep Onset and the Low/High Frequency ratio significantly increasing ($P < 0.001$; $P = 0.002$).

CONCLUSION: The findings of this study suggest that high training loads might cause individuals to prepare for sleep earlier on the night of training, as indicated by an increase in TIB. Medium and high training loads before sleeping disrupted sleep continuity and increased sleep fragmentation. Future should investigate the potential mechanisms through which training loads influence sympathetic nervous activity and physiological stress, to better understand the biological pathways involved.

IMMUNOLOGICAL CHANGES IN THE CIRCULATION OF CANCER PATIENTS IN RESPONSE TO 10- AND 30-MINUTE ACUTE EXERCISE

KOIVULA, T., NORHA, J., HOLLMÉN, M., JUHANOJA, E., SUNDBERG, C.J., MINN, H., RUNDQVIST, H., RINNE, P., HEINONEN, I.
UNIVERSITY OF TURKU

INTRODUCTION: Exercise has many systemic effects. Epidemiological studies suggest that exercise can improve the prognosis of cancer patients, but the mechanisms are largely unknown. In animal models, exercise has been shown to slow tumor growth by enhancing the immunological response to tumors. The aim of this study was to investigate the effects of acute exercise on circulating immune cell and cytokine levels in humans with newly diagnosed lymphoma or breast cancer.

METHODS: Participants were 15 lymphoma patients (mean (SD) age 59 (17) years) and 29 breast cancer patients (57 (10) years) who had not yet started their cancer treatments. The patients performed either a 10-minute or a 30-minute exercise bout on a bicycle ergometer. Venous blood samples were drawn before, during, and 30 minutes after the exercise to analyze immune cell mobilization and cancer-specific cytokines.

RESULTS: Acute exercise increased the number of circulating neutrophils, lymphocytes, monocytes, eosinophils, basophils, CD4+ T cells, T helper (Th) 1 cells, Th2 cells, Th17 cells, regulatory T cells, CD8+ T cells, CD4-CD8- T cells, CD19+ B cells, and

CD56+ natural killer (NK) cells. The mobilization of the immune cells was similar in lymphoma patients during the 10- and 30-minute exercises. In breast cancer patients, the mobilization of CD4+ T cells and NK cells was greater during the 30-minute exercise compared the 10-minute exercise, but other cells mobilized similarly during the exercises. The level of IP-10 increased during exercises in both lymphoma and breast cancer patients. Further, the level of Eotaxin, IL-1 β , IL-13, and MIP-1 α increased during the exercises and the level of MIP-1 β , PDGF-BB, and TNF- α decreased 30 minutes after the exercises in breast cancer patients. The levels of Eotaxin and IP-10 increased more during the 30-minute exercise compared to 10-minute exercise in breast cancer patients.

CONCLUSION: Acute exercise stimulates the mobilization of anti-tumoral and pro-tumoral immune cells, which is fairly similar during and after 10- and 30-minute exercises. Further studies on the effects of exercise on the tumor microenvironment and tumor growth are needed in humans.

ARE TRAINING VOLUME AND HEART RATE VARIABILITY INJURY RISK FACTORS AMONG CROSSFIT ATHLETES IN SOUTH AFRICA?

CHRISTIE, C., SKAE, K., PIENAAR, L., MACMILLAN, C.
RHODES UNIVERSITY

INTRODUCTION: Reported CrossFit injury rates are high; however, there is a paucity of research on injury risk factors. This study investigated if training volume (TV) and heart rate variability (HRV) are injury risk factors among CrossFit athletes.

METHODS: This observational longitudinal study included 33 non-elite CrossFit athletes who completed weekly online injury surveys and daily TV. Training volume was calculated as session duration multiplied by the rating of perceived exertion (sRPE) and expressed in arbitrary units (AU). The A:C ratio "safe zone" was set at (0.8-1.3 AU). Acute (total TV over seven days) and chronic (three-week rolling average of the acute TV) TV ratios (A:C ratios) were also calculated. Heart rate variability was assessed using the "HRV4Training" mobile application. Injuries were surveyed using the Oslo Sports Trauma Research Centre (OSTRC) Overuse Injury Questionnaire, adapted to collect data on acute injuries.

RESULTS: Mean weekly TV was 1299 ± 675.4 AU, session duration 55.2 ± 32.4 minutes and sRPE 7.4/10. Of the 33 participants, 65.6% of A:C TV was outside the "safe zone." Thirteen participants (40.9%) sustained injuries and 51 injuries were reported, of which 69% were overuse and 31% acute injuries. The shoulder and ankle were the most common sites of acute and overuse injuries. In the univariate model, TV and HRV were not associated with injury risk. Injury rates were higher among participants aged ≥ 51 years, males, commitment levels four to five (medium), and training two to three times per week. Non-competing CrossFit Open participants had a higher overall injury count with a more significant percentage of injuries than competing participants. Injury probability increased from 11% in week one to 31% in week 16, peaking in those with two years of training experience.

CONCLUSION: Training volume (A:C ratios) and HRV were not associated with injury risk. Injury rates were higher among males, participants older than 51 years, with medium training commitment, medium to high frequency of training, and less experience. Although TV and HRV were not identified as individual injury risk factors, they might be related to an increased risk of injury when considered with other variables. Future studies with larger sample sizes should investigate these variables using a multivariate model.

REALLOCATION OF TIME BETWEEN DEVICE-MEASURED 24-HOUR MOVEMENT BEHAVIOURS AND INCIDENCE OF HIP AND KNEE OSTEOARTHRITIS

MURA, M., PORTUGAL, B., MOUTON, C., SEIL, R., MALISOUX, L.
LUXEMBOURG INSTITUTE OF HEALTH

INTRODUCTION: Osteoarthritis is the second most prevalent musculoskeletal disorder and mostly affects hip and knee joints. Hip and knee osteoarthritis (HKO) age-standardized prevalence is 3,867 per 100,000 inhabitants in Western Europe. In absence of a curative treatment for HKO, literature supports that physical activity is one of the major treatment option to reduce pain and increase physical function in these patients. In addition, sedentary behaviour was associated with poor health outcomes, including osteoarthritis. Yet, previous studies that investigated physical activity and sedentary behaviour consequences in this population were based on questionnaires, which are sensitive to recall bias and do not capture the full movement behaviours spectrum. Indeed, these studies did not take into account sleep time nor the compositional nature of movement behaviours. This prospective study aims to investigate the association between objective device-measured movement behaviour and HKO incidence in participants from the UK Biobank cohort, while addressing the compositional nature of movement behaviours.

METHODS: Data from the UK Biobank cohort were used, which included individuals from England, Scotland and Wales registered in the National Health Service and aged 40-69 years old. Incident HKO cases were ascertained on hospital inpatient data. Movement behaviour was measured with a wrist-worn triaxial accelerometer used during 7 days. Raw data was processed with the GGIR R-package in order to classify the time spend in different movement behaviours, such as sleep, sedentary behaviour, light physical activity (LIPA) and moderate to vigorous physical activity (MVPA). Compositional cox proportional hazard models with age as the time scale and adjusted for sex were used to investigate how reallocating time from one movement behaviour to another (one-to-one reallocation) was associated with HKO incidence.

RESULTS: In total, 90,028 participants without KHOA diagnosis in 2013-2015 were included. During a mean follow-up of 8 years, 5,641 participants developed HKOA. Results showed that reallocating 30min/day to MVPA from sedentary behaviour (HR=0.95, 95%CI=0.94-0.96) or LIPA (HR=0.91, 95%CI=0.89-0.93) was associated with lower HKOA incidence. In addition, reallocating 30min/day to sleep from sedentary behaviour (HR=0.96, 95%CI=0.95-0.97) or LIPA (HR=0.92, 95%CI=0.90-0.93) was also associated with lower HKOA incidence.

CONCLUSION: This is the first study using objective measures of physical activity to provide evidence that moderate-to-vigorous physical activity plays a role in HKOA prevention, while accounting for the other movement behaviours. Our results also highlight that increasing sleep duration may help prevent HKOA. This study warrants further studies to elucidate the mechanisms underlying these associations.

HIGH RISK OF LOW ENERGY AVAILABILITY, EATING DISORDERS AND EXERCISE ADDICTION AMONG PERSONAL TRAINERS IN NORWAY.

RUSTADEN, A., TORSTVEIT, M.K.

INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Personal trainers (PTs) work in an environment where body pressure and striving for well-trained bodies are commonly experienced. Previous research indicates a high prevalence of disordered eating behaviors and exercise addiction (ExAdd) among fitness instructors, but less is known among PTs. PTs are often engaged in extensive exercise and dietary regimens which, intentionally or unintentionally, may increase their risk of low energy availability (LEA), eating disorders (EDs) and ExAdd. These behaviors may all lead to a range of negative health consequences, in addition to reduced physical and mental performance.

Thus, the purposes of this study were firstly to investigate the risk of LEA, EDs and ExAdd among PTs in Norway, and secondly investigate possible associations between the risk of LEA, EDs, and ExAdd in the same sample.

METHODS: In this cross-sectional study, n=49 Norwegian PTs answered a digital questionnaire. Risk of LEA was assessed using the LEA in Females Questionnaire (LEAF-Q) for females and the LEA in Males Questionnaire (LEAM-Q) for males. Risk of EDs was assessed using the Eating Disorder Examination Questionnaire (EDE-Q) and risk of ExAdd using the Exercise Addiction Inventory (EAI).

RESULTS: Totally, 28 females and 21 males (mean age 34.4 ± 9.9 years, mean hours weekly exercise 5.8 ± 3.5) were included. As much as 40.8% of the participants had increased risk of LEA, 50.0% of the females and 28.6% of the males ($p > 0.05$). Increased risk of EDs was found among 16.3% of the participants, 21.4% of the females and 9.5% of the males ($p = 0.041$). Increased risk of ExAdd was found at 14.2% of the participants, 17.8% of the females and 9.5% of the males ($p < 1.00$). A low association between the risk of LEA and EDs was found among the females ($r = 0.467$, $p = 0.012$), but not among the males ($r = 0.381$; $p = 0.088$), or the total sample combined ($r = 1.86$; $p = 0.173$). Moderate associations were found between EDs and ExAdd among the females ($r = 0.457$; $p = 0.015$) and the total sample (0.385 , $p = 0.006$), but not among the males (0.337 , $p = 0.135$).

CONCLUSION: This is the first known study investigating LEA, EDs and ExAdd among personal trainers, and our findings indicate that a significant proportion of PTs in Norway are at risk for all three conditions, especially female PTs. Furthermore, the study suggests an association between the risk of LEA and EDs, as well as between EDs and ExAdd among female PTs. Future research including higher sample sizes and objective measures is warranted.

MOST COMMON INJURY AMONG A FOOTBALL REFEREE COHORT IN FRIULI VENEZIA GIULIA: A CROSS-SECTIONAL STUDY

SABOT, R., BUOITE STELLA, A., DEODATO, M., TONONI, M., CANTON, G., MURENA, L.

UNIVERSITY OF TRIESTE

INTRODUCTION: While extensive research exists on injuries in soccer players, limited data is available on injury patterns and management in soccer referees. They may experience distinct injury profiles, with a higher prevalence of overuse injuries compared to players (1, 2, 3). This study aimed to investigate (i) injury incidence, (ii) characteristics and (iii) physiotherapy utilization among Italian football referees.

METHODS: A cross-sectional design study was conducted to investigate injury patterns and management among football referees in the Friuli Venezia-Giulia region, Italy. Data were collected from August 2023 to June 2024 via an online questionnaire administered to referees from various playing levels. Inclusion criteria included refereeing within the region and a minimum of 3 years of refereeing experience. The questionnaire assessed training habits, injury history, treatment modalities and risk factors. Data were collected at three time points: early (Sep-Oct), mid (Jan-Feb), and late season (May-Jun).

RESULTS: This study investigated injury incidence and management in 235 Italian football referees (22 ± 7 years, 88.1% were male) during the 2023-2024 season. An injury incidence of 14.1 per 1000 total hours and 15.9 per 1000 hours of play were observed, with a higher incidence early in the season. Lower limb musculoskeletal injuries, particularly muscle injuries (60.4%) and Achilles' tendinopathies (23.3%) were the most prevalent. Physiotherapy was reported in 77.7% of cases, with active exercise and manual therapy being the most common interventions. The findings highlight the importance of injury prevention strategies and accessible physiotherapy services for football referees, and a low recurrence rate in referees who underwent physiotherapy sessions (22%).

Overuse injuries, such as Achilles' tendinopathy were particularly common, in line with previous literature (2, 4), which also reports high rates of overuse injuries in this population. An injury rate of 15.9 per 1000 hours of play was observed, consistent with previous findings by Wilson et al. (4) reporting (16.4 per 1000 hours).

CONCLUSION: This study suggests a high prevalence of overuse injuries among football referees, aligning with previous research (2,3). As such, these findings emphasize the need for targeted prevention programs to address these injuries, also highlighting the crucial role of physiotherapy in injury management. Future research is recommended to investigate long-term injury trends in referees, comparing data across different populations and regions.

THE USEFULNESS OF FUNCTIONAL TESTING IN PREDICTING PERIPHERAL NEUROPATHY: A VALUABLE ASSISTANCE FOR MEDICAL DIAGNOSIS?

CHATRENET, A., MARIE, N., PEYROT, N., MELET, T., TORREGGIANI, M., AUDEBRAND, J.M., PICCOLI, G.B.
INSTITUTE OF PHYSICAL EDUCATION AND SPORTS SCIENCES, UCO ANGERS

INTRODUCTION: Diabetes and Chronic Kidney Disease (CKD) are two distinct pathologies with a common complication: the peripheral neuropathy (PN) defined as a progressive degeneration of sensory and motor neurons, leading to a wide range of painful symptoms while impairing force production capacity. PN can affect more than 50% of these patients. If PN is not identified in time, it can worsen and may require limb amputation, which is a dramatical burden for patients and society. Among the diagnostic tests available, clinical assessments suffer from time-consuming protocols and a high variability due to human subjectivity, while electrophysiological tests remain difficult-to-access and can only detect large axons only, in the later stages. Our recent findings suggest that the quantification of postural balance and single-leg balance time has been shown to accurately predict diabetes-related PN. Therefore, the aim of the current study is to validate these previous results and to collect diversified physical and balance performance tests in order to determine whether physical performances can accurately predict PN in individuals with diabetes and CKD.

METHODS: The study is prospective and interventional. Inclusions lasted from February to May 2025 in endocrinology and nephrology outpatients' unit. The inclusion criteria require participants to be aged between 60 and 80 years, with a body mass index ≤ 35 kg.m⁻² and a diagnosis of diabetes (type I or II) and/or CKD with a renal function < 30 ml/min not in dialysis. The exclusion criteria include disabling cognitive, neurological, musculoskeletal, osteoarticular comorbidities or recent lower limb fractures.

Participants were tested for PN using the validated Michigan Neuropathy Screening Instrument. They performed 6 tests in order to quantify walking abilities, proprioceptive performances and lower-limb muscle force: 10m walk test, timed-up and go, joint position sense, star excursion balance test, balance tests and ankle muscles strength assessment. The predictive equation will be developed using a regression method.

RESULTS: Given the previous results reporting a very high area under the ROC curve (0.960), a high specificity (97.4%) with moderate sensitivity (77.8%) using balance tests compared to clinical diagnosis, the expected results of the present study, focusing even more on proprioceptive capabilities, are promising.

CONCLUSION: Due to the limited availability and reliability of screening tools, many patients live with undiagnosed PN, which can lead to severe consequences in the event of foot injuries or bedsores. Physical performance declines even in the early stages of PN, accompanied by intrinsic foot muscle remodeling and gait impairments. A systematic, low-cost, rapid, and validated method for estimating PN risk would facilitate timely medical referral, thereby reducing the physical and socioeconomic burden of undiagnosed PN in patients with diabetes and CKD.

RESEARCHING THE MOST EFFECTIVE ROBOTIC OR CONVENTIONAL TRAINING TO IMPROVE WALKING ABILITY IN PEOPLE WITH MULTIPLE SCLEROSIS: PRELIMINARY RESULTS FROM THE PROGR-EX STUDY

BARONI, A., LAMBERTI, N., PERACHIOTTI, G., CREPALDI, A., PIVA, G., MANFREDINI, F., STRAUDI, S.
UNIVERSITY OF FERRARA

INTRODUCTION: Gait disorders are frequent in people with multiple sclerosis (PwMS) and the use of robotic devices as exoskeletons has been proposed as effective for gait rehabilitation. Previous studies showed an inverse relationship between the intensity of exercise and the improvement in walking speed. Furthermore, benefits of a low-intensity training have been observed from clinical, muscular and hemodynamic perspective in several neurologic conditions. For this

reason, this study aims to evaluate the effects of a low-intensity RAGT at progressively increasing intensity (LowRAGT) compared to conventional RAGT and OGT in PwMS and moderate to severe walking impairment.

METHODS: In this randomized control trial, we recruited PwMS aged 18-65 years with disability rate defined by an Expanded Disability Status Scale score 6-7. All participants received three weekly treatment sessions of 3 hours each for 4 weeks. In the first two hours of treatment, each patient received a personalized, intensive, and task-specific rehabilitative intervention. During the last hour, subjects received specific gait training according to the assignment group. Subjects allocated to the LowRAGT group received gait rehabilitation on the Lokomat device set at 60% robotic assistance, 50% load suspension, and a speed initially set at 1.0 km/h, with progressive increments of 0.1 km/h at each training session. The working time consisted of bouts of 3 minutes of work alternated by 1 minute of recovery, to be repeated 8 times. Subjects allocated to the RAGT group received gait rehabilitation on the Lokomat device, and the parameters for setting the machine was determined on patients characteristics; the effective duration of treatment was 30 minutes. Subjects allocated to the OGT group received one-hour supervised walking training session. Mobility, walking function, balance, and patient-reported outcomes measures (PROMs) were assessed before and after treatment and at the three-month follow-up.

RESULTS: One-hundred twenty-two PwMS were screened and twenty-four were enrolled (17 female, median age 55 years). All the enrolled subjects safely completed the study protocol. Significant improvements in walking function at post treatment evaluation were recorded only in LowRAGT and OGT group (endurance +30m, speed +0.11m/s, $p<0.05$); mobility (-2.12s, $p<0.05$), and balance (+7pts, $p<0.05$) improved in all three groups, without differences between them. At the three-month follow-up only the PwMS in the LowRAGT group retained improvements in walking endurance (+27m, $p<0.05$), mobility (-1.97s, $p<0.05$), and balance (+6.5pts, $p<0.05$).

CONCLUSION: Mobility and gait improvements represent a realistic and achievable goal in PwMS and severe walking impairment. LowRAGT and OGT are effective in improving walking function, mobility, and balance; the retention of treatment effects at the three-month follow-up makes the LowRAGT a valuable strategy to maintain positive changes over time, also outside the rehabilitation setting.

ASSOCIATION OF FITNESS TESTING BATTERY, PHYSICAL ACTIVITY, HEALTH-RELATED QUALITY OF LIFE AND THE IMPACT OF THE DISEASE IN WOMEN WITH FIBROMYALGIA

SOCORRO, J., CHALER, J., CASTRO, M.J., ALMIRALL, M., BLANCH, J., ROMAN, B.

UNIVERSITAT RAMON LLULL - FUNDACIÓ BLANQUERNA

INTRODUCTION: Fibromyalgia (FM) is a chronic disease characterized by chronic widespread pain, fatigue, unrefreshing sleep, cognitive and gastrointestinal disorders, anxiety, depression, headaches, and dizziness. Such symptoms often incapacitate patients, hindering their ability to engage physical activity (PA), perform daily living tasks and are associated with significant impairment in perceived function and reduced physical performance. This study aimed to assess the association of spontaneous physical activity, performance on a set of functional tests, health-related quality of life (HRQoL) and the impact of the disease in women with FM based on their employment status and in comparison with healthy women.

METHODS: A cross-sectional observational study was carried out, in which 81 women with FM aged 52.06 ± 9.21 years were evaluated. PA level (sedentary, light, moderate, moderate to vigorous, and vigorous) was assessed using triaxial accelerometry. Physical fitness was assessed using the 6-min walk test, handgrip strength and the 8 feet up and go test, and HRQoL domains and the overall disease impact were assessed using the 36-item Short-Form Health Survey (SF36) and Revised Fibromyalgia Impact Questionnaire (FIQR) respectively. An ANOVA analysis was performed to assess group differences.

RESULTS: Participants were divided into four groups: 1) Women with FM who are actively working ($n=28$); 2) Women with FM on sick leave and claiming disability ($n=17$); 3) Women with FM with permanent work disability ($n=13$); and 4) A control group of sedentary women without FM ($n=23$). Patients with FM showed less PA level and more sedentary time than control women. Moreover, participants with FM performed worse than control women in all the fitness tests studied ($p<0.05$). Regarding groups with FM, handgrip strength test showed significant differences between actively working group and claiming disability group ($p<0.05$). No significant differences were found between FM groups in the 6MWT and 8 feet up and go test.

CONCLUSION: Women with FM show less level of PA, more sedentary time and significantly worse results than healthy women in the 6mwt, handgrip, and 8 feet up and go tests. This battery of tests has been shown to be capable of distinguishing between women with the condition and those without it. Furthermore, strength appears to be the key component for differentiating between subgroups based on employment status, as promising results have been observed between the active group and the group claiming disability.

ASSESSING THE EFFECTS OF A NOVEL PHYSICAL-COGNITIVE TRAINING ON CHILDREN WITH AUTISM SPECTRUM DISORDER AND IDENTIFICATION OF THEIR NEURAL CORRELATES

DELLA VALLE, C., DI MARTINO, G., AYDIN, M., DI RUSSO, F., CALCAGNO, G., DI CAGNO, A.

UNIVERSITY OF VERONA; UNIVERSITY OF MOLISE; UNIVERSITY OF ROME "FORO ITALICO"

INTRODUCTION: Autism Spectrum Disorder (ASD) is characterised by deficits in social communication and restricted, repetitive behaviours. The predictive impairment hypothesis suggests that abnormal neural development and dysfunction in

synaptic plasticity in the prefrontal cortex impair anticipatory motor and cognitive processes. Recent evidence indicates that physical activity can enhance social interaction, communication, and self-regulation in individuals with ASD, with dual-task cognitive-motor training (CMDT) proving more effective than exercise alone.

METHODS: This study evaluated the efficacy of a 12-week CMDT programme in enhancing anticipatory mechanisms and normalising prefrontal activity in children with ASD compared to Typically Developing Children (TDC). We hypothesised that children with ASD would exhibit suppressed anticipatory brain activity in the prefrontal cortex relative to their TD peers. Twenty children (10 with ASD, 10 TD), aged 9 to 14 years, participated. Pre- and post-intervention assessments included electrophysiological recordings via EEG and motor performance evaluations using the Movement Assessment Battery for Children–Second Edition (M-ABC2). EEG analyses focused on event-related potentials (ERPs): the P3 component, associated with cognitive resource allocation and stimulus evaluation, and the Bereitschaftspotential (BP), linked to motor preparation. Data were analysed using repeated-measures ANOVA.

RESULTS: The analysis of variance revealed significant effects of both group (ASD vs. TD) and time (pre- vs. post-intervention) on response times, as well as a significant interaction between these factors ($p < 0.05$). Specifically, TD children exhibited faster response times, while the ASD group demonstrated a marked post-intervention improvement that effectively eliminated the significant pre-test difference between groups.

In addition, the M-ABC2 scores demonstrated significant post-training improvements in motor coordination and dynamic balance ($p = 0.02$), with the ASD groups performance approaching that of their TD peers.

CONCLUSION: These findings support the efficacy of CMDT in enhancing sensorimotor integration in children with ASD by improving anticipatory processing and cognitive-motor performance. This work contributes to the development of evidence-based clinical and rehabilitative interventions aimed at improving socialisation and autonomy in daily life.

MUSCULAR FATIGUE AND PERCEIVED PHYSICAL EXERTION IN ESPORTS ATHLETES – A QUASI-EXPERIMENTAL TRIAL

THOLL, C., HANSEN, L., FROBÖSE, I.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Muscular fatigue is a key determinant of health, performance, and safety in both daily activities and sports. Esports or competitive gaming involve sedentary behavior with monotonous postures and repetitive upper extremity movements, which may elevate the risk of muscular fatigue. Consequently, sustained engagement in competitive gaming can lead to increased muscular fatigue and perceived exertion, potentially contributing to long-term musculoskeletal disorders (MSD). This study examines the effects of competitive gaming on muscular fatigue and perceived exertion, addressing a critical gap in the literature.

METHODS: Thirty-two healthy male esports athletes (23.8 ± 3.4 years) participated in two competitive video gaming sessions lasting 90-120 minutes each, interrupted by a 10-minute passive sedentary break. Surface electromyographic (EMG) data of upper trapezius and wrist extensors were recorded for both body sides during video gaming sessions. The median frequency (MDF) and root mean square (RMS) were used to quantify muscular fatigue. RMS was normalized with the baseline average of the first 2 min of recording. Additionally, repeated measures of perceived physical exertion (Borg Category-Ratio-10 scale) were recorded before and after each video game session (T0-T3). One-way repeated measures ANOVA with Bonferroni correction for post-hoc comparisons was used for statistical analysis.

RESULTS: The Borg scale increased significantly over time (T0: 1.0 ± 0.95 , T3: 3.0 ± 1.63 ; $F(2.23, 69.2) = 41.23$, $p < 0.001$). Post-hoc analysis confirmed a significant increase after both the first and second gaming sessions ($p < 0.001$), followed by a reduction after the sedentary break ($p < 0.001$). MDF in wrist extensors decreased significantly over time ($p < 0.001$), with reductions observed in both the left (99.24 ± 20.10 Hz to 95.59 ± 20.40 Hz, $F(3, 90) = 9.18$) and right side (97.86 ± 15.47 Hz to 94.60 ± 15.42 Hz, $F(1.64, 45.82) = 10.83$). Similarly, RMS amplitude declined significantly ($p < 0.001$) in both wrist extensors (Left: $103.28 \pm 14.70\%$ to $90.78 \pm 26.63\%$, $F(2.57, 74.48) = 8.21$; Right: $103.28 \pm 7.52\%$ to $84.50 \pm 14.80\%$, $F(1.71, 47.96) = 24.06$). For the upper trapezius, only the MDF of the right side showed a significant decrease over time (77.31 ± 22.98 Hz to 72.52 ± 22.96 Hz, $F(1.79, 53.65) = 4.81$, $p = 0.015$). No significant changes were observed in any EMG parameter after the sedentary break.

CONCLUSION: The findings indicate a progressive increase in physical demand in esports over time, especially following consecutive gaming sessions. Only the Borg scale showed a reduction after a sedentary break. The lack of neuromuscular recovery post-break suggests a risk of cumulative muscular fatigue. Without compensatory physical activity, these repetitive loads may increase the risk of MSD. Therefore, the results indicate the necessity of preventive holistic training approaches and regular active breaks in esports.

AN INVESTIGATION INTO THE INFLUENCE OF MENTAL HEALTH ON SCAT6 BASELINE SYMPTOMS IN FEMALE RUGBY UNION PLAYERS

CASHMORE, I., PROSSER, S., STORM, A., DEMARCHI, A., WALTON, D., COE, J., I'ANSON, H., TAYLOR, A., ROGERS, J., O'HALLORAN, P., STEVENS, A., BELLI, A., WHITE, C., LUCAS, S.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Concussion-related symptoms often overlap with those associated with mental health conditions, potentially posing challenges for health care professionals. This relationship may mean clinicians struggle to distinguish between symptoms related to mental health and those emerging post-concussion. This study aims to investigate whether females with a mental health diagnosis exhibit increased baseline symptom count and severity compared to those without a diagnosis.

METHODS: Sixty female university-level rugby union players completed a baseline (pre/early-season) assessment utilising the Sport Concussion Assessment Tool, 6th Ed (SCAT6). The present study focused on the symptom checklist which measures the presence and severity of 22 symptoms, with each symptom rated on a scale from 0 (none) to 6 (severe). Individual ratings are combined to produce an overall symptom severity score (/132) and total symptom count (/22). Participants also provided information about their mental health background, specifically, whether they had received a diagnosis for anxiety, depression or any psychological disorder. This information was used to divide participants into two groups: a control group (n = 51) and a mental health group (n = 9). Mean symptom count and severity were calculated for each group and individual symptom, which were then compared between groups.

RESULTS: The mental health group exhibited a greater symptom severity score (28.8 vs. 9.8) and increased total symptom count (12.3 vs. 6.2) relative to the control group. Severity scores were elevated in all symptoms of the mental health group with eleven symptoms rated as severe. 19.7% of participants diagnosed with a psychological disorder reported at least one symptom rated three or above, in contrast to only 4.3% of the control group. The most pronounced differences in severity were observed in nervousness or anxiety (2.8 vs. 1.2), trouble falling asleep (2.1 vs. 0.6), irritability (2.1 vs. 0.6), and neck pain (1.56 vs. 0.29). Furthermore, 21 of the 22 symptoms were reported more frequently in participants with a mental health condition, with the largest increases observed in neck pain (+47.1%), sensitivity to light (+45.1%), and trouble falling asleep (+44.4%).

CONCLUSION: These findings demonstrate that individuals with mental health disorders experience greater symptom severity and frequency at baseline. This indicates that mental health conditions may influence SCAT6 symptoms, potentially complicating concussion evaluation and treatment within this population. Thus, Health Care Professionals may be setting unrealistic standards post-concussion when comparing individuals with mental health issues to normative data. Finally, this research further highlights the importance of baseline assessments for athletes when diagnosing concussions.

EXPLORING SPORT SCIENCE AND MEDICINE RESEARCH IN HIGHLY TRAINED, ELITE AND WORLD-CLASS FEMALE ATHLETES: A SCOPING REVIEW

GALAN-LOPEZ, N., MARKEY, K., STEELE, C., BRADE, C., SPENCE, A., AIELLO, F., ZANINI, M., GIRO, R., CARTER, S., MCKAY, A., HENDERSON, M., MOUNTJOY, M., DONALDSON, A., FINNOFF, J., ANDERSON, T., ADAMS, W.M., ESH, C., CHRISMAS, B., TAYLOR, L.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: The paucity of sex-specific data to optimise female athletes health and performance, can be attributed to: (i) sex-based bias in sport science and medicine (SSM) research; (ii) a translational gap between research and practice; and (iii) the underrepresentation of high-performing athletes in SSM literature. While publication volume on female athletes is increasing, a structured inclusive approach is needed. This review will identify demographics, and female-specific SSM research themes, creating a contemporary evidence map whilst surfacing future research needs for highly trained, elite and world-class female athletes.

METHODS: A systematic search was conducted in PubMed, Scopus, SPORTDiscus, Web of Science (last search, June 2024), and BASE for grey literature, to identify studies involving highly trained (Tier 3), elite (Tier 4), or world-class (Tier 5) female athletes (including retired within 10 years; >16 years old), and/or female athlete support staff. Title, abstract, full-text screening and data extraction were conducted by a total of 10 reviewers. Descriptive statistics (publication counts with percentages) for demographics, SSM (general SSM fields) and female-specific (prevalent topics in current female athlete health literature) research themes are presented.

RESULTS: From 12,579 records, 3,566 publications were eligible, including 2,990 (84%) original and 576 (16%) non-original research (e.g., literature reviews, recommendations) spanning 54 years. Among original research, 2,968 (99%) focused on athletes [Tier 3: n=1,158 (39%); Tier 4, n=1,743 (59%); Tier 5, n=379 (13%)], with 128 (4%) on athletes with disabilities, 54 (1.8%) on retired athletes, and 37 (1.2%) on master athletes. The most researched SSM themes were physiology (994, 33%), performance analysis (872, 29%), and injury (762, 25%), while equipment (79, 3%), law (17, 1%) and business (8, 0.3%) were the least common. The most researched female-specific SSM themes were musculoskeletal health (358, 23%), mental health (228, 16%), and cardiovascular health (175, 12%), while pelvic floor health (24, 1.7%), breast health (11, 0.8%), and menopause (2, 0.1%) were the least common. In 2023 specifically, the top SSM themes remained the same, while the most researched female-specific themes were mental health (36, 24%), musculoskeletal health (30, 20%), and menstrual (& other gynaecological) health (21, 14%).

CONCLUSION: Although representation in SSM research on female athletes appears low across competition level (i.e., world-class), career stage (i.e., retired and master), and those with disabilities, these subpopulations are proportionally small and challenging to access. However, we should still strive to access them appropriately, given their specific needs. Furthermore, while certain female-specific themes (e.g., menstrual health) are not represented among overall top themes in this review, they are within 2023, suggesting a shift towards recognising the importance of contemporary female-specific topics.

COMBATING GENDERED MICROAGGRESSIONS EXPERIENCED BY FEMALE PHYSIOTHERAPISTS WORKING IN MEN'S PROFESSIONAL SPORT

REYNOLDS, M., TALBERG, H., CARSON, F.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: While graduates of physiotherapy programs globally are predominately female, the number working in professional sport is considerably low [1]. Advances in gender equality in sport have been made, but it is still known that females in the sport workforce experience regular gendered microaggressions and discrimination [2]. Despite these barriers being well known, few concrete strategies have been suggested to address these. Therefore, the purpose of this study was to better understand the nuances for female physiotherapists working in professional sport and allow those who are a voice to better support the inclusion of more females into this domain.

METHODS: Applying a phenomenological research design, 12 female physiotherapists who work in professional men's rugby union (average 5.3 years) were interviewed. A semi-structured interview guide, developed from literature on the experiences of females working in sport [2], [3], was utilised, to explore the barriers faced and to encourage discussion of strategies to increase the recruitment and retainment of female physiotherapists in the professional sport.

RESULTS: Initiatives suggested by the physiotherapists include offering more flexibility to better work-life balance, creating family-friendly support structures and robust back-to-work processes, and ensuring that travel, uniform, and facilities are accessible and intended for all. Physiotherapists identified that having a supportive mentor alleviated the challenge of being the only female in the workforce and played a crucial role in enabling them to stay in their roles.

CONCLUSION: Female physiotherapists in professional men's sport continue to experience gendered microaggressions and structural barriers despite broader efforts towards gender equity. These challenges often discourage long-term retention in the field. To promote gender equity in the sports workforce, it is vital for organisations to take decisive action toward increasing female representation and dismantling gendered structures. Policy frameworks and equity position statements need firmer enforcement, so initiatives are not just symbolic but lead to change. Addressing these issues requires targeted policy reforms, mentorship programmes, and organisational support systems to foster inclusivity and equity. Transparent recruitment processes and increased visibility of women in these roles can challenge traditional norms and inspire greater female representation in men's professional sports.

THE EVALUATION OF NEUROCOGNITIVE FUNCTION AND MOTOR ABILITIES OF PROFESSIONAL FORMER SOCCER PLAYERS

GÜLER, Ö., SAHIN, F., ERSOZ, G.

HEALT SCIENCES

INTRODUCTION: Soccer is a popular sport globally, with more than 265 million people, amateur or professional. Soccer is the only contract sport in the world where the ball is headed intentionally to control or direct the ball. It is thought that heading into soccer may cause acute traumatic brain injuries, concussion, or neurodegenerative dysfunction experienced by soccer players, negatively affecting the players in sociological, psychological, and physiological terms. This study aims to compare former players neurocognitive and motor skills with those of licensed former swimmers.

METHODS: A total of 47 participants, n=27 soccer players and n=20 swimmers, aged between 45-65 years, were included in this study. The anthropometric values of the soccer players were age 54.7 ± 7.33 , height 176 ± 5.2 , body mass: 82.5 ± 7.19 , body mass index: 26.58 ± 1.95 , and body fat percentage 23.6 ± 3.85 the anthropometric values of swimmers were age: 54.52 ± 6.44 , height: 179 ± 4.6 , Body mass: 87.32 ± 4.5 , body mass index: 27.25 ± 1.45 Body fat percentage: 25.55 ± 2.98 . In this study, Stroop, an immediate memory task delayed memory task, was used to evaluate participants cognitive function. Biodex SD Balance System (Biodex, Shirley NY) device was used to measure the balance ability of the participants. Descriptive anthropometric and demographic data statistics were calculated as mean value and percentage distribution. Data normality distribution was determined by the Shapiro-Wilk statistical method. An independent sample t-test was applied to determine the difference between soccer players and swimmers. All statistical analyses were carried out with the SPSS 23.0 package program. In all statistical analyses, the alpha value was considered to be 0.05.

RESULTS: A statistically significant difference was found between the soccer player (893.269 ± 163.841) and the swimmer (767.239 ± 114.518) groups according to the comparison of the mean reaction time values of the Stroop test ($p = 0.005$).

According to the comparison of control reaction time values, a statistically significant difference was found between the football player ($856,610 \pm 151,811$) and swimmer ($752,244 \pm 105,597$) groups ($p = 0.013$)

CONCLUSION: As a result of this study, the Stroop test compatible trial, incompatible trial, and control reaction scores of the soccer players were statistically significantly higher than the swimmers. A statistically significant difference was found between players immediate memory task expression on commission error and swimmers immediate memory task expression on commission error. There was no statistically significant difference between other parameters in an immediate and delayed memory task. In line with these results, it is seen that the executive functional functions of soccer players differ from those of swimmers of similar age. Also, according to the results of the instant memory task test, the soccer players impulsivity control was greater than that of the swimmers.

OP-SH25 Anxiety and Stress

PRE-SEASON ASSESSMENT OF SLEEP & SELECTED PSYCHOLOGICAL PARAMETERS IN UNIVERSITY ATHLETES

FENUTA, A., KAMPMAN, K.1, DRILLER, M.2, COTE, A.T.1, HERGOTT, C.1, GHOBRIAL, N.1, BODNER, M.E.1

[1] TRINITY WESTERN UNIVERSITY, LANGLEY, CANADA; [2] LA TROBE UNIVERSITY, MELBOURNE, AUSTRALIA

INTRODUCTION: Pre-season training is a time of physical and psychological transition for university athletes. While pre-season physical performance assessments are germane, health assessments related to sleep/sleep behaviours and psychological parameters are understudied. We assessed sleep (i.e. quantity, quality and hygiene), stress and mood in university athletes during pre-season.

METHODS: University athletes ($n=159$; 55% male; 20.6 ± 2.3 years) completed an online survey (August-September 2023) including the following validated questionnaires: Athlete Sleep Screening Questionnaire [1], Athlete Sleep Behaviour Questionnaire [2], Perceived Stress Scale [3] and Brunel Mood Scale [4]. Data is mean $\pm$ SD ($p < 0.05$).

RESULTS: Average sleep duration was 7.6 ± 0.9 hours (67.1% reported ≥ 7 hours) with 58.1% 'somewhat' to 'very satisfied' with sleep quality. Despite 85.5% exhibiting poor sleep behaviours, 67.7% reported 'none' to 'mild' sleep difficulty. 77.5% of athletes reported 'moderate' psychological stress. The highest mood dimensions were 'vigour' (e.g. active, alert) (7.7 ± 3.5) and 'fatigue' (e.g. tired, worn out) (6.9 ± 3.6). Sleep difficulty was associated with 'confusion' (e.g. mixed up, uncertain) ($r=0.412$) and poor sleep behaviours ($r=0.389$). Stress was associated with 'confusion' ($r=0.548$), sleep difficulty ($r=0.381$), and poor sleep behaviours ($r=0.316$). Females reported poorer sleep behaviours, higher stress, less 'vigour' and greater 'fatigue' than males. First-year athletes reported greater 'confusion' versus returning athletes which was associated with greater stress ($r=0.730$ vs. $r=0.496$) and sleep difficulty ($r=0.491$ vs. $r=0.392$).

CONCLUSION: Pre-season is opportune to address sub-optimal sleep behaviours and psychological health of university athletes. Sleep education is warranted, particularly for females, to develop optimal sleep hygiene before the academic/competitive season, given sleep's association with stress. While increased 'vigour' and 'fatigue' vis-à-vis physical training in pre-season is expected, the relationship between 'confusion', psychological stress, and sleep difficulty, particularly for first-year athletes, warrants additional consideration by athlete support personnel.

EFFECTS OF DIVERSE HIGH-INTENSITY INTERVAL TRAINING PROTOCOLS ON INHIBITION FUNCTION IN ADULTS WITH MILD ANXIETY

GUO, L., LIU, N., YUAN, W.

DALIAN UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Anxiety disorders, a common mental health issue, are increasingly prevalent and significantly impact cognitive functions. Traditional treatments primarily address emotional symptoms, often neglecting cognitive deficits. Recent evidence suggests that high-intensity interval training (HIIT) can enhance cognitive function, but its effects on inhibitory function under negative emotional states are still unclear. This study explores how different HIIT protocols influence inhibitory function in individuals with mild anxiety.

METHODS: This study recruited 45 participants aged 18–24 years, randomly assigned to three groups (A, B, and C; 15 each). Inclusion criteria included: State-Trait Anxiety Inventory (STAI) ≥ 50 , Self-Rating Anxiety Scale (SAS) 40–48, International Physical Activity Questionnaire (IPAQ) < 600 MET-min/week, no exercise contraindications, and no use of medica-

tions that affect metabolism or the nervous system in the past six months. Groups A and B performed HIIT at 85–90% and 90–95% of maximum heart rate, respectively, with 1 minute of exercise followed by 1 or 2 minutes of rest and repeated 10 times. Group C received neutral health education. Pre- and post-intervention assessments included the Stroop Task, Event-Related Potentials (ERP) data, and salivary cortisol levels.

RESULTS: Exercise intensity and interval ratio did not significantly affect the accuracy of the Stroop Task ($P > 0.05$), but their interaction was significant ($P < 0.05$). At a 1:1 interval ratio, higher-load exercise improved accuracy more than lower-load exercise ($P < 0.05$). For reaction time, the interval ratio had a significant effect ($P < 0.05$), with both 1:1 and 1:2 intervals improving reaction time compared to baseline ($P < 0.05$). ERP data showed no significant main effects for P300 amplitude at Fz ($P > 0.05$), but significant interaction effects at Cz and Pz. At Cz and Pz, higher load with a 1:1 interval reduced P300 amplitude compared to baseline and lower-load exercise ($P < 0.05$). Cortisol levels significantly increased only in the higher-load, 1:1 interval group ($P < 0.05$).

Discussion: The study explores that the effectiveness of HIIT in improving inhibitory function among individuals with anxiety is influenced by both exercise intensity and interval ratio. Specifically, a 1:1 interval ratio combined with higher exercise intensity (90–95% HRmax) significantly enhanced behavioral performance in inhibitory function but simultaneously reduced neural efficiency. This suggests that while such HIIT protocols can improve cognitive performance, they may also impose greater physiological stress. Therefore, when designing HIIT interventions for individuals with anxiety, it is crucial to balance behavioral gains with neural workload and physiological stress. Future research should focus on identifying optimal HIIT protocols that maximize cognitive benefits while minimizing negative impacts on neural efficiency and stress levels.

CARDIORESPIRATORY FITNESS MODERATES STUDENTS PHYSIOLOGICAL AND PSYCHOLOGICAL REACTIONS DURING A MATHS EXAM

GERBER, M., RÄBER, D., LOOSER, V.N., LUDYGA, S.
UNIVERSITY OF BASEL

Objectives: The influence of physical activity and fitness on physiological and psychological stress reactivity has long been the subject of scientific research. Under laboratory conditions, research has shown that fitness can lead to a blunted stress reaction. In this study, we examined whether cardiorespiratory fitness is effective as a moderator of the physiological and psychological stress reactivity in adolescents during a real-life stress situation (maths exam relevant for the end-of-the-year results).

Methods: The study was conducted with 79 students ($M = 14.19 \pm 0.79$ years; 49.4 % girls) from grade 8 and 9. Physiological stress reaction was measured via heart rate variability during a maths exam and a normal maths lesson (baseline). Low frequency (LF) was used as main indicator. A psychological questionnaire was used to assess current mood and anxiety. Cardiorespiratory fitness was assessed with the 20-meter Shuttle run test. Participants were categorized into groups with low vs. high fitness via median split (separately for boys and girls). Stress reactivity was compared via rANO-VAs with test-condition as a within-subject factor (baseline vs. stress) and group (low vs. high fitness) as a between-subject factor.

Results: Statistically significant condition by group interaction effects were found for heart rate variability (LF), mood and anxiety. Whereas the fitness groups did not significantly differ from each other during baseline, the high fit group had lower LF scores, more positive mood and lower anxiety levels during the stress condition.

Conclusion: Cardiorespiratory fitness acts as a moderator of the physiological and psychological stress reactivity also under real life conditions. These findings show that students with higher cardiorespiratory fitness are better equipped to cope with everyday problems. Improving fitness is one possible pathway how young people can be empowered to better master the everyday challenges. Programs are needed that meet young people's needs and efficiently improve their cardiorespiratory fitness.

EFFECTS OF A SINGLE BWM-T SESSION ON STRESS RESPONSE HRV IN AMATEUR ATHLETES DURING A STRESSFUL TASK: A PILOT STUDY

MARCO, B., COZZOLINO, M., TINELLA, L., CELIA, G.
UNISA

The management of stress and anxiety is vital for athletic performance and well-being. Techniques modulating autonomic nervous system responses, such as biofeedback and controlled breathing, effectively reduce anxiety and enhance coping skills (Lehrer et al., 2020; Sakakibara et al., 2022). The Brain Wave Modulation Technique (BWM-T), a mind-body intervention integrating relaxation, visualization, and controlled breathing, aims to reduce stress and promote psychological well-being. However, its application in sports contexts remains underexplored.

This pilot study investigates the effects of a single BWM-T session on physiological and psychological stress responses in amateur athletes during a cognitive stress task. Eighty amateur athletes were randomized to either a BWM-T group or a control group (passive relaxation). Heart rate variability (HRV), perceived stress (PSS), and coping abilities (CISS) were measured at baseline (T0), post-intervention (T1), and after a mental arithmetic task (T2, T3). The intervention consisted of a 16-minute BWM-T session, while controls experienced 16 minutes of passive relaxation.

Preliminary results indicate that the BWM-T group exhibited significantly higher HRV during the stress task, suggesting improved autonomic regulation. Additionally, BWM-T participants reported lower perceived stress and better coping abilities than controls.

This study highlights that a single BWM-T session can effectively reduce physiological and psychological stress responses in amateur athletes, underscoring its potential for enhancing performance and well-being in sports settings.

QUALITY OF LIFE, TIME USE AND PERCEIVED SOCIAL PRESSURE AMONG STUDENT-ATHLETES AND GENERAL POPULATION STUDENTS: A COMPARISON OF NORWEGIAN LOWER SECONDARY SCHOOLS

BJØRNDAL, C., BAKKEN, A., AUNE, L.S., SAARINEN, M.

NORWEGIAN SCHOOL OF SPORT SCIENCES

This study assesses differences in quality of life, time use, and perceived social pressure between student-athletes in lower secondary sport schools and general population students in ordinary lower secondary schools. We conducted our analysis using a sample of 1,353 students from 16 sport schools, along with data from the national Ungdata Survey. The Ungdata Survey is a national data collection system in Norway designed to provide a representative sample for cross-sectional surveys of adolescents aged 13 to 19. We analysed responses from both student-athletes and general population students from non-sport schools using general linear models, controlling for age, gender, and socioeconomic status. Our findings indicate that student-athletes experience a higher overall quality of life compared to general population students. This trend was reflected in higher reported satisfaction levels in multiple life domains, including relationships with parents and friends, school environment, and overall health. Despite these positive indicators, our analysis also revealed that student-athletes faced increased pressures specifically related to their sports performance. Conversely, they reported experiencing less pressure regarding their academic performance and physical appearance compared to their peers in general population schools. Differences in time use between the two groups were relatively small. General population students were more engaged in non-sporting organised activities, while student-athletes allocated significantly more time to sports and exercise activities. Despite the rigorous demands of their athletic commitments, student-athletes did not report lower levels of social interaction compared to general population students. In fact, male student-athletes reported spending more time with friends than their male peers in non-sport schools, whereas female student-athletes reported slightly less time with friends compared to female general population students. Notable gender differences emerged throughout our analysis. Female student-athletes reported lower levels of appearance-related and academic pressure compared to female general population students, suggesting that sport school environments may provide a protective buffer against certain societal pressures. Additionally, the benefits of sport school attendance in terms of overall life satisfaction appeared to be greater for female student-athletes than for their male counterparts. Our findings highlight the potential role of sport schools as a complementary component of the broader secondary education system. However, given that access to sport schools is often influenced by socioeconomic background, further research is needed to examine the long-term impact of these schools on different social groups. Addressing barriers to access, particularly for students from lower socioeconomic backgrounds, should be a priority for policymakers and educational institutions.

THE ROLE OF SPORT IN EMBODIED SOCIALIZATION OF YOUTH IN A DEPOPULATION-AFFECTED RURAL ENVIRONMENT

HÖGMAN, J., CARLMAN, P.

KARLSTAD UNIVERSITY

Background

The development of youths physical activity practices occurs through a complex interplay of social, cultural, and geographical factors. Previous research highlights the dual role of sport in rural communities, where it fosters social belonging and identity but also reinforces exclusion and traditional ideals.

Aim

This study examines how embodied socialization occurs among youth in a depopulation-affected rural environment in Sweden. Research questions were: What type of sporting body is shaped by growing up in a rural environment? Which activities contribute to the creation of this body?

Method:

This study draws on Elders socialization theory, where a places physical and sociocultural traits, along with parents, institutions, and socio-historical events, shape life trajectories. Embodied socialization was, thus, examined in relation to the areas social environment as well as rural culture, traditions, and economic decline.

A qualitative approach was used, employing retrospective biographical interviews with six young individuals (girls=3). Each participant was interviewed individually on two occasions to allow for in-depth analysis. Data were analyzed using reflexive thematic analysis.

RESULTS: Three themes were produced from the analysis: 'Physical activities run in the family' highlights how generationally transmitted activities shape young peoples understanding of desirable physical activity and bodies. The theme "Traditions in social institutions" illustrates how schools and local community organizations reproduce preferences for nature-based activities such as hunting, fishing, cross-country skiing, biathlon, alpine skiing, and running. The third theme, "New sports – same ideals", reveals how modern fitness activities, such as gym training, becoming more popular, align with traditional ideals of a healthy, strong, and resilient body, making them accepted within the local community.

Discussion: The results illustrate how family and community institutions reinforce traditional bodily ideals, with the rural environment and nature playing a central role. This particular rural area is oriented towards forestry, hunting, and fishing rather than farming, which is reflected in the types of bodily ideals that emerge in the narratives of young people. Nostalgia is also evident in the older generation's efforts to encourage youth to continue with traditional sports such as biathlon, ski jumping, and cross-country skiing. This nostalgia, which sustains traditional values in the shaping of bodies, can be understood as a response to societal restructuring and the decline of rural communities. A potential consequence is the limitation of opportunities for youth to explore new movement identities beyond traditionally valued physical activities.

CHARTING PHYSICAL ACTIVITY ACROSS DEVELOPMENT WITH TRAJECTORIES OF SPORT AND ACTIVE LEISURE FROM TODDLERHOOD TO EMERGING ADULTHOOD

HARANDIAN, K., PRIVITERA, M., CORREALE, L., PAGANI, L.S.

UNIVERSITY OF MONTREAL

Background. Technology is increasingly omnipresent in our lives. Consequently, youth is currently challenged by sedentariness. Physical activity may counter today's effortless lifestyle. This is particularly important for development from early childhood to adolescence. Active leisure guided by parents, coaches, and instructors likely contributes to cognitive, social, emotional, and motor skill development and active lifestyle habits. This is reinforced through social modeling and structured activities. To date, there is no documentation that examines distinct pathways of active leisure and sport participation from toddlerhood to emerging adulthood. Using a longitudinal birth cohort of millennial boys and girls, we generate trajectories of sport and physical activity participation in early childhood, middle childhood, and adolescence.

Methods. Participants from the Quebec Longitudinal Study of Child Development (QLSCD) with complete participation data at trajectory start-point ages (2.5, 6, and 12 years) resulted 1995 early childhood participants (50.4% boys), 1492 middle childhood participants (49.2% boys), and 1344 participants in adolescence (47.8% boys). Parents reported on the frequency at which they participated in sport, active hobbies/games with their child from ages 2.5 to 5 years as well as the frequency at which their child participated in organized sport from ages 6 to 10 years. Youth self-reported their level of leisure physical activity (frequency, duration, and perceived intensity) from ages 12 to 17 years. Sex-stratified growth mixture modelling analyses identified series of trajectories: active family leisure in early childhood, extracurricular sport in middle childhood, and active leisure in adolescence.

Results. Longitudinal latent class growth analyses identified trajectories at three childhood periods from early childhood to emerging adulthood. Two early childhood trajectories: low-decreasing trajectory (70% boys, 72% girls) and high-decreasing trajectory (30% boys, 28% girls). Two middle childhood trajectories: for boys, low trajectory (64%) and moderate-increasing trajectory (36%) and for girls, low-increasing trajectory (33%) and high-increasing trajectory (67%). Several trajectories were distinguished in adolescence. For boys, three trajectories were identified: consistently-low (44%), high-decreasing (14%), and high-increasing (42%). For girls, two trajectories were identified: low-decreasing (68.5%) and high-increasing (31.5%).

Conclusion. Throughout childhood and adolescence, active leisure takes many forms and changes over time. Adults provide guidance and opportunities for enriched development and lifestyle habits. As a first, this study highlights the distinct trajectories of sport and physical activity participation of boys and girls at important developmental periods. The findings inform parents, educators, and policy-makers about trends and critical turning points for physical activity participation.

RESEARCH ON THE DEVELOPMENT OF CHINAS

ZHAO, Z.

SHANGHAI UNIVERSITY OF SPORTS

INTRODUCTION: As the global aging society becomes the norm, a potential market foundation is laid for the silver economy. "Sports, Health, and Wellness" (SHW), as an important component driving the development of the silver economy, plays a significant role in enhancing the physical fitness and improving the quality of life of the elderly. However, the development of the SHW pattern in China currently faces such as insufficient demand, homogeneous supply and low efficiency of industrial integration, making it difficult to meet the increasingly diversified needs of the elderly population in China. This study aims to explore the optimization paths of the SHW pattern under the silver economy, enrich the theoretical framework of the SHW pattern.

METHODS: Employed mixed-methods approach. (1) By collecting and analyzing literature, policy documents, and expert interpretations from international sources, summarized China's current status and future development paths of the SHW

pattern. (2) Fifteen elderly individuals from Anhui and Shanghai were interviewed to investigate their awareness and needs regarding the SHW pattern across different provinces and cities. (3) Two sports towns in Anhui and Shanghai were examined on-site to understand the actual operation, service content, and satisfaction levels of the elderly with the SHW pattern. Through quantitative data analysis, the study compares the health data, participation frequency in SHW activities, and consumption patterns of the elderly in the two regions, revealing the developmental differences of the SHW model in different areas and the actual needs of the elderly.

RESULTS: (1) Opportunities: In recent years, driven by improved economic and social conditions, policy dividends, and a shift in social attitudes, the awareness of fitness for all has been increasingly awakened in China, unleashing the potential for the development of the SHW pattern. (2) Challenges: Due to the relatively late development of the SHW pattern in China, there are still issues to be addressed, such as incomplete policy formulation, homogeneous service products, and insufficient public awareness. Additionally, the SHW pattern has not yet been widely promoted in China, and the demand from the public, especially the elderly, needs to be further stimulated. (3) Pathways: The development of the SHW pattern in China requires a multi-dimensional approach, starting from the top-level design, market cultivation, technological innovation, and talent supply. Strengthening health education for the elderly is also essential to fundamentally address these issues and unleash the potential of the SHW pattern in the silver economy to cope with aging.

CONCLUSION: The development of the SHW pattern in China should adhere to the people-centered development philosophy. By constructing a new model and pattern for SHW, creating a more fulfilling and happy life for the elderly.

REBUILDING DEMOGRAPHIC DIVIDEND : A STUDY ON SPORTS PARTICIPATING SOCIAL GOVERNANCE OF POPULATION ISSUES IN CHINA

SUN, Z., XIA, M.

BEIJING SPORT UNIVERSITY

INTRODUCTION: China's population issues encompass not only problems related to population size but also challenges in population structure. This demographic shift affects resource allocation, the environment, the economy, migration, and other areas, while also exerting significant pressure on the development of sports.

METHODS: To conduct an in-depth analysis of the impact of China's population issues on sports, this study analyzes authoritative statistical data released by the National Bureau of Statistics and the Ministry of Education.

RESULTS: 1. Combined with changes in population structure, the heavy pressures of elderly care and child-rearing will lead to a decrease in regular sports participation, a reduction in the frequency of sports activities, a decline in sports consumption, and lower levels of participation in sports activities. This, in turn, will affect the development of the sports industry.

2. In a society with a declining birthrate and an aging population, educational resources, including sports education, will face new distribution challenges. On one hand, due to the reduction in the child population, some regions or schools may struggle to fully utilize their sports education resources due to insufficient student numbers. On the other hand, in order to address the challenges posed by an aging society, educational resources will increasingly be directed toward elder care, healthcare, and other related fields.

3. The declining birthrate and aging society also indirectly impact sports education and talent development. The reduction in the youth population may make it more difficult for sports education institutions to recruit students, affecting the cultivation and selection of sports talent.

Discussion: 1. Regular physical activities can enhance the physical condition and immunity of the elderly, thus reducing the risk of illness and dependence on medical and care resources. The popularization and promotion of sports can "flatten" the sharp increase in medical service demand caused by aging.

2. Population dividends are usually linked to an abundant supply of young labor, but as China transitions into an aging society, the advantage of this demographic dividend is gradually weakening. The popularization and deepening of sports education and activities have become key ways to optimize labor quality, enhance productivity, and improve labor efficiency. By improving the physical fitness of the elderly and extending their healthy life expectancy, sports can, in effect, create a "new demographic dividend" for society.

Therefore, Sports is not just a means to promote individual health; it also plays an important role in social governance. As the modernization of sports governance systems continues to improve, the "shock-response model" needs to be re-structured into a new development mindset, which actively participates in population governance models.

IMPROVEMENT OF ACCURACY OF POSE ESTIMATION USING RGBD IMAGES WITH ICP IN SPORT CLIMBING

KAWAMURA, A., MORINAGA, W., NAKAMICHI, T., AIHARA, S., KURAZUME, R.

KYUSHU UNIVERSITY

INTRODUCTION: Sport climbing is a sport in which players climb various artificial walls with climbing holds. There is still no uniform performance indicator for evaluating climbing skills, since climbers climb walls of various angles in complex postures. Therefore, researches have been conducted on motion measurement and analysis of sport climbing movements. As in other sports, optical motion capture is mainly used for motion measurement in sport climbing [1], and it provides highly accurate posture measurement. However, there are environmental constraints, such as the need to install multiple cameras for measurement. In contrast, several pose estimation methods using RGBD images have been proposed [2]. However, the accuracy of pose estimation is highly dependent on the climbers posture. We propose a new method for highly accurate human pose estimation using the ICP algorithm with RGBD images. This method applies model fitting based on a three-dimensional ICP algorithm to the two-dimensional pose estimation results obtained from OpenPose [3].

METHODS: The proposed method improves the accuracy of 2D pose estimation results using OpenPose by model fitting with ICP to achieve pose estimation for various postures. The proposed method uses model fitting based on the ICP. The system estimates the climber's posture by fitting a predefined human body model to depth images. First, the 2D position of each joint obtained by OpenPose from the RGB image is projected onto the depth image and converted to a 3D position. These positions are used as the initial positions in each frame of the human body shape model in ICP. Next, the human shape model is fitted to the depth image by ICP for 3D pose estimation. The body model, divided into parts, is prepared in advance. Then, robust 3D pose estimation can be achieved by referring to the model positions in the previous frame when the 2D pose estimation by OpenPose fails.

RESULTS: To evaluate the accuracy of the proposed method, an experiment was conducted in an indoor climbing gym. The subjects were two advanced climbers and one intermediate climber.

The posture measurement results from the optical motion capture system were used as the true values for accuracy evaluation. Compared with the conventional methods, the accuracy of the proposed method was improved. From the experiment, it was qualitatively confirmed that the ICP works effectively. It was also shown that the proposed method estimates 3D position of each joint accurately even when OpenPose failed to estimate 2D position of each joint.

CONCLUSION: In this study, we proposed the method for highly accurate human pose estimation using the ICP with RGBD images. From the experiment conducted in an actual climbing gym, it was confirmed that the proposed method can estimate climbers posture with higher accuracy than conventional methods. As a future work, we aim to generate body models from RGBD images as well.

EFFECTS OF ARM MOVEMENT AND SUPPORT SURFACE IN YOUNG ADULTS PERFORMING A DYNAMIC BALANCE TASK IN A POSTURE THREATENING VIRTUAL ENVIRONMENT

SCHEDLER, S., KLOSTER, L., MUEHLBAUER, T.

UNIVERSITY OF DUISBURG-ESSEN

INTRODUCTION: Previous studies have shown that in young adults balance performance is affected by arm movements, especially during challenging, posture threatening conditions (e.g., balancing at height) [1] as well as by support surface [2]. Additionally, it has been shown that virtual reality (VR) is a suitable tool to expose individuals to posture threatening situations using simulated height scenarios [3]. However, little is known about the effects of free versus restricted arm movements and using (in-)congruent support surfaces during a dynamic balance task performed in a posture threatening virtual environment (VE) provided through a head-mounted display (HMD).

METHODS: Thirty healthy, non-acrophobic young adults (16 f, 14 m; age: 22.3 ± 2.2 years) were exposed to a posture threatening VE using a HMD (Oculus Quest 2, Meta Inc. USA). Participants were instructed to balance forward across a 3-m long and 0.1-m wide virtual wooden beam extending from the 80th floor of a skyscraper and then return while walking backward. Each participant performed two trials (i.e., one with and one without arm movement) on incongruent (i.e., even ground) and congruent (i.e., physical wooden beam) support surface, respectively. The position and dimensions of the physical beam matched those of the virtual beam and the order of test conditions was randomized. Balancing times were recorded and analysed using a 2 (arm condition: free, restricted) $\times$ 2 (support surface: ground, beam) repeated measures

ANOVA. Additionally, the iGroup Presence Questionnaire was administered after balancing on congruent and incongruent surface, respectively in order to analyse how present individuals experienced themselves in the VE.

RESULTS: The ANOVA revealed a significant main effect for arm condition ($F = 13.132$, $p < .01$, $\eta^2p = .31$) as well as for support surface ($F = 40.817$, $p < .01$, $\eta^2p = .59$), but there was no significant interaction effect ($p = .08$) between these factors. Balancing times were significantly larger when participants walked with restricted compared to free arm movements and when walking across the beam compared to walking on the ground. Further analysis revealed that perceived presence in the VE was significantly larger ($t = 2.952$, $p < .01$, Cohen's $d = .54$) when participants balanced on the physical beam compared to even ground.

CONCLUSION: Similar to the real environment, restricting arm movements and/or changing the support surface seem to be effective means to modulate task difficulty during balance testing and/or training with healthy young individuals in VR. Larger balancing times during the trials using the physical beam may be explained by increases in participants perceived presence. This highlights the need to align visual and somatosensory input when a posture threatening environment is used in VR.

USING A PRE-TRAINED MACHINE LEARNING MODEL TO ESTIMATE THE 3D-GROUND REACTION FORCES DURING RUGBY SCRUMMAGING WITH INSTRUMENTED INSOLES

POMARAT, Z., SAVIO, T., LACOMBE, V., DUFOUR, J.E., PASSIEUX, J.C., WATIER, B.

LAAS-CNRS, ICA, STADE TOULOUSAIN

INTRODUCTION: Rugby scrummaging represents a crucial phase of the game, characterized by high-intensity physical efforts and a significant impact on match outcomes [1]. The horizontal force generated by the entire pack is a key determinant of scrum success. However, existing measurement systems are unable to provide 3D, individual, and on-field assessments of ground reaction forces (GRF). A previous study developed a Machine Learning (ML) model to predict the 3D-GRF with instrumented insoles during scrummaging but this was conducted on recreationally active subjects without specific scrummaging experience [2]. Thus, this study aimed to investigate to what extent this model can be used to predict the 3D-GRF for elite rugby players.

METHODS: Twelve elite rugby players (12 males; age: 20 ± 1 ans; height: 191 ± 7 cm; weight: 116 ± 13 kg) performed three pushing trials of 15 seconds, against a fixed scrum machine. They wore commercial instrumented insoles (Loadsol Pro®, Novel, Germany, 200Hz) inside their shoes with each foot on a force plate (Sensix, 1000Hz) covered with artificial turf. The force plate data served as the reference for 3D-GRF measurements. For each subject, one trial was used to infer data from the pre-trained ML model, while the remaining two trials were utilized to personalize the model for each subject. The model's performance was assessed by computing the Root Mean Square Error (RMSE) between the prediction and the reference, the correlation coefficient (r), and the percentage of RMSE compared to the mean resultant force.

RESULTS: The initial model inference yielded mean RMSE values of 42 ± 9 N on the Medio-Lateral (ML) axis, 168 ± 87 N on the Antero-Posterior (AP) axis, and 180 ± 49 N on the Vertical (V) axis, with correlation coefficients r of 0.708 ± 0.110 (ML), 0.825 ± 0.102 (AP), and 0.571 ± 0.123 (V). RMSE percentages relative to the mean resultant force were $4.2 \pm 0.7\%$ (ML), $15.8 \pm 5.0\%$ (AP), and $18.0 \pm 4.8\%$ (V). After personalization, RMSE were 32 ± 10 N (ML), 99 ± 41 N (AP), and 135 ± 38 N (V), and correlation coefficients r were

0.838 ± 0.062 (ML), 0.911 ± 0.044 (AP), and 0.680 ± 0.168 (V). The mean percentages of RMSE compared to the average resultant force were $3.1 \pm 0.6\%$ (ML), $9.7 \pm 2.8\%$ (AP), and $14.0 \pm 5.5\%$ (V).

CONCLUSION: The findings of this study indicate that an ML model pre-trained on data from recreationally active individuals without specific rugby scrummaging experience is not optimal for accurately estimating 3D-GRF in elite rugby players. Model personalization for each participant improved performance, suggesting that personalization is a promising approach for enhancing ML model performance when the model is trained on a non-specific dataset. However, further improvement in model performance could be achieved by pre-training the model on a dataset more closely aligned with the data used for personalization, to ensure reliable predictions.

INFLUENCE OF GRIP POSITION AND HANDLE SHAPE ON FORCE PRODUCTION AND MUSCLE ACTIVATION OF THE UPPER LIMB DURING HORIZONTAL SEATED ROWS

ERTEL, G., SIMON, F.R., MORNIEUX, G., GAUCHARD, G.C.

UNIVERSITÉ DE LORRAINE

INTRODUCTION: The horizontal pull pattern is highly represented in sports such as rowing, or during training with exercises such as seated rows. This pattern is executed through handles which serves as human/device interface. Variations in grip position or handle shape are available to adapt this movement. The impact of grip position on shoulder and back muscles activation and pulling force has been tested, showing increased strength with a neutral grip and reduced shoulder abduction¹. Nevertheless, to the authors knowledge, the influence of handle shape on a pulling pattern has only been tested in rowing². The purpose of this study was to evaluate the impact of different grip positions and handles on performance and neuromuscular activity of upper limb muscles during seated rows.

METHODS: Thirty-six healthy adults were included and tested three grip positions: pronation, semi-pronation and neutral with three individualized handle pairs: circular, elliptic and irregular hexagon. Each of these nine conditions consisted of five maximal concentric seated rows at 40% bodyweight and a maximal isometric pull on a pulling machine equipped with a strain gauge at the handle (150Hz). Subjects were equipped with EMG electrodes (Delsys, USA, 2000Hz) on Flexor Digitorum Superficialis (FDS), Flexor Carpi Ulnaris (FCU), Flexor Carpi Radialis (FCR), Brachioradialis (BRA), Extensor Digitorum (EXD), Extensor Carpi Radialis (ECR), Extensor Carpi Ulnaris (ECU), Biceps Brachii (BIB), Triceps Brachii Longus (TBL), Deltoideus Anterior (DTA), Deltoideus Lateralis (DTL), Deltoideus Posterior (DTP), Trapezius Medialis (TRM) and Latissimus Dorsi (LAD). Force production and EMG recruitment between the conditions were compared using repeated measures ANOVAs.

RESULTS: EMG recruitment was significantly increased for FCU ($p < 0.01$) with pronation grip compared to other grip positions. EMG recruitment of EXD, ECU, ECR, BIB, TRM and LAD ($p < 0.05$) was significantly higher with semi-pronation and neutral grips compared to pronation grip. No significant difference was found in force production.

CONCLUSION: Changing grip position or handle shape influenced wrist and finger muscles activation. Higher FCU activity and lower EXD, ECR and ECU activity with pronation grip may be linked to the impact of having both palms not facing each other. Thus, needing less extensors contribution to maintain the hand equilibrium³. Hence, pulling in a pronation grip may be better when having extensor tendinitis. Semi-pronation and neutral grips, which induced higher muscular activity of the pulling effectors, could be a better setting when performing seated rows with a hypertrophy focus. Nevertheless, no influence was found for performance regarding force production during dynamic or isometric conditions.

VALIDATION OF CENTER OF MASS ESTIMATION: COMPARING MARKER-BASED AND 2D AI-BASED MARKERLESS MOTION CAPTURE SYSTEMS DURING COUNTERMOVEMENT JUMPS – A PILOT STUDY

CHAN, Y., YANG, Y.H., CHEN, M.Y., FUCHS, P.X.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Artificial Intelligence (AI) is driving innovation in biomechanics by offering cost-efficient, accessible, practical, and scalable alternatives to traditional, highly accurate, marker-based 3D motion capture (MoCap) systems like Vicon. AI-based markerless MoCap addresses the limitations of conventional systems (e.g., high costs, complexity, and feasibility restricted to laboratory settings), provided it demonstrates comparable measurement accuracy. Center of mass (CoM) estimation is crucial in kinematic analyses (e.g., jump tests) and may be more robust to tracking errors than single-marker analysis since it integrates data from multiple landmarks. Assessing CoM accuracy during countermovement jumps (CMJ) is particularly valuable as CMJ is widely used tests to evaluate jump performance and lower limb muscular power across various sports and clinical settings. This pilot study aimed to assess the accuracy of CoM estimation from a 2D AI-based MoCap system compared to a gold-standard marker-based system during CMJ.

METHODS: A healthy male participant (age: 32 years, body height: 1.69 m, mass: 80.0 kg) performed a CMJ while being simultaneously recorded by two smartphones (30 Hz) from frontal and sagittal angles and eight Vicon Vero v2.2 cameras (200 Hz). Marker-based MoCap involved a full-body PlugIn-Gait marker set, with CoM estimated via Visual3D software. The AI approach employed a publicly available pose detection tool (MediaPipe Pose) to derive skeletal landmarks comparable to the Visual3D model. A self-developed script calculated CoM using the same equation applied in Visual3D. Time-normalized, instantaneous vertical CoM was analyzed over the entire time-series from the start of the countermovement until CoM stabilized after landing. Absolute and relative root mean square errors (RMSE), Lin's concordance correlation coefficient (CCC) with 95% confidence intervals (CI), and Bland-Altman's 95% limits of agreement (LoA) were computed to assess concurrent validity.

RESULTS: The absolute vertical CoM location (Vicon) ranged from 695 to 1547 mm throughout the time-series. AI-derived CoM showed an RMSE of 28 mm (2.8%) in the frontal view and 29 mm (2.9%) in the sagittal view. CCC was 0.986 (95% CI: 0.978–0.991, $p < 0.001$) for both views. Bland-Altman analysis revealed biases of -3 mm (LoA: -59 to 52 mm) in the frontal view and 1 mm (LoA: -56 to 59 mm) in the sagittal view.

CONCLUSION: The AI method demonstrated excellent agreement with traditional MoCap in estimating vertical CoM throughout the entire time-series. The promising findings suggest that smartphone-based AI MoCap provides accurate CoM estimation, supporting its potential for biomechanical research, clinical applications, and real-world use outside laboratory settings. Future studies should validate these findings across diverse participants, movements tasks, and specific CoM parameters (e.g., peak velocity and acceleration).

INFLUENCE OF DETRAINING ON ARTERIAL STIFFNESS IN BODYBUILDERS

LIAO, H., LEE, I., YU, C., LI, Y., FU, S.

UNIVERSITY OF TAIPEI

INTRODUCTION: Arterial stiffness, commonly assessed via brachial-ankle pulse wave velocity (baPWV), is a major cardiovascular risk factor [1]. Although high-intensity resistance training may raise arterial stiffness, moderate- or low-intensity training can maintain or lower it [2]. Limited research examines how detraining affects arterial stiffness in bodybuilders. This study explored whether a 4-week detraining phase post-competition influences arterial stiffness and body composition.

METHODS: Ten male bodybuilders (age 20–35 y) underwent their usual pre-competition protocol—including 1-day dehydration—and were then randomized post-competition into either a detraining group (DeTr, $n = 5$) or a continued-training group (Tr, $n = 5$). Arterial stiffness was assessed via baPWV and ankle-brachial index (ABI) using a VP-2000 device (Omron Colin Co., Japan). Body composition was measured by InBody 270 (Biospace Inc., CA, USA) and GE Lunar iDXA (GE Healthcare, Madison, WI, USA). Assessments took place at 1 week before competition (baseline), 1 day before competition (dehydration phase), 1 day post-competition, and at 1 and 4 weeks post-competition.

RESULTS: At 1 day before competition, left-side PWV significantly increased from baseline (1198.8 ± 56.7 vs. 1258.3 ± 64.2 cm/s, $p < .05$). One day post-competition, left PWV declined (1159.2 ± 59.8 cm/s, $p < .05$ compared to dehydration phase), whereas left ABI remained elevated (1.03 ± 0.12 vs. 1.10 ± 0.09 , $p < .05$). Over the 4-week period, the DeTr group showed no significant change in PWV or ABI, but in the Tr group, ABI significantly decreased (1.03 ± 0.12 to 0.95 ± 0.08 , $p < .05$), and body fat percentage was lower than in DeTr (Tr: $12.1 \pm 4.0\%$ vs. DeTr: $16.5 \pm 4.2\%$, $p < .05$).

CONCLUSION: Our results show that short-term dehydration can acutely raise arterial stiffness. Resuming moderate-intensity training mitigated vascular strain and preserved body composition. This aligns with findings that low- to moderate-intensity resistance training may offer vascular benefits [3]. In contrast, high-intensity resistance exercise has been linked to increased arterial stiffness due to heightened blood pressure responses [4]. In the current study, the detraining group did not show further stiffening but also failed to improve vascular indices or maintain low body fat—underscoring the importance of ongoing training. Coaches and athletes should consider gradual retraining strategies post-competition to promote cardiovascular health and optimal physique. Future studies with larger cohorts and extended follow-up should clarify how different intensities, volumes, and recovery approaches affect arterial stiffness in strength-trained populations.

MATCH PERFORMANCE ANALYSIS OF ELITE MENS SABER IN THE 2021-2024 WORLD CUPS

TING YU, L., YIN HUA, C.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Saber is the fastest weapon among the three fencing disciplines. Literature has shown that male players score most frequently using attacks, but there is no consensus regarding specific scoring target areas [1]. Moreover, there is little understanding about the impact of score status (leading, even or trailing) and winning the 1st round on the outcome.

METHODS: This study analyzed 120 men's saber matches from the Budapest World Cup (Hungary), Orléans Grand Prix (France), and Seoul Grand Prix (South Korea) from 2021 and 2024, using notational analysis. We examined the relationship between techniques (used and scored) and match outcomes (in winners and losers), and further in different score status and target areas.

RESULTS: Winners were ahead in the 1st round nearly 80% of the matches. Both winners and losers used attacks most frequently, followed by counter-attacks. However, winners had a higher proportion of attack compared to losers, while losers counterattacked more. In terms of techniques scored, both winners and losers scored most often with attacks,

followed by ripostes. Both winners and losers demonstrated association between techniques, both used and scored, with score status, with both expanding their proportion of techniques scored compared to techniques used in leading status. However, winners exhibited a significantly higher proportion of leading status, contributing to the difference in win/loss outcomes. Notably, only winners could effectively perform ripostes while leading, highlighting their superior defensive capabilities. Both groups predominantly targeted the head and the non-dominant side's outer area. For attacks, the dominant-side inner area and non-dominant-side outer area were targeted. Ripostes targeted the dominant-side upper arm and non-dominant-side arm, while counterattacks targeted the dominant-side forearm. Losers exhibited a more dispersed distribution in ripostes and counterattacks, showing a lack of optimal adjustment.

CONCLUSION: The results of this study reveal that world-class saber fencers adjust their techniques based on score status and preferring specific target areas. These findings provide valuable insights for coaches to design situational training and offer tactical guidance during competitions.

NETWORK ANALYSIS OF TACTICAL INTERACTIONS BETWEEN ELITE UNIVERSITY SOCCER TEAMS IN JAPAN.

MAGOME, T., TANAKA, T.

OTEMON GAKUIN UNIVERSITY

INTRODUCTION: In recent years, the integration of Artificial Intelligence (AI), Internet of Things (IoT), and sensor technologies has significantly advanced sports analytics. For instance, in team sports like soccer, players often wear sensors equipped with GPS and accelerometers to comprehensively measure movement metrics, such as distance covered and overall exercise intensity during practices and games. By analyzing tracking data from soccer matches, new insights have been uncovered, particularly in predicting injury prevention. This study focuses on visualizing the offensive and defensive tactics and team strategies of Japanese university elite soccer teams using network analysis. This approach is effective in identifying the characteristics of a team's strategic planning and quantifying the contributions and interactions of individual players.

METHODS: We analyzed a top league match of domestic university soccer using an acceleration sensor 1, and applied the results to a unique algorithm to analyze and evaluate the network (player coordination). We investigated the changes in the acceleration of the players, derived random variables, and evaluated the entropy of the movement through statistical processing. This index is an index of synchronization between players, and sheds light on the characteristics of team performance (offense and defense) during a match.

[1] Magome, T. et al. The development of automatic training analysis using 3D accelerometer in male young elite soccer team, In Proceedings of the 12th (icSPORTS 2024), pp. 160–167.

RESULTS: We analyzed official matches between university teams of comparable skill levels, obtained acceleration data, and performed network analysis. We statistically analyzed the coordination between each player using phase shift entropy. We found that in matches where team tactics were more effective, players' coordination was better, and there was a significant difference in players' coordination between periods when organized attacks were successful and periods when they were less effective ($p > 0.05$). Furthermore, our results suggest that network assessment may be able to assess the performance and injury risk of individuals within a team structure.

CONCLUSION: In this study, we were able to evaluate match performance based on the cooperation between players, visualize the quality of tactics, and obtain insights that can lead to injury prediction. These, combined with the data of individual players, can lead to an understanding of team performance. However, it is difficult to analyze all tactics in detail. Therefore, we aim to work with teams and players to visualize specific data that is key to offense and defense, and provide feedback to the entire team. In the future, we will explore the value of quantifying team performance to confirm and optimize high-quality movements. These are likely to have a ripple effect throughout the sports world and are useful.

DIFFERENTIATING WORLD-BEST FROM NATIONAL-LEVEL 100M FREESTYLE SWIMMERS: A RACE VIDEO ANALYSIS AND MACHINE LEARNING APPROACH

POSTIGLIONE, G., ABBOTT, S., NEWMAN, P., MITCHELL, L., ELIPOT, M., BARCLAY, G., COBLEY, S.

THE UNIVERSITY OF SYDNEY

INTRODUCTION: Elite swimming performance is determined by a complex interplay of anthropometric, physiological, biomechanical and technical factors. While previous research emphasises the role of explosive power, physiological conditioning and technical precision in 100m Freestyle, 'in-race' factors discriminating World-class from international and national-level swimmers has not been examined. This study uniquely examined race-phase metrics associated with World-National level performance.

METHODS: High-definition race-analysis software examined race performances of 204 male swimmers recorded at World-National level competitions (2019–2024). Race indices including stroke rate, stroke length, turn efficiency, underwater durations, and 5m interval velocities were extracted. Random forest models and feature importance methods distinguishing World- (0–2.5%), International- (2.5–5%), and National-level (5–10%) swimmers based on proximity to world record performance.

RESULTS: Random forest modelling = 89.5% classification accuracy. Swimmer velocities at 65–70m, 70–75m & 60–65m were the most discriminatory features (relative importance = 0.086, 0.081, 0.053). Shapley Additive exPlanations (SHAP) and Partial Dependence Plots validated mid-race velocity importance as distinguishing factors across performance levels.

CONCLUSION: Given the unique analysis approach, results overall identified how mid-race speed maintenance differentiated World-National level 100m. Findings offer practical implications for performance analysts and coaches, suggesting benefit from assessing race-phase velocity profiles and for targeted training within the 100m event.

EFFECT OF CONSECUTIVE JUMPING TRIALS ON ANKLE AND KNEE BIOMECHANICS DURING TAKE-OFF AND LANDING: A REPLICATION STUDY.

BANET, L., DUCHENE, Y., HANEN, N.C., MURPHY, J., GAUCHARD, G.C., MORNIEUX, G.
UNIVERSITÉ DE LORRAINE

INTRODUCTION: Replication involves testing a claim with new data to confirm its validity. The Sports Science Replication Centre was established to assess the replicability of research in sports and exercise science. As part of this initiative, we replicated Lam et al. 2021 (1), which examined the effects of single vs. consecutive countermovement jumps on lower limb biomechanics. Hence, the objective was to closely replicate this study, investigating the differences of both conditions on ground reaction forces (GRF), ankle and knee joint kinematics and kinetics.

METHODS: Forty basketball players, recruited from French university teams and clubs, performed six countermovement jump trials in single and consecutive conditions. Motion capture and force plates recorded biomechanical data, with 22 markers on the pelvis and dominant leg. The experimental design and methods were similar to the original study. Performance variables (i.e. jump heights, takeoff velocity, GRF) as well as ankle and knee biomechanics (i.e. peak angle, velocity and power) were computed during takeoff and landing. Paired t-tests assessed jump condition effects on performance and biomechanics, while a z-test was used to evaluate the compatibility of the replication and original effect sizes.

RESULTS: Single jumps resulted in greater height, takeoff velocity, and peak GRF at landing ($p < 0.001$). Ankle dorsiflexion was larger in consecutive jumps while angular velocity and power were greater for single jumps during landing. Knee extension velocity and power were lower in consecutive jump takeoff and the extension moment was higher. During landing, peak knee flexion angle was larger in consecutive jumps and power was greater in single jump condition ($p < 0.001$). Regarding the replicability of the original study, only 4 variables were successfully replicated, 3 considered as practical failure to replicate, 7 as inconclusive and 6 as informative failure to replicate (2).

CONCLUSION: During takeoff, consecutive jumps induced lower jump height and takeoff velocity, which is consistent with lower knee extension velocity and power. In contrast, the original study showed higher joint power during consecutive jump. During landing, consecutive jumps led to greater ankle and knee flexion angles but lower joint power and peak GRF, indicating stiffer landing in single jumps. However, our findings differed from the original study regarding ankle and knee mechanics as only 4 out of the 20 variables investigated were replicated. The differences in participant's athletic performance and in shoe model between the two studies could potentially explain these discrepancies, as they can impact joint kinematics and kinetics. Therefore, we are confident to state that overall, the results of the original study were not replicable and couldn't be generalized to the basketball male population.

PARADIGM INNOVATION IN ATHLETIC TRAINING DRIVEN BY ARTIFICIAL INTELLIGENCE AND BIG DATA ANALYTICS: CONVERGENCE OF TRAINING OPTIMIZATION, TECHNICAL AND TACTICAL ANALYSIS, AND HEALTH MANAGEMENT

WU, Q., ZHU, Q., QI, B.
BEIJINGSPORTUNIVERSITY

INTRODUCTION: Scientific training in competitive sports is shifting from experience-driven to data-driven methods. Traditional models often rely on subjective judgment, leading to biased decisions and inefficiencies. AI and big data offer solutions through multimodal data collection, dynamic modeling, intelligent decision-making, and training optimization. This study explores AI's impact on training, tactics, and health management while addressing ethical and scientific challenges.

METHODS: This study used experimental, data analysis, and video analysis techniques:

- **Data Acquisition:** Sensors (IMUs, myoelectric sensors), computer vision (motion capture), and environmental devices (GPS trackers, pressure sensors) collected real-time biomechanical, tactical, and environmental data.

- **Algorithm Model Construction:**

- o **Training Optimization:** Personalized action recognition using LSTM and reinforcement learning, enhanced by K-means++ clustering.

- o **Tactical Analysis:** A team dynamic model with Graph Convolutional Networks (GCN) and spatio-temporal attention, plus VR simulations for adversarial training.

- o **Health Management:** A Temporal Convolutional Network (TCN) predicted muscle fatigue and injury risk, incorporating metabolomics and genetic data for personalized plans.

- **Validation Design:** A double-blind study with 120 athletes compared AI-driven and traditional training methods in terms of performance, tactical accuracy, and injury rates.

RESULTS: The AI group showed a 23.6% improvement in movement standardization ($p < 0.01$) and a 17.4% shorter training cycle. The GCN model predicted opponent tactics with 82.3% accuracy, and VR simulations improved tactical response

times by 31.5%. The TCN model predicted muscle injury risk 48 hours in advance with an AUC of 0.91. Genetically tailored nutrition reduced recovery time by 29%.

Ethical concerns arose, with 30% of athletes concerned about data privacy, and only 64.2% of coaches adopting AI recommendations due to the "black-box" nature of algorithms.

CONCLUSION: AI enhances training precision, shifting from "trial-and-error" to individualized methods. It improves tactical decision-making and creates a "prediction-intervention-feedback" cycle in sports medicine, transitioning from treatment to prevention. However, three challenges remain:

1. Human intuition vs. data-driven insights: AI should complement, not replace, coaches' decisions.
2. Ethical risks vs. technological benefits: Clear standards for biometric data use and algorithm transparency are crucial.
3. Sport-specific suitability: AI's adaptability varies, and sports should develop domain-specific models rather than using generalized ones.

Future research should focus on multimodal models, metaverse training ecosystems, and sports biomarker mapping. International organizations must establish ethical governance standards for AI in competitive sports.

PACING PROFILES AMONG ELITE 800M ATHLETES: K-SHAPE CLUSTERING AND MACHINE LEARNING CASE STUDY FROM THE 2024 DIAMOND LEAGUE

WALT, M., CASADO, A., LE GOFF, J.M.

UNIVERSITY OF LAUSANNE

INTRODUCTION: Pacing behavior is a key determinant of 800 m performance, reflecting an athlete's energy distribution, and physiological and psychological regulation across the race. While positive pacing is mostly adopted, little is known about variability in pacing approaches among elite athletes. This study applied time-series clustering and Random Forest to (1) identify pacing profiles, (2) determine their impact on performance, and (3) quantify performance sensitivity to pacing strategy changes.

METHODS: Race split data from 135 elite 800 m performances (68 males, 67 females) of the 2024 Diamond League were standardized and analyzed. K-shape clustering identified pacing profiles based on split-time patterns, with the optimal cluster number determined via Elbow Method and Silhouette Index approaches. Performance differences were assessed using Wilcoxon tests, while a Random Forest model predicted finishing time using pacing profile, power law-derived speed and endurance parameters, and 400 m and 1500 m performances. From this model, a sensitivity analysis was conducted by randomly reassigning pacing clusters and measuring the impact on predicted performance.

RESULTS: Six distinct pacing profiles were identified: Fast start & end, Aggressive positive, Aggressive & even, Reverse J-shaped, Aggressive U-shaped, and Prudent positive. Wilcoxon tests revealed significant associations between pacing strategies and performance, with Aggressive U-shaped and Prudent positive pacing producing faster times than Reverse J-shaped for males, and Aggressive U-shaped also outperforming Aggressive & even. Among females, Aggressive U-shaped yielded the fastest performances, while Fast start & end and Reverse J-shaped were significantly faster than Aggressive positive. The Random Forest model ($R^2 = 95.6\%$, $RMSE = 1.87$ s) reinforced these findings, confirming the role of pacing profiles in performances. Sensitivity analysis demonstrated that switching to Aggressive U-shaped (1.4 s) or Prudent positive (0.45 s) pacing improved predicted times for males, while Reverse J-shaped (-1.14 s) and Aggressive positive (-0.8 s) pacing led to slower performances. For females, Fast start & end (1.08 s) and Reverse J-shaped (1.38 s) pacing was advantageous, whereas Aggressive positive pacing resulted in slower predicted times (-0.9 s).

CONCLUSION: This study confirms that pacing strategy significantly influences elite 800 m performance. Male athletes benefit from Aggressive U-shaped and Prudent positive pacing, while female athletes perform better with Fast start & end and Reversed J-shaped pacing profiles. In contrast, Reverse J-shaped and Aggressive positive pacing may not be very effective in males and females, respectively. These findings underscore the importance of optimizing mid-race pace regulation and race strategy development.

THE IMPACT OF DISTANCE AND ALTITUDE ON SEX DIFFERENCES IN ULTRA-TRAIL PERFORMANCE

EUSTACHE, E., RABERIN, A., MILLET, G.

UNIVERSITY OF LAUSANNE

INTRODUCTION: Despite the growing participation of female athletes in recent years, there is a lack of data on female-specific responses to endurance sports, including trail running. It has been hypothesized that women may gain a relative competitive advantage in ultra-trail events as the distance increases [1]. Mountain ultra-trails present unique environmental challenges, such as altitude and large elevation gain (D+), which may influence sex differences in performance [2-3]. Therefore, this study explores the impact of distance, altitude, and D+ on sex differences in DNF rates and performance in ultra-trail running.

METHODS: This study included 56 trail running races from the 2024 UTMB World Series circuit, covering all European events classified as 50 km (50K, $n = 20$), 100 km (100K, $n = 19$), and 170 km (100M, $n = 14$). For each race, the mean altitude, distance, and D+ were extracted from GPS traces. The study examines the relationship between race characteristics and sex differences (women vs. men) in DNF rates and median race times, using Pearson correlation coefficients for statistical analysis.

RESULTS: Mean DNF rates increased with race distance in both females (50K: 7%; 100K: 20%; 100M: 36%) and males (50K: 6%; 100K: 19%; 100M: 33%), with similar trends observed in both sexes. Sex differences in median race time decreased as distance increased (50K: 9%; 100K: 7%; 100M: 5%). Sex differences in DNF rates were not correlated with race distance or D+, but were positively correlated with mean altitude in the 100K ($r = 0.51$, $p = 0.02$) and 100M ($r = 0.58$, $p = 0.02$) races, indicating a larger altitude effect on females DNF rates compared to males. In contrast, sex differences in median race time were negatively correlated with both race distance ($r = -0.37$, $p = 0.005$) and D+ ($r = -0.47$, $p < 0.001$), but not with mean altitude.

CONCLUSION: The mean altitude amplifies sex differences in DNF rates in trail running, particularly in longer races, while it does not affect sex differences in median race times. Females are known to face greater altitude-related challenges, such as exacerbated pulmonary limitations or hypoxemia [3]. Additionally, sex differences in uphill velocity are more pronounced (18-22%) compared to endurance sports on flat terrain (9-12%) [2]. These findings raise questions about the appropriateness of applying the same time barriers for both females and males in ultra-trail races, regardless of the race profile, and may help explain the higher DNF rates and slower median times observed in females. Further research is needed to explore the causes of DNF in women, considering race characteristics (distance, elevation gain and loss, etc.) and environmental factors (altitude, temperature, etc.), as well as to determine whether cutoff times are too stringent for female athletes.

FEMALE AND MALE PERFORMANCES IN THE VERTICAL KILOMETER RACE OF THE YOUTH SKYRUNNING WORLD CHAMPIONSHIP 2023

RIVAROLI, S., ZANCA, C.2, INSALATINI, F.2, CARACENI, P.2, ROI, G.S.1,2
ISPORT EDUCATION TEAM; 2UNIVERSITY OF BOLOGNA, ITALY.

INTRODUCTION: Skyrunning is a mountain running sport reaching an altitude of at least 2000 meters above sea level, where symptoms of acute mountain sickness can appear. This sport has recently gained significant popularity, with an increasing number of participants from youth age. In this study we analyze youth performances in the Vertical Kilometer (VK) race of the Skyrunning World Championship 2023, a competition through a path of 1,000 m of uphill vertical climb, with an average slope of 26%.

METHODS: The time trial race, starting every 30 s, took place on August 2023, from Fonte Cerreto (Italy) to Campo Imperatore at 2,150 m of altitude. Female (F) and male (M) participants, representing 28 countries, were divided into four age categories: YA, YB, YC, and U23. They wear a sensor to record the time performance. Blood lactate concentration from a microsample taken from the earlobe (Lactate Scout, EKF Diagnostic, UK) was measured within 5 minutes after crossing the finish line.

Data were analyzed by descriptive statistics. Differences between means were assessed by unpaired Student's t-test, with $P < 0.05$ significance. Relationships between age and time performance was assessed by least-squares method.

RESULTS: A total of 233 athletes (74 F, 32%; 159 M, 68%) participated in the VK race. The mean ($\pm$ DS) ages were: YAF ($n=13$) 15.7 ± 0.5 yrs; YAM ($n=28$) 15.9 ± 0.5 ; YBF ($n=21$) 17.8 ± 0.5 ; YBM ($n=37$) 17.6 ± 0.6 ; YCF ($n=18$) 19.5 ± 0.5 ; YCM ($n=38$) 19.7 ± 0.5 ; U23F ($n=22$) 22.2 ± 0.9 ; U23M ($n=56$) 22.4 ± 0.9 ($P > 0.05$ between F and M).

All the categories showed significant differences of weight and height ($P < 0.05$) between F and M; no significant differences were found on body mass index (BMI; $P > 0.05$). No significant differences in weight and height were found between U23 and YC ($P > 0.05$); YB and YA tend to have lower weight, height and BMI than U23 and YC. The differences are significant for YA ($P < 0.05$), indicating that in this category participants have not yet completed their somatic growth.

M winners report significantly lower race times than F ones in their respective age categories. The average performance difference was $19.8 \pm 3.9\%$, with the smallest difference in the YA category ($F=00:46:39$ vs $M=00:40:03$; 14%).

The average time taken tend to decrease with increasing age in F ($R^2=0.985$) and M ($R^2=0.671$). However, the coefficient of variation was 19% and 11% in F and M respectively.

Blood lactate at the end of the race showed mean values of 9.9 ± 3.8 and 12.0 ± 4.3 mM in F and M, without significant differences between age categories and without relationships with race time.

CONCLUSION: F participants are only 32% of participants. Their performances were about 20% lower than those of M, with a significant contribution of anaerobic metabolism regardless of age. Inter-participant variability of performance depends on genetic, growth and training characteristics of the athletes selected to represent their country in the World Championship, that need further research.

DROPOUT PREVALENCE AND DEMOGRAPHICS IN BIG CITY MARATHONS

MELVILLE, J., GORDON, D., GORDON, R.
ANGLIA RUSKIN UNIVERSITY

INTRODUCTION: Not all runners who start a marathon finish, and those who do not are classified as Did Not Finish (DNF). DNFs can result from factors such as dehydration, musculoskeletal injuries, or cutaneous wounds (1). In elite marathon events, the DNF rate has been reported at 25% for men and 41% for women, as seen in the 2019 Doha World Athletics Championships (2). However, DNF prevalence and demographics in mass-start marathons remain largely unexplored. Understanding these factors is essential for race organisers to provide optimal medical support and race-day logistics.

METHODS: DNF prevalence and demographics were analysed across six marathons (Boston, Chicago, London, Hamburg, Houston, and Stockholm) from 2013 to 2023. Data were collected via web scraping, yielding 1,246,144 records, with 17% removed due to missing values, anomalies, and DNS cases. Binary coding was applied for statistical analysis, and the direct method of standardisation was used to adjust for confounding factors such as age and gender. Statistical analyses, conducted in SPSS, included chi-squared tests for categorical comparisons and binary logistic regression to assess associations between DNFs and key demographic variables.

RESULTS: The overall DNF rate across all marathons was 2.52% (20.52 per 1,000 runners), with significant differences between the six events ($\chi^2(5, N = 1,030,603) = 5296.5, p < 0.001$). Men had a significantly lower crude DNF rate (2.01%) compared to women (2.12%) ($\chi^2(1, N = 1,030,603) = 15.0, p < 0.001$). A significant association was found between DNF rate and age category ($\chi^2(7, N = 1,030,603) = 1767.7, p < 0.001$), with runners aged 70+ years exhibiting the highest DNF rate (8.0%), while those aged 40–44 years had the lowest (1.65%). Multivariate analysis showed that women had 13.5% lower odds of dropping out than men (OR = 0.865, 95% CI: 0.839–0.993), while runners aged 70+ had the highest odds of DNF compared to all other demographics (OR = 2.576, 95% CI: 2.344–2.831).

CONCLUSION: This study is the first to establish that the DNF rate in mass-start marathons is lower than in elite events. Findings suggest that gender and age significantly influence the likelihood of dropping out, with male runners aged 70+ being at the highest risk. These results emphasise the need for targeted medical and logistical support for high-risk groups. Future research should investigate the underlying causes of DNFs to improve race planning and runner support strategies.

IS EXPLORATORY RESEARCH MISUNDERSTOOD IN SPORT AND EXERCISE SCIENCE?

DITROILO, M., MESQUIDA, C.2, ABT, G.3, LAKENS, D.2

UNIVERSITY COLLEGE DUBLIN; 2 EINDHOVEN UNIVERSITY OF TECHNOLOGY; 3 INDEPENDENT RESEARCHER

INTRODUCTION: Exploratory research is well established in the literature (Kimmelman et al 2014). It involves exploring a dataset, freely and without existing hypotheses or research questions in mind, to detect patterns and associations that may look interesting and even unexpected, with the aim of generating new hypotheses. A confirmatory study should then support or question these hypotheses using a new dataset. This implies a logical sequence of events, with an exploratory study occurring first, i.e. the background work that enables a researcher to properly plan their hypothesis testing analyses in a subsequent confirmatory study (Ditroilo et al 2024). It is however important to emphasise that in exploratory studies the error rate of statistical tests is not controlled, therefore no scientific claims should be made, as the probability that these claims are misleading cannot be controlled. Yet in the sport and exercise sciences we contend that many exploratory studies are passed off as being confirmatory. Accordingly, the aim of this study was to review the literature to examine if sport and exercise science studies described as exploratory are truly exploratory.

METHODS: PubMed was searched for sport and exercise science papers that described their study as exploratory (Jan 2025) using: "exploratory stud*" or "exploratory research" or "exploratory anal*" and ("sport science*" or "exercise science"). Inclusion criteria: quantitative original studies; studies published in one of the 127 Sport Sciences journals (Clarivate Journal Citation Reports); studies stating somewhere in the paper that it is an exploratory study or that used methods of exploratory research or that used exploratory analyses. Exclusion criteria: non original studies (e.g. review papers); unable to source full text.

A study to be exploratory must: 1) have no pre-specified hypothesis to be tested; 2) have no a-priori power analysis and sample size calculation; 3) make no claims about their results. A study with a mix of confirmatory and exploratory analyses would still be selected if the exploratory section met the criteria (Ditroilo et al 2024).

RESULTS: A total of 247 papers were retrieved and 43 were selected based on inclusion/exclusion criteria (sample size: 9-1139). While 20 studies had no pre-specified hypotheses and 38 studies had no sample size calculation and power analysis, only 3 studies were classified as exploratory as they made no claims and highlighted their hypothesis generation role.

CONCLUSION: Although several studies reported as exploratory did have some elements of exploratory research, most of them made claims as if they were confirmatory studies.

Often the word 'exploratory' is used as a synonym of preliminary, first attempt at investigating a topic, pilot, feasibility, study with small sample size, etc.

It appears most researchers do not know how to properly carry out and present this type of research.

SPORT AND EXERCISE SCIENCE EXCELLENCE THROUGH DATA SCIENCE (SPEEDS) – AN ONLINE REPOSITORY OF STATISTICS EDUCATION MATERIALS IN SPORT AND EXERCISE SCIENCE

GOVUS, A., SACHKOU, E., CAREY, D., HUYNH, M., SUPPIAH, H.
LA TROBE UNIVERSITY

INTRODUCTION: Wearable devices, GPS and other technologies have led to an explosion in the volume of data available to Sports Scientists. But there is now a mismatch between the amount of data available and the skills required to make sense of it.

METHODS: The Australian Institute of Sport (AIS) has identified enhancing data science literacy in sport scientists as a strategic priority area. In collaboration with the AIS, La Trobe University have developed an online learning platform written in the R statistical programming language to improve data exploration and visualisation skills within sport and exercise scientists called the SPEEDS (Sport and Exercise Science Excellence Through Data Science) project. This project aims to enhance data exploratory data analysis, data visualisation, and statistical modelling skills within sport and exercise scientists.

RESULTS: We hope the SPEEDS project can help address the lack of specificity of existing data science resources with sport and exercise science, which tend to focus on and provide examples from other disciplines which practitioners often find difficult to apply to the high-performance sports arena.

CONCLUSION: We aim to expand the resources over the next few years and encourage contributions from sport and exercise scientists and data scientists, which will then be reviewed by our team for quality and then published on the website. Quantitative and qualitative data about the reach and significance of the impact of the site will be gathered towards the end of 2025.

The SPEEDS Project: <https://speeds.quarto.pub/speeds/about.html>

EFFECTS OF EXERCISE-RELATED ENHANCEMENT OF TRICEPS SURAE CAPACITIES ON MUSCLE-TENDON KINETICS DURING HORIZONTAL JUMPS

KHARAZI, M., EPRO, G., LAMBRIANIDES, Y., KARAMANIDIS, K.
UNIVERSITÄT KOBLENZ

INTRODUCTION: Muscle and tendon respond differently to mechano-metabolic stimuli, with tendons requiring high-strain loading (4.5–6.5%) for optimal adaptation, while muscles increase force and mechanical power-generating capacity even at moderate mechanical loads when exposed to high metabolic stress [1]. Given that tendon stiffness influences contractile dynamics during locomotion [2], we aimed to assess whether a mechano-metabolic exercise-induced increase in triceps surae (TS) strength, with and without changes in Achilles tendon (AT) stiffness, result in distinct muscle-tendon unit (MTU) kinetics during maximal unilateral forward jumps.

METHODS: Nine healthy males completed 12 weeks of resistance training with cyclic fatiguing isometric isometric plantar-flexion contractions (3 sets at 80% MVC) to induce high metabolic stress. One leg trained in dorsiflexion (DF: high mechanical loading), the other in plantarflexion (PF: moderate loading). Pre- and post-exercise TS biomechanical properties were assessed via MRI, dynamometry, and ultrasonography. Motion capture and ultrasonography analyzed TS MTU kinetics during unilateral forward jumps. AT strain was measured from the curved displacement between the gastrocnemius medialis (GM) myotendinous junction and calcaneal tuberosity [3], and AT force was estimated using pre-calibrated force-strain relationships during MVC.

RESULTS: After training, both legs showed comparable increases in TS muscle volume (~6%) and strength (~20%). However, AT stiffness increased only in DF ($p < .05$), while muscle fascicle length remained unchanged in both legs. During the ground contact phase of horizontal jumps, the DF leg exhibited higher average AT velocity, leading to greater mechanical AT power during push-off (on average, -133 vs. -227 W). There were no exercise-related effects on MTU kinetics in the PF leg, while the relative change (post/pre) in GM mechanical power during push-off was 20% greater in DF compared to PF.

CONCLUSION: Our data confirm that an exercise-related increase in TS muscle strength and AT stiffness in the DF leg led to altered MTU kinetics during horizontal jumps, increasing AT mechanical power during ankle push-off. However, an exercise-induced enhancement in TS muscle force and maximal mechanical power generation capacity in the PF leg, without changes in AT stiffness, did not affect MTU kinetics during jumping. Given that our analysis showed that the GM belly exhibited a stretch-isometric-shortening cycle during ground contact, with up to ~8cm/s shortening velocities and ~800°/s joint angular velocities, we might suggest that the adaptive changes in TS muscle biomechanical properties (higher muscle volume without any changes in fascicle length) were insufficient to improve MTU kinetics during maximal unilateral horizontal jumps. This highlights the relevance of tendon mechanical properties for plyometric tasks.

CAN VISUAL CHANGES IN RIDER POSITION WITHIN THE CROSS-COUNTRY PHASE OF EVENTING INFLUENCE HORSE PERFORMANCE?

BEEBY WYNN, G., WILLIAMS, J., MARLIN, D.

HARTPURY UNIVERSITY, GLOUCESTER, GL19 3BE, UK

INTRODUCTION: Horse welfare in Eventing is being increasingly questioned by the public. Research to date has focused on risk factors in the cross country (XC) associated with falls, and physiological demands of riders. During competition officials can eliminate combinations if their safety appears compromised. This study explored whether visual assessment of rider position during XC can provide an indication of rider fatigue and inform decision-making to promote safety.

METHODS: Notational analysis using an ethogram was developed by 3 researchers after watching videos of XC footage taken from a flat section on course between jumps during a UK Novice Event. Videos (~5s duration) taken near the start, middle and end of the course (n=285 video clips) of horse and rider combinations were analysed by a trained observer, at 0.25 speed in a random order. Positional factors including, trunk position: forwards/neutral/backwards, hand position: forwards/backwards, hand stability: stable/unstable, hand height: consistent/ varying, leg stability: still/swinging, leg position: in front of girth/ on girth/ behind girth, knee motion: bent absorbing force/ locked out resisting force, seat variation: sat down/ off horses back/ rising with light saddle contact/ rising with hard saddle contact and centre of mass movement: stable/ unstable. Differences in the frequency of behaviours across the course were examined using Friedman's analyses with post-hoc Wilcoxon Signed-rank tests (Significance: $p \leq 0.05$).

RESULTS: Five factors: hand stability, hand height, leg position, knee motion and seat variation differed significantly across the course ($p \leq 0.05$); post-hoc tests found no differences between the start-middle-end for hand stability, leg position, and knee motion. Decreased hand height stability ($p < 0.001$) and seat variation changes were seen from the start to the middle of the XC, with a decrease in riders rising with light saddle contact off the horse's back position to more rising with hard saddle contact ($p = 0.04$).

CONCLUSION: Changes in rider seat variation and hand height were observed in the middle of the course; these observations warrant further exploration as potential visible indicators of fatigue in riders. Identification of repeatable and objective signs of fatigue can help inform rider training to ensure rider fitness supports horses' performance and could provide objective measures to inform competition official decision-making when judging if combinations should be eliminated supporting Eventing's social licence to operate.

THE SIGNIFICANCE OF HORSE BEHAVIOURS IN IDENTIFYING FATIGUE IN ELITE EVENTING

WILLIAMS, J., DE CHAVES, Z., MARLIN, D.

HARTPURY UNIVERSITY

INTRODUCTION: Eventing is an equestrian discipline where horse and rider combinations are tested physically and mentally. The potential impact on horse welfare has placed the sport in a position to be scrutinised by the public. Research to-date has focused on risks associated with jumping during the cross-country phase of the sport to develop ways to increase safety. Fatigue is an overlooked factor that can contribute to these risks as an unfit horse will not meet the demands of the competition risking injury and serious falls. During competition officials can eliminate combinations if their safety appears compromised. This study explored if identifying early onset fatigue could decrease risks and inform official decision-making.

METHODS: Horse and rider combinations were purposively sampled from Burghley Horse Trials 5* 2023 (n=137 videos). Using ~5 second videos (viewed 0.5x speed) from flat sections at the beginning, middle, end of the course, a trained, blinded observer used an ethogram to score behaviours identified by experienced equine researchers, who also assigned a fatigue score. Data met non-parametric assumptions; therefore, behaviour frequencies were analysed using Friedman's analysis and post-hoc Wilcoxon Signed-rank tests to evaluate fatigue changes across the course.

RESULTS: Nine factors reported significant ($p \leq 0.05$) differences across the course. Five factors: rider balance ($p = 0.023$), varied rider balance ($p = 0.046$), tail carriage ($p = 0.024$), tail swishing ($p = 0.004$) and fatigue ($p = 0.001$) showed no difference in post-hoc testing. Horse and rider harmony decreased from the beginning to the end of the course ($p = 0.011$). Varied tail carriages were observed from the beginning to the end but with no distinct trends ($p = 0.011$). Ear position also varied from the beginning to the end of the XC ($p < 0.001$) and from the middle to the end ($p = 0.017$); horses started out with forward and alert ears and progressively this position changed to a more loose and slightly back position.

CONCLUSION: Behavioural changes can precede physical signs of fatigue and could be used to inform riders, trainer's and stewards with evidence-based reasons to manage horse welfare during competition. Measurable markers of fatigue are more difficult to identify within elite horses; however these observations may help progress research into these behaviours to aid safeguarding of the sport.

COMPARATIVE ANALYSIS OF TECHNICAL AND ARTISTIC TENDENCIES IN ELITE WOMENS AND MEN'S PAIRS IN ACROBATIC GYMNASTICS.

AZEVEDO, A., ARNS, S., COSTA, R., LAMAS, L.

UNIVERSITY OF BRASILIA

INTRODUCTION: Acrobatic Gymnastics (ACRO) is an official discipline of the Gymnastics International Federation. It is performed in pairs or groups and requires great collaboration between partners to perform elements of difficulty and efficient

use of space and time during the competitive routine [1]. Teams perform three exercises (Balance, Dynamic, and Combined) in competition. The scoring criteria fosters teams' creativity, challenging performance assessment [2]. This study aimed to compare the technical and artistic performance of top-level Women's (W) and Men's (M) Pairs.

METHODS: Data were collected from 47 exercises, including Balance, Dynamic, and Combined (26 W; 21 M) from the Acrobatic Gymnastics World Championship 2022. A single observer (sports scientist, national ACRO judge and coach) collected all data from official videos supported by previous reliability assessment (Cohen's Kappa: 0.90). Techniques were categorized according to ACRO official classes. Balance: mount (M0-1), grip (G1-6), support (SU1-4), top position (TP1-8), base support (B1-2), and motion (MT0-6). Dynamic: top's initial position (TI1-6), top's final position (TF1-4), salto direction (SA0-2), rotation quarters (Q0-8), element category (C1-4), twist (TW0-1). Spatial analysis considered the execution of elements within a grid of nine zones on the competition floor (bottom, center, top; left, middle, right). Temporal analysis compared time spent performing either techniques or choreography. The comparison of technical elements was only descriptive due to the great dispersion of frequencies among techniques. A chi-square test was applied to analyse the usage of floor zones. Generalized Estimating Equations were applied to analyze the time spent with techniques and choreography ($\alpha = 0.05$).

RESULTS: Technical elements: i) Balance: grip - W: G1 (40%); M: G6 (57%); support - W: SU1 (91%); M: SU4 (57%); top position - W: TP5 (47%); M: TP4 (30%); ii) Dynamic: quarters - W: Q8 (39%); M: Q4 (54%); twist - W: TW0 (55%); M: TW1 (64%); iii) Combined: grip - W: G1 (50%); M: G6 (92%); support - W: SU1 (96%); M: SU4 (92%); top position - W: TP5 (56%); M: TP4 (33%); quarters - W: Q8 (53%); M: Q4 (53%); twist - W: TW0 (60%); M: TW1 (73%). Spatial analysis - Balance: W and M performed more elements, respectively, on the top and on the center of the floor ($p < 0.05$); Combined: W performed more elements on the center. W and M similarly allocated time for techniques and choreography.

CONCLUSION: Top-level ACRO Women's and Men's Pairs exhibited different patterns of technique execution and floor zones utilization. However, both groups allocated similar amounts of time to techniques and choreography. These findings offer valuable benchmarks for high-performance preparation and provide broad technical references for coaching at all levels of practice.

ESTABLISHING THE MINIMAL IMPORTANT DIFFERENCE OF THE VISUAL ANALOG SCALE FOR ASSESSING EXERCISE-INDUCED FATIGUE

GAN, J.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Exercise-induced fatigue is a physiological state characterized by performance decline. The Visual Analog Scale (VAS) is one of the most commonly used subjective methods for evaluating exercise-induced fatigue. However, there is a limited interpretation of how much a change in this method indicates a fatigue status that matters to the exercise performance due to the lack of a well-established minimal important difference (MID).

METHODS: This study is a secondary analysis of data from three trials. We analyzed individual participant data before and after exercise-induced fatigue. Anchor-based methods were used to determine the MID of the VAS for fatigue, using Countermovement Jump (CMJ) height as an anchor. Specifically, the MID was calculated using mean change, receiver operating characteristic (ROC) curve analysis, and linear regression methods.

RESULTS: Data from 71 participants (80.28% male, 22.85 ± 2.51 years), corresponding to 230 person-time measurements, were included in this analysis. The CMJ height fulfilled the requirements to be used as an anchor. MIDs for mean change, ROC curve, and linear regression analysis were 48.51, 44.13, and 43.08, respectively. The Youden's Index indicated that the MID calculated by the mean change method was the most relevant and reliable in distinguishing between fatigued and non-fatigued states.

CONCLUSION: When assessing exercise-induced fatigue in trained adults using the VAS, it is crucial to evaluate whether changes exceed the MID threshold of 48.51, ensuring accurate identification of its actual impact.

QUANTIFYING TRAINING LOADS OF COMPETITIVE SOUTH AFRICAN OPTIMIST SAILORS IN DIFFERENT WIND INTENSITIES

WALKER, C., LAMBERT, M., WELMAN, K.

STELLENBOSCH UNIVERSITY

INTRODUCTION: More effort is required from a sailor during stronger wind intensities (WIs). The extent to which WIs influences the amount of stress (training load; TL) imposed on the sailor is unclear. Therefore, the primary aim of this study was to describe and compare TLs of Optimist sailors in different WI conditions during on-water training sessions. Secondary aims were to use estimated energy expenditure (EE) as a criterion to compare different TL measures within the different WIs.

METHODS: Twelve competitive Optimist sailors ($n = 8$ boys, 4 girls) were monitored during 21 sailing training sessions in light, medium and strong WI exposures. The coaches determined all training sessions beforehand, and the researchers did not make any changes to the planned training. The sailors were familiarised with the subjective Category Ratio scale (CR-10 RPE) [1] and the session-RPE protocol. Heart rate (HR) was monitored via a chest-based HR monitor (H10, Polar Electro®, Kempele, Finland), where HR was recorded at one second intervals. The CR-10 RPE were recorded within 30

minutes after returning to shore. For all data, Kruskal-Wallis and Mann-Whitney tests were used to compare any differences between WI categories within the TL methods. All the TL measures were additionally compared to EE by assessing the level of correlation.

RESULTS: Sailors' EE were higher during strong compared to light and moderate WIs ($p < 0.01$). Median TL (IQR) for all sessions was calculated at 95 (59-128) AU, 222 (1501-306) AU and 438 (292-598) AU for TRIMP, SHRZ and session-RPE, respectively. TRIMP (Median: 104 vs. 99 AU) and session-RPE (Median: 479 vs. 328 AU) ($p < 0.05$) TLs were higher in strong compared to light WIs. Conversely, the HR-based methods were highest in medium WI (Median: TRIMP=120 AU; SHRZ=246 AU). More time was spent in SHRZ zones 4 and 5 during stronger compared to lighter WIs ($p < 0.05$). Correlations between EE and TL variables were between $\rho = -0.36$ and 0.61 ($p < 0.01$).

CONCLUSION: Wind intensities apply an external stimulus to the sailor, thereby contributing to internal loads (physiological and psychological response) imposed on the sailor, especially when comparing strong and light WIs. These findings demonstrate that an increased effort is required to sail an Optimist dinghy in increasing WIs. It is, therefore, necessary to monitor the TLs of Optimist sailors in different WIs to be sure the athlete is optimally adapting to the training stimulus, as well as not becoming overloaded. Furthermore, TLs in different WIs suggest the need for specific training programs for competitive Optimist sailors. Where adjustments when expecting certain conditions in future regattas, i.e. a session with a prescribed training intensity, can be manipulated by either sailing in lighter/stronger wind intensities or by decreasing/increasing the session duration.

CP-AP12 Coaching IV - Elite Athletes

THE PHYSICAL DEMANDS OF ELITE FEMALE FIELD HOCKEY ATHLETES DURING MATCHES AND THE ENLIGHTENMENTS OF FIELD HOCKEY TRAINING

CAI, X., MAO, L.2, LOMBARD, W.3, REN, Y.3, JIANG, H.3, CHEN, X.4

NANJING NORMAL UNIVERSITY

INTRODUCTION: Field hockey is a team sport that requires a lot of technical, tactical and physical activity. Players need to use the hockey stick to control the hockey, and cooperate with teammates to complete a variety of technical and tactical actions [1]. The 2015 new FIH rules increased the requirements of physical activities of athletes in the matches [2]. In addition, the application of GPS and inertial motion analysis (IMA) in the field of hockey matches further improved the match-analysis level of field hockey games [3,4]. Thus, using the latest GPS and IMA technology to reveal the physical demands of elite female hockey players under the 2015 new FIH rules is very important.

METHODS: 21 high level matches' data of 22 elite Chinese females field hockey athletes [Age: (23.5±4.9) years old; Height: (168.5±4.6) cm; Weight: (62.4±5.3) kg; BMI: (22.0±1.7) kg/m²] were recorded by IMA units (Optimeye S5, Catapult Sports, Australia, 10Hz). The paired sample T-test was used to compare the differences between different positions and different quarters, significant difference was set at $P < 0.05$, and very significant difference was set at $P < 0.01$.

RESULTS: The elite female field hockey athletes covered 45.5±15.5 min average playing time, 5021.5±1535.0 m average total running distance (544.0±210.8 m in high-speed running, 11.2%±3.8% of total running distance), 52.6±24.0 times medium and high (M&H) IMA movements and 112.9±14.0 m/min average running speed per game. Regarding the sprint performance, the elite female field hockey athletes performed 167.9±85.3 m total sprint distance, 11.2±5.5 times sprint times and 15.2±3.8 m average sprint distance per game. Compared with the strikers and midfielders, defenders performed significant lower high-speed running (HSR) distance percentage, average running speed, HSR distance percentage per minute ($P < 0.01$), and significant higher total M&H IMA movement, M&H acceleration movements, M&H deceleration movements, M&H change of direction left, M&H change of direction right ($P < 0.05$).

CONCLUSION: The elite female field hockey athletes should have more substitutions, lower playing time in future competitions; the high-speed running distance percentage should above 20% in the future high intensity training sessions; should focus on intermit running and recovery sessions, to improve the ability of intermit running and recovery; should have specific training schedule to develop the high-speed running capacity of strikers and midfielders, and the explosive capacity of defenders.

WEEKLY WORKLOAD DISTRIBUTION IMPACT IN ELITE FOOTBALL PERFORMANCE - SCIENTIFIC HYPOTHESIS OR EMPIRICAL EVIDENCE: A SYSTEMATIC REVIEW

LAFRANCE, G., DUPONT, G., AMAIDIA, S., ABAIDIA, A.E.

UNIVERSITÉ AMIENS

INTRODUCTION: In elite soccer, weekly workload management is commonly used with the aim objective of enhancing performance and reducing fatigue. Despite the widespread implementation of weekly workload monitoring in professional clubs, the relationship between load distribution and performance remains unclear.

METHODS: A systematic search was conducted using PubMed and ScienceDirect databases until December 2024. The analysis was performed in two steps: first, characterizing weekly workload distribution patterns within microcycles, and second, examining their effects on performance outcomes. The Newcastle-Ottawa Scale was used to assess methodological quality.

RESULTS: Thirty-six studies met the inclusion criteria, with a moderate methodological quality score ($5 \pm 0.84/9$). Analysis revealed a consistent weekly periodization model characterized by three phases: post-match recovery (MD+1/MD+2), peak load distribution (MD-4/MD-3), and pre-match tapering (MD-2/MD-1). While this general framework was common across teams, variations were observed in its practical implementation across all phases of the microcycle. Regarding performance outcomes, only two studies (5.4%) examined the direct impact of load distribution through specific performance tests, with limited evidence to establish clear impacts of weekly training load patterns on physical performance.

CONCLUSION: Despite a common weekly periodization framework across elite football teams, substantial variations exist in its practical implementation throughout each phase of the microcycle. Most importantly, there is a critical lack of evidence regarding the impact of these different load distribution strategies on performance outcomes. Future research should prioritize examining this impact to establish evidence-based recommendations for practitioners.

COORDINATIVE WARM-UP AND ITS INFLUENCE ON TECHNICAL PERFORMANCE AND STRESS BIOMARKERS IN ELITE SOCCER PLAYERS

DI CLAUDIO, G., CENTORBI, M., BUONSENSO, A., MODOLO, L., DI FONZA, D., MEDORO, A., MARZILIANO, N., DAVINELLI, S., DI CAGNO, A., CALCAGNO, G., FIORILLI, G.

UNIVERSITY OF VERONA

INTRODUCTION: Coordination training in soccer plays a crucial role in the integrated development of players' technical, physical, and tactical skills. Several studies have highlighted the close correlation between high levels of physical fitness and specific coordination skills, demonstrating how these factors improve cognitive functions related to the game [1, 2]. Another key element in soccer is the role of cortisol—the stress hormone—which is released in response to motivational and goal-relevant tasks in competition [3]. This study evaluated the effectiveness of an experimental warm-up protocol designed to improve motor coordination and optimize biomarker levels in elite soccer players.

METHODS: Thirty-two male soccer players (age: 24.7 ± 3.1 years) from two elite regional teams were randomly assigned to either an experimental group (EG; $n = 18$) or a control group (CG; $n = 14$). Over 12 weeks, the EG performed a specialized warm-up consisting of four progressive coordination exercises for the upper and lower limbs using various balls, four times per week (including game days), while the CG maintained their usual routine focusing on joint mobility and muscle activation. Technical and coordination abilities were assessed pre- and post-intervention using the Y Pre-Planned Agility Test, the Y Reactive Agility Test, the Illinois Change of Direction Test (ICODT) with and without the ball, and the Loughborough Soccer Shooting Test (SHOT). Urine samples were collected before and after the intervention to measure levels of cortisol, dopamine, adrenaline, and noradrenaline.

RESULTS: RM-ANOVA revealed significant improvements in the Illinois Ball Test and Technical Index, with the experimental group showing significant progression from pre- to post-assessment ($p < 0.001$) and performing significantly better than the control group ($p = 0.017$). Significant improvements were also found in the Unplanned Y Test and Reaction Index, with the experimental group demonstrating marked gains from pre- to post-assessment ($p < 0.001$) and performing significantly better than the control group ($p < 0.05$). In addition, significant differences were observed in shooting accuracy, with the experimental group showing marked improvement from pre- to post-assessment ($p < 0.001$) and performing significantly better than the control group ($p < 0.05$). The experimental group also exhibited a significant reduction in cortisol levels ($p = 0.0007$); post-intervention comparisons between groups ($p = 0.003$) and delta analysis ($p = 0.036$) further confirmed a more pronounced reduction in cortisol levels in the experimental group.

CONCLUSION: The study highlights that the adoption of a coordinative warm-up protocol not only enhances technical performance and change of direction ability but also promotes a more favourable regulation of cortisol level in elite soccer players.

INTRODUCTION: In acrobatic gymnastics, the interplay between force production and movement velocity (F-V) is fundamental for performance optimization (1,2). Furthermore, gymnasts' lower limb muscle characteristics have been shown to influence both isometric force production and the efficiency of the stretch-shortening cycle, which are essential for executing complex gymnastic movements (3). This study aimed to assess the relationship between muscle size, muscle architecture, body mass index and strength and power performance in young elite acrobatic gymnasts (ACRO).

METHODS: Eighteen elite females base ACRO participated (13.83±1.62 years; body mass index (BMI): 21.03±2.39 kg/m²). Maximal dynamic strength was measured by the one-repetition maximum test in the squat exercise (1RM-SQ). F-V relationship was evaluated in the squat exercise (Selection MED, Technogym, Italy) using a lineal encoder (ADR System, Toledo, Spain). From the F-V regression equation, several variables were derived, including maximum isometric force (F0), maximum unloaded velocity (V0), optimal force (Fopt), optimal velocity (Vopt), and maximum muscle power (Pmax). Jumping ability was measured by the countermovement jump height (CMJmax) using a force plate (Hawkin Dynamics Inc., USA) and the modified reactive strength index (mRSI) was measured. Body composition was determined via bioelectrical impedance (Tanita BC-601). Ultrasonography (MyLab 25, Esaote Biomedica, Italy) was used to assess vastus lateralis anatomical cross-sectional area at 35, 50, and 65% of femur length and muscle volume was estimated, while muscle architecture was assessed at 50% of femur length. Images were analyzed using Fiji and SMA software. Pearson correlations and multivariate regression models adjusted for maturation status (Tanner scale) were used (SPSS v26.0, IBM, USA).

RESULTS: Model 1 predicted 1RM-SQ and included BMI, vastus lateralis muscle volume, F0, Fopt and Tanner Scale as predictors ($p=0.017$, $R^2=0.496$). Model 2 predicted Pmax-SQ and included BMI, vastus lateralis muscle volume, and Tanner Scale as predictors ($p=0.006$, $R^2=0.485$). Model 3 predicted CMJmax and included vastus lateralis muscle volume, mRSI and Tanner Scale as predictors ($p=0.107$, $R^2=0.203$).

CONCLUSION: Vastus lateralis muscle volume and BMI were significant predictors of strength and power performance, indicating their role for base acrobatic gymnasts. Thus, the vastus lateralis muscle emerges as a key muscle to prioritize training for this population. Muscle volume and mRSI alone did not predict jump height, suggesting that other biomechanical and neuromuscular factors may affect explosive performance. Future research should use larger groups and more performance variables to better understand how muscular architecture affects gymnastics performance.

OVERALL ANALYSIS OF PERFORMANCE PARAMETERS IN ELITE ARCHERS: FOCUS ON THE AIMING PHASE

JACQUOT, R., BOUILLET, K., BEN MANSOUR, K., JEHL, J.P., GAUCHARD, G.
UNIVERSITÉ DE LORRAINE

INTRODUCTION: Archery is an Olympic sport where archers aim at a 122 cm target placed 70 m away, scoring points based on the concentric rings hit. Performance depends on multiple phases of movement, with aiming and follow-through phases being essential for accuracy and control. Factors like neuromuscular activation, postural stability, kinematic of drawing arm, and temporal strategy vary with performance level, highlighting distinct strategies between elite and novice archers (Vendrame et al., 2022). While most studies focus on analyzing each type of performance determinant separately, our approach stands out by simultaneously assessing these factors. The aim is to provide a comprehensive view of their overall contribution to success at the elite level.

METHODS: Eight high-level French archers (4 men, 4 women; 19.1 ± 2.7 y.o.), ranked in the national top 20 in 2024, participated in this study with informed consent. They shot eight rounds of nine arrows at a 70 m target using their own equipment. The five highest scores (HS) and five lowest scores (LS) for each participant were analyzed. During the aiming phase, measurements includes temporal strategies (aiming duration and clicker reaction time), muscle activity (mean %EMG on MVC for 14 upper body and core muscles), drawing arm kinematics (elbow flexion, shoulder abduction), postural control (center of pressure displacement), and breathing patterns (breathing amplitude). HS and LS were compared using paired t-tests for all the variables measured.

RESULTS: All HS (10.6 ± 0.1) were higher than LS (7.4 ± 0.5). Among the performance parameters measured, only muscle activity appeared to be a discriminating factor. Higher activity in the drawing-side flexor digitorum superficialis (FDS), the drawing-side deltoid posterior (DPI), and the drawing-side external oblique (EO) was significantly associated with poorer performance ($p < 0.05$). Additionally, a tendency was observed for the chord-side deltoid middle, the chord-side upper trapezius, and both multifidus muscles ($p < 0.08$), suggesting that increased activity in these muscles may also be linked to poorer performance. The other parameters measured, including postural control, kinematics of the drawing arm, temporal strategy, and respiratory movement, did not significantly contribute to explaining elite-level performance.

CONCLUSION: Results for the FDS and EO align with those of another study, but the DP result contrasts (Simsek et al., 2018), likely due to our focus on elite athletes versus their mixed-level study. Comparing groups of different skill levels could offer valuable insights. The tendency for three trunk muscles suggests the need for further research on their role in elite archery. Advanced methods like partial least squares regression could also clarify the contribution of each parameter to performance.

ANXIETY LEVELS IN ELITE ARCHERS IN COMPETITION AND ITS EFFECTS ON ATHLETES' PERFORMANCE

SOUZA, D., AOKI, M.S., BACURAU, R., BORGES, T.O., FECHIO, J.

UNIVERSIDADE DE SÃO PAULO

INTRODUCTION: In precision sports, it is important for athletes to manage their anxiety levels as it can affect their motor performance. Competitive anxiety can have a significant impact on an athletes performance. It triggers emotional, behavioral, cognitive, and physiological responses such as the release of cortisol.

METHODS: This cross-sectional study evaluated 40 elite archers, all male and with at least 5 years of archery experience, who volunteered to be monitored during a national archery championship. The Sport Competition Anxiety Test (SCAT), salivary cortisol (s-cortisol), and salivary IgA (s-IgA) were measured 30 minutes before free practice (day 1) and 30 minutes before the official competition (day 2). A sub-sample of eight participants was also monitored for four weeks prior to the competition.

RESULTS: A t-test analysis indicated that s-cortisol ($p < 0.001$, Cohens $d = 1.20$), s-IgA ($p < 0.01$, Cohens $d = 0.5$) and SCAT ($p < 0.001$, Cohens $d = 1.20$) levels were statistically different when compared between competition and free training, with an increase in competition. One-way repeated measures ANOVA showed a significant increase in anxiety (SCAT) from training to competition [$F(1.46) = 15.54$, $p < 0.001$]. The increase was significant over time (four ($p < 0.05$), three and two ($p < 0.01$) weeks prior to competition). Finally, the rate of increase in anxiety was moderately negatively correlated with competition performance ($r = -0.7$; $p < 0.01$).

CONCLUSION: This study highlights how competitive anxiety affects elite archers. The increase in cortisol, IgA, and SCAT scores during competition suggests higher stress levels. Anxiety gradually increases leading up to competitions, impacting performance negatively. Interventions like relaxation training and cognitive-behavioral techniques may help improve performance by managing anxiety.

The psychophysiological anxiety and stress responses of professional archers increase significantly in competition, and this process develops gradually during the archers training process up to four weeks before official competition. This condition can negatively impact the accuracy of shots, impairing the performance of precision's athletes during a competition.

WHAT MAKES AN ATHLETE READY FOR TEAM SELECTION IN PROFESSIONAL AUSTRALIAN FOOTBALL? PERSPECTIVES FROM COACHING AND SUPPORT STAFF.

TURNER, C., VICKERY, W., DWYER, D., BRUCE, L.

DEAKIN UNIVERSITY

INTRODUCTION: The transition from sub-elite to elite Australian Football is a significant milestone for athletes striving for a professional career. To achieve this, athletes need to be drafted by one of the 18 clubs in the Australian Football League (AFL) [1]; however, that does not guarantee success as only 22 (of 44 athletes) are selected each week. This study aimed to describe the perceptions of key club personnel on what attributes make an athlete ready for selection into the team each week. Findings will provide athletes a clear and comprehensive understanding of what is required to be ready for weekly AFL team selection.

METHODS: Participants were recruited using a purposive sampling procedure. Twelve current staff members from one AFL club participated in individual 30–60-minute semi-structured interviews. Staff members were involved in the men's team selection and/or preparation of athletes (coaches ($n = 4$), physical preparation staff ($n = 3$) and other football department staff ($n = 5$)). Interviews were transcribed verbatim prior to analysis. Data analysis followed the six-phase framework for reflexive thematic analysis.

RESULTS: A total of thirteen lower-order themes and four higher-order themes were identified that related to the individual athlete attributes as described by staff in this context. The four higher order themes were Physical and Physiological, Technical and Tactical, Psychological, and Performance. Staff generally agreed on the importance of physical and physiological, and performance attributes, with less consensus observed within the technical and tactical, and psychological attributes. However, the specific attributes required by an athlete depend on what position they are being considered for. Findings suggest that two categories of attributes may exist in the assessment of readiness, the first consisting of attrib-

utes considered essential and possessed by a larger portion of athletes (e.g., health or running capabilities), while the second consists of attributes seen as less essential but more critical to performance (e.g., speed or football IQ).

CONCLUSION: These findings provide novel insights within a football department about what determines player readiness, which could lead to an aligned interdisciplinary approach to developing athletes. Findings also have the potential to benefit playing groups across the league, giving athletes greater clarity of what is expected of them to be considered ready for selection into an AFL team.

1. Agnew et al. 2018. Deselection from elite Australian football as the catalyst for a return to sub-elite competitions: when elite players feel there is 'still more to give.'. *Qual Res Sport Exerc Health*, 10(1):117-36.

THE SCIENCE OF CHAMPIONS: CASE STUDY INSIGHTS INTO LONG-TERM DEVELOPMENT OF WORLD-CLASS ATHLETES' TRAINING AND PHYSIOLOGY

STRØM SOLLI, G., YAMASHITA, D., MUJKA, I.

NORD UNIVERSITY

INTRODUCTION: Sports science typically relies on group designs comparing experimental and control groups or pre- and post-intervention results. However, in elite sports, the focus shifts to individual adaptation rather than group averages. Single-subject or case-study designs offer valuable insights into long-term development of training and physiology that larger sample sizes cannot capture [1]. Therefore, this narrative review aims to provide a comprehensive overview of case studies on the long-term development of world-class and elite athletes in Olympic and Paralympic sports, advancing the field by identifying trends, highlighting knowledge gaps, and guiding methodological improvements.

METHODS: A systematic search of ScienceDirect, PubMed, and SPORTDiscus identified case studies on world-class or elite athletes (Tier 5 or 4, McKay et al., [2]) that provided long-term data (>2 years) on training characteristics or physiological performance factors in Olympic or Paralympic sports.

RESULTS: Twenty-six peer-reviewed studies met the inclusion criteria, covering nine sports including running (6 studies), triathlon (5), rowing (3), biathlon (2), swimming (2), tennis (2), cross-country skiing (2), cycling (1), and Nordic combined (1). Athletes from 8 countries were included, with the majority from Norway (9), Spain (6), and the United Kingdom (4). The studies included 29 athletes, with limited data on female (31%), Paralympic (14%), and non-endurance athletes (8%). The mean study duration was 7.1 ± 4.6 years.

Of the included studies, 23 reported long-term training data, showing a 10-438% increase in annual training volume over 2-17 years, with varying trends in training intensity distribution. Fourteen studies examined physiological performance, with eight reporting VO_2max increases of 4-42% over 2-11 years, while three documented declines of 4-17% post-retirement. Twelve studies analyzed submaximal performance indicators, showing power output or velocity at threshold values (VT2, LT, or 4 mmol) increased by 13-101% over 2-11 years. The percentage of VO_2peak at different threshold values remained stable or increased by up to 13 %-points. Only two studies reported data on efficiency/economy, showing a decline of 9% and 14% in VO_2 at similar submaximal speeds over 4-11 years, respectively.

CONCLUSION: This review summarizes available evidence on long-term development of training and physiology in world-class or elite athletes. Detected knowledge gaps include long-term data on female and para-athletes, as well as training in specialized environments like heat and altitude. Developing better frameworks for reporting long-term training data on world-class and elite athletes (e.g., intensity distribution and exercise modes) represent key areas for methodological improvement.

CP-AP20 Power and Strength III

THE RELIABILITY OF HORIZONTAL REACTIVE STRENGTH INDEX

HAN, S., LIN, J., LI, W.

BEIJING SPORT UNIVERSITY

INTRODUCTION: The Reactive Strength Index (RSI), defined as the ratio between jump height and ground contact time, is used to assess vertical reactive strength and has been shown to be reliable both during (1) and between training intervals (2). A possible limitation of the RSI is that they only assess reactive strength in the vertical direction, whereas horizontal movements, such as sprinting and CoD in many sports are critical. For example, research has shown that horizontal force generation is a major determinant of sprint acceleration. It is critical to assess the horizontal RSI of horizontal sport athletes. However, the reliability of horizontal RSI derived from different horizontal jumps is unclear. Therefore, the aim of this study was to determine the reliability of sprint bounding and single-leg hopping.

METHODS: Thirty-six male college players (21.29 ± 2.16 yr, 180.73 ± 4.02 cm, 79.32 ± 15.27 kg) with well-trained background were recruited in this study. All subjects randomly performed three sprint bounding and single-leg hopping trials in random order. The 2-3 min rest interval was allowed between trials and 5 m interval between tests. For the sprint bounding and single-leg hopping test, participants started with a 5 meter sprint and completed a 5-step forward jump, the contact time and distance was recorded using 10 pair Optojump. The average contact time and jump distance of each jump was used for further analysis. Horizontal DSI was defined as the ratio of jump distance and contact time. For the assessment of reliability, and given our repeated measures design, a two-way mixed effects intraclass correlation model was used, where both the reliability of a single (best) trial (ICC [3,1]) and the average of three trials (ICC [3,k]) were assessed. Furthermore, the coefficient of variation (CV %) was also calculated, thus providing us with a measure of relative and absolute reliability. The combination of the ICC and CV% enabled the interpretation of overall reliability as follows: excellent (ICC > 0.9 and CV% < 5), good ($0.75 < \text{ICC} \leq 0.9$ and CV% < 10), fair ($\text{ICC} \leq 0.75$ or CV% > 10) and poor ($\text{ICC} \leq 0.75$ and CV% < 10) (3).

RESULTS: For the sprint bounding, good reliability was observed in contact time (ICC = 0.78, CV% = 9.4%), jump distance (ICC = 0.82, CV% = 8.3%), and horizontal RSI (ICC = 0.81, CV% = 3.4%). For the single-leg hopping, contact time (ICC = 0.89, CV% = 9.2%) and jump distance (ICC = 0.89, CV% = 9.2%) exhibited good reliability, excellent reliability was observed in horizontal RSI (ICC = 0.91, CV% = 2.4%).

CONCLUSION: Both sprint bounding and single-leg hopping showed accepted reliability, the horizontal RSI derived from single-leg hopping exhibited excellent reliability. Therefore, practitioners can choose sprint bounding or single-leg hopping to assess player's horizontal RSI.

COMPARING LINEAR ENCODERS AND INERTIAL MEASUREMENT UNITS IN NEUROMUSCULAR PROFILING: A PRELIMINARY STUDY

ROMAGNOLI, C., EDRISS, S., CAPRIOLI, L., QUATTRUCCI, E., CARIATI, I., CAMPOLI, F., SERGI, G., TANCREDI, V., BONAIUTO, V., PADUA, E., ANNINO, G.

UNIVERSITY OF SAN RAFFAELE

INTRODUCTION: The functional assessment of sports performance is fundamental throughout an athlete's season. In various sports such as kayaking, water polo, soccer, and swimming, linear encoders are widely used to monitor the neuromuscular profile (1-4). The linear encoder (MuscleLab™ system, Norway), introduced and validated by Bosco et al., (1995) is a mechanical device capable of measuring time and displacement to estimate respectively the force-velocity and power-velocity ratio.

Recently, new encoders and inertial measurement units (IMUs) (e.g., Vitruve, Movella Xsens) have been employed to assess kinematic and dynamic performance in land exercises such as bench press, squat, and prone bench pull. Given these advancements, this study aims to investigate whether these new devices provide data as reliable as the gold-standard MuscleLab system.

METHODS: All devices involved in the study (MuscleLab, Vitruve, Xsens) were fixed and calibrated on the barbell. The sample acquisition rate was 100Hz for Vitruve and MuscleLab and 120Hz for Xsens. The test protocol provided six repetitions for each load (from 20,30,40,50 and 60kg) performed by the same athlete (Semi-Pro water polo athlete, Male, 32 years, 1.87m height, 83.5 weight) at maximum velocity, on the bench press (Smith machine). Between each series, an optimal recovery of 4 minutes was considered. The data provided for each device were respectively range of motion [ROM] (m), time (s), mean propulsive velocity [MPV] (m/s), and power (W). Repeated measures analysis of variances (ANOVA) has been used to compare the similar parameters measured by different devices on the same subject.

RESULTS: The results showed no significant differences between MuscleLab and Xsens ($p > 0.05$). However, Vitruve exhibited statistically significant differences with MuscleLab and Xsens specifically for MVP, power, ROM, and time ($p < 0.01$). Instead, the MVP showed no significant differences between the devices, only at 60kg.

CONCLUSION: This preliminary study showed that the parameters measured with Vitruve are different from the MuscleLab linear encoder and Xsens for light loads. Thus, to focus on the velocity and power in the power-based exercises it could be suggested to implement MuscleLab or Xsens.

VALIDITY AND RELIABILITY OF FLYWHEEL RESISTANCE TECHNOLOGY AS AN ASSESSMENT METHOD AND ITS ASSOCIATION WITH SPORTS PERFORMANCE AND ASYMMETRY: A SYSTEMATIC REVIEW

MAK, C., BICHOP, J., BEATO, B.

UNIVERSITY OF SUFFOLK

INTRODUCTION: Flywheel technology is commonly used in training but remains underutilized for monitoring and testing. Flywheel devices can provide valuable data from mechanical outputs during both concentric and eccentric movements. This systematic review assesses its validity and reliability for evaluating sports performance and limb asymmetry.

METHODS: Searches were conducted in PubMed, SPORT-Discus, Google Scholar, and Web of Science following PRISMA DTA guidelines, focusing on keywords related to flywheel testing.

RESULTS: The initial search yielded a total of 310 articles (figure 1). The data were imported to the Zotero™ reference manager software version 6.0.30 (Vienna, Virginia, USA). Duplicates (30 titles) were subsequently removed, either automatically or manually. The remaining 280 articles were screened for their relevance based on their titles and abstracts. Of those,

260 articles were removed, and the full texts of the remaining studies were then inspected. After the automatic search, 20 articles remained for data extraction and further analysis. Following the citation of the list of 20 articles, 7 more eligible titles were suggested, reviewed, and integrated. Consequently, a total of 27 articles were included in the final systematic review.

CONCLUSION: Results show that flywheel testing is reliable and valid for the athletic population who when subjects undergo two familiarization sessions and perform with 1-2 pre-repetitions followed by 5-10 recording repetitions with 1-4 sets and 2-3 minutes of rest between sets and with proper equipment (e.g., rotary encoders, force plates, linear encoders, and inertial measurement units) are used (ICC=0.66-0.99, $r=0.69-0.97$, $\alpha=0.85-0.98$). Moment of inertia can be customized based on the athletes experience and the type of flywheel device used. Key metrics for assessment encompass speed, force, and power, with peak power being the most commonly employed parameter. Few samples of evidence showed that increased asymmetry in concentric power may negatively affect change of direction performance, emphasizing the need for more high-quality studies. In conclusion, flywheel technology offers valuable insights across various movements, providing strength and power assessment while potentially improving athletic performance and injury prevention. Continued research is vital to explore its effectiveness in diverse athletic contexts.

RELIABILITY OF A NOVEL ISOMETRIC MAXIMAL STRENGTH TEST FOR HIP THRUSTS: A STUDY WITH ELITE ATHLETES

SCHÄRER, C., GREMAUD, D.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN

INTRODUCTION: Hip Thrusts are widely used in elite athletes training to increase maximal strength of the posterior chain muscles in the lower limbs, to enhance performance, provide hip, knee, and core stability and to reduce injury risks.

Therefore, we aimed to calculate reliability of a novel isometric maximal strength test for the Hip Thrusts under different conditions, compare muscle activity and assess maximal strength differences across these conditions.

METHODS: Eleven elite athletes from seven different sports (age: 22.4 ± 2.6 years) participated at two testing sessions. The protocol included bilateral and unilateral isometric maximal strength measurements (force plate) in a horizontal Hip Thrust position against a barbell fixed at knee height. Testing was conducted at two knee angles (90° and 150°) and under two conditions: stable and unstable (feet on an independently moving cart system). To evaluate differences between these conditions, muscle activity (EMG) of the biceps femoris (BF), gluteus maximus (GM), rectus femoris (RF), and erector spinae (ES) and relative maximal isometric strength (F_{max_rel}) was measured.

RESULTS: Results showed high reliability for F_{max_rel} across all conditions (ICC: 0.90–0.99). Coefficient of variation (CV%) values were acceptable for bilateral conditions (90° stable: 5.9%, unstable: 5.0%; 150° stable: 6.0%, unstable: 3.2%) and unilateral conditions at 90° (stable: 4.4%, unstable: 4.6%), though variability was higher at 150° (stable: 11.3%).

Comparisons of EMG measurements at 90° knee angle revealed a significant decrease in muscle activity of RF under the unstable condition ($-57.1\% \pm 22.0$, $p < 0.001$). Conversely, a non-significant increase in muscle activity was observed for BF ($+29.8\% \pm 75.4$, $p > 0.05$).

Comparing stable conditions at 90° and 150° showed significantly higher muscle activity for BF ($+163.8\% \pm 149.2$, $p < 0.01$) and significantly lower activity for RF ($-60.5 \pm 25.6\%$, $p < 0.001$) and GM ($-37.4\% \pm 25.1$, $p < 0.001$) at 150° knee angle.

Analysis of F_{max_rel} at 90° knee angle showed a reduction in isometric strength of $21.1\% \pm 8.9$ when performed under unstable compared to stable conditions ($p < 0.001$). Comparing F_{max_rel} under stable conditions at 90° and 150° demonstrated a $50.0\% \pm 9.2$ lower maximum strength at 150° ($p < 0.001$).

CONCLUSION: The results demonstrated sufficient reliability under most tested conditions (except unilateral 150°). Further research is required to validate the test and establish its relevance to elite sports performance. The findings suggest that posterior chain muscles fulfill distinct roles depending on foot stability and knee angles during the execution of Hip Thrusts. Accordingly, targeted training regimens could optimize training stimuli, enhance performance and reduce the risk of injury. Finally, implementing an unstable variation of hip thrusts appears to be a highly effective strategy for promoting correct activation patterns in posterior chain muscles.

APPLYING MULTIPLE-SPRINT FATIGUE INDICES TO FLYWHEEL SQUAT: A RELIABILITY STUDY

TORRADO PINEDA, P., SALSE BATÁN, J., MARINA EVRARD, M., CARBONELL JORDI, A.

INEFC

INTRODUCTION: Fatigue indices have been employed to assess athletic performance decrements in repeated sprint ability tests (RSA) where short resting periods are allowed between repetitions [1]. Flywheel devices (FD) are widely used in resistance training for their adaptive resistance, enabling maximal exertion per repetition [2]. FD are ideal for assessing fatigue since, unlike RSA, there is no rest between repetitions. Therefore, performance can decline within the set, in spite of being stable between sets. Despite numerous studies focused on fatigue with FD, there is a gap regarding the best formulae to quantify the drop-off in performance. This study aims to explore the reliability of eight established fatigue indices, typically used in RSA tests, applied to the squat exercise on a FD.

METHODS: Seven males and 11 females performed 2 sets of 6 half-squat repetitions at maximal velocity at an inertial load of 0.13 kg·m² with 3 minutes of rest in between.

Fatigue during each set was calculated from mean power of the concentric phase using eight formulae [3]. A paired T-test was conducted to evaluate differences between sets in repetition one and mean value of each set. Reliability was presented as intraclass correlation coefficient (ICC) and coefficient of variation (CV).

RESULTS: Sixty one percent of highest mean power values occurred in repetition one in set 1, compared with 50% in set 2. There were no significant differences between sets neither in repetition 1 ($p=0.897$) nor in the mean value of the set ($p=0.765$). The ICC values ranged from 0.718 to 0.833, showing good relative reliability across the different formulas [4]. In contrast, absolute reliability (CV) was $\geq 20\%$ in all formulas except in those which consider the highest and lowest mean power values of the set.

CONCLUSION: While most methods demonstrated good reliability, some exhibited considerable variability as previously reported [3]. Although the usefulness of these measures is questioned to calculate fatigue during RSA due to the lack of reliability [5], we found

that methods considering the highest and lowest mean power values exhibited lower variability while maintaining good reliability. However, these indices only represent the percentage of change, without considering whether performance declines or increases from the beginning of the set. For FD squat exercise, where it is important to determine the time-course of fatigue throughout the set, we suggest as the most appropriate indexes, those that consider the percentage difference between the beginning and the end of the set, particularly the first and last repetition.

STATISTICALLY SIGNIFICANT BUT PRACTICALLY IRRELEVANT CHANGES IN JUMP HEIGHT AFTER REPEATED BOUTS OF COUNTER-MOVEMENT-JUMPS: A NON-INFERIORITY STUDY

WIEDENMANN, T., RAPPELT, L., NIEDERER, D., BAUMGART, C., HEINKE, L., JAVANMARDI, S., MOMMARTZ, O., HELD, S., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: The counter-movement-jump (CMJ) is commonly used to estimate training readiness and neuromuscular fatigue [1]. Typically, multiple jumps (sets of 3 – 5) are performed to enhance test sensitivity and reduce variability. However, repeatedly performing maximal jumps in a short period of time may itself induce fatigue, complicating the interpretation of results. This non-inferiority study aimed to determine the maximum number of CMJ sets that can be performed in a single session without inducing statistically significant and practically relevant decreases in jump height.

METHODS: Therefore, 97 young active (female & male) adults attended the lab twice. The first visit consisted of anthropometric evaluations and CMJ familiarization. The second visit started with a standardized cycling warm-up (10 min; 100 W; 80 rpm) and three submaximal CMJ. After 2 min of rest, participants completed sets of 3 maximal CMJ (15 s rest between jumps) at Baseline (T0) and every subsequent three minutes (T3–T24; 9 sets in total). Jump height was estimated using two distinct methods: (i) the flight time method and (ii) the impulse–momentum method. For both methods, performance was analyzed as the mean of all three jumps, the two highest jumps, the highest jump, and the median jump. To determine equivalence between timepoints, the maximal difference between the jump heights at T0 (DmaxT0; highest – lowest jump) was determined. Jump height at T3–T24 were deemed equivalent to T0, if their mean difference and corresponding 95% confidence intervals were entirely within the ‘irrelevant margin’, defined as $T0 \pm 0.5 \times DmaxT0$.

RESULTS: An ANOVA revealed statically significant time-effects for all four data handling methods in both the impulse–momentum ($F(8, 760) \geq 34.50$, $p < 0.001$, $\omega^2 \leq 0.26$) and the flight-time method ($F(8, 760) \geq 19.71$, $p < 0.001$, $\omega^2 \leq 0.16$). For the impulse–momentum method, post-hoc testing revealed a statistically significant reduction from T9 (median, two highest, and highest) and T12 (mean) onwards compared to T0. For the flight-time method, post-hoc testing revealed a statically significant reduction from T9 (highest), T12 (median, two highest) or T15 (mean) onwards compared to T0. However, all changes from baseline across all time points and analysis methods remained within the irrelevant margin.

CONCLUSION: To improve the accuracy and sensitivity of jump height estimation, practitioners and researchers should assess multiple jumps at each time point and use an average of at least two jumps. While jump height declined significantly after only 4 to 5 sets of 3 jumps, the decrease was smaller than the baseline noise and thus likely too small to be considered a practically relevant fatigue-related performance decline.

THE RELATIONSHIP BETWEEN INTENSITY AND NUMBER OF REPETITIONS FOR CMJS

HOWALDT, J., BARZYK, P., GRUBER, M.

UNIVERSITY OF KONSTANZ

INTRODUCTION: The countermovement jump (CMJ) is widely used in sports as a diagnostic tool and as an exercise to assess lower-limb function and enhance neuromuscular jump performance. CMJ-based training regimen typically follow best-practice guidelines, emphasizing maximal intensity and predefined volumes. However, submaximal CMJs may impose similar loads on the ankle and knee while reducing hip joint demand, indicating unexplored potential by varying the intensity of jumps during training (Lees et al., 2004). Moreover, jumps have been used recently to create a high intensity interval training (Kramer et al., 2019), requiring a high number of jumps throughout one training session. In order to individualise submaximal jump-training, the relationship between jump height (intensity) and number of repetitions (volume) must be known. At present, this relationship has not been studied and is unknown. Thus, the aim of the present study was to assess the relationship between jump height and number of repetitions until failure for CMJs.

METHODS: In a within-subject design, 16 young, healthy adults (7 female, 9 male) performed randomized trials of repetitive CMJs until exhaustion at target intensities of 55%, 70%, 85% and 100% of their maximal baseline CMJ height. Participants received visual feedback on their jump intensity after every jump. Break time was standardized with an auditory signal 1 s after ground contact, and trials stopped when participants fell below their target range (target intensity -7.5%) for three consecutive jumps.

RESULTS: Results showed progressively more repetitions until failure at lower intensities with an average of 11 (SD = 7) repetitions at 100%, 55 (SD = 42) repetitions at 85%, 134 (SD = 75) repetitions at 70% and 424 (SD = 334) repetitions at 55%.

CONCLUSION: These results create baseline values for intensity-dependent standardizations of CMJ-based training protocols and training interventions. The observed relationship between intensity and repetitions until failure appears to follow a hyperbolic curve, resembling common power-duration relationships. The present study paves the way for future research to explore whether CMJs adhere to established power-duration models and how this relationship might inform training prescriptions and fatigue management strategies for jump-training.

JUMPING FOR EFFICIENCY: EXPLORING COUNTERMOVEMENT JUMP PROFILES IN SHANGHAIS SUB-ELITE YOUTH ATHLETES

XU, L., XIAOFENG, Y., CHEN, J.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: The measurement of vertical ground reaction force (GRF) during countermovement jumps (CMJ) is the most used assessment for lower extremity power in athletes. Previous studies have shown that CMJ profile characteristics, such as curve shape and peak force timing, can distinguish movement patterns in adult athletes[1,2]. This study aimed to validate the ability of CMJ profiles to differentiate movement efficiency in youth athletes.

METHODS: GRF data from CMJs performed by Shanghai city-level sub-elite youth athletes were analyzed. Jumps were conducted with arms akimbo on dual force plates (VALD, ForceDeck Lite) as part of routine monitoring, following standardized procedures. A single best jump per athlete (243 total trials: 143 males, 105 females; aged 14.7 ± 1.3 years) was included. Sports represented included track and field, baseball, swimming, and others. Jumps were categorized based on (1) peak force timing, specifically whether peak force occurred at the lowest center of mass (COM) position, and (2) GRF curve shape (unimodal or bimodal) using predefined criteria[2,3]. Performance metrics (jump height, modified reactive strength index), movement pattern metrics (e.g., phase times, countermovement depth), and phase-specific force and power metrics were analyzed. Data normality was assessed using the Shapiro-Wilk test. T-tests or Mann-Whitney U tests were applied for group comparisons, with effect sizes reported. Profiles were further classified into four groups for additional analysis. ANOVA or Kruskal-Wallis tests were used for multi-group comparisons. The significance threshold was set at $p < 0.05$.

RESULTS: In males, jumps where peak force coincided with the lowest COM position showed superior performance (9% higher jump height, 12% greater reactive strength index) and braking phase metrics (12%–36% higher outputs). Unimodal profiles demonstrated faster movement patterns (7%–15% shorter phase durations) and deeper countermovement (21% greater depth) compared to bimodal profiles, though jump height was similar. Further classification revealed that among four categories, unimodal profiles, where peak force coincided with the lowest COM position, demonstrated superior outputs across most metrics, indicating that this may represent the optimal movement strategy. Among females, significant differences were observed only with GRF curve shape, with shorter phase durations, deeper countermovements, and higher braking phase outputs, while no significant differences were associated with peak force timing.

CONCLUSION: GRF profiles can differentiate CMJ efficiency in male youth athletes, with jumps exhibiting peak force at the lowest COM position and unimodal curve shapes showing superior efficiency. These findings suggest that this combina-

tion represents the most effective jump strategy, producing higher outputs in shorter durations. However, differences were less evident in female athletes, warranting further study.

CP-AP23 Cycling

RELIABILITY, CONCORDANCE AND AGREEMENT OF A STEP-RAMP-STEP CYCLING PROTOCOL TO EVALUATE ENDURANCE PERFORMANCE VARIABLES IN TRAINED TRIATHLETES.

ROUSSEAU, Q., RABITA, G., SIBLOT, A., MORALES-ARTACHO, A.J.

INSEP

INTRODUCTION: Ramp-incremental (RI) cycling protocols may allow to determine the constant work rate (CWR) oxygen uptake (VO₂)-Power Output (PO) relationship(1) and hence the full spectrum of exercise intensity prescription(2). Endurance performance variables like the Gas Exchange Threshold (GET), the Respiratory Compensation Point (RCP), the maximal VO₂ (VO₂peak) and the energy depleted above RCP (Wramp) can be derived from a Step-Ramp-Step (SRS) protocol(2,3). However, reliability of these variables determined with the SRS protocol has not been reported and the agreement of the corrected PO at RCP (PORCP) and Wramp with gold-standards is equivocal(2,4,5). Also, recent research has focused on moderately active populations (Tier 0 and 1(6)) and studies with fitter individuals are lacking. Therefore, the goals of this study were to: 1) study the reliability of endurance performance variables from a modified SRS protocol in trained triathletes and 2) evaluate the agreement between PORCP and Wramp derived from the SRS protocols with the critical power (CP) and the quantity of energy depleted above CP (W) computed from 4 CWR exercise trials to failure.

METHODS: Twelve trained triathletes (Tier 2(6), 31 ± 6 yr, 72.2 ± 4.3 kg, VO₂peak = 67.9 mL.min⁻¹.kg⁻¹) attended the laboratory 8 times to conduct a SRS protocol (visit 1), multiple CWR trials to failure (visits 2-5), a modified SRS protocol (twice, visits 6 and 7) and a CWR into the heavy-intensity domain (visit 8). PORCP was corrected similarly to recent studies(2,3) and W'ramp>CP or W'ramp>RCP were computed as the energy depleted above CP and PORCP respectively.

RESULTS: Coefficients of variation for VO₂ variables were within a range of 2.1 to 3.7 % (CI95% : [1.5, 3.6] to [2.6, 6.3] %), for corrected PO at GET and RCP 3.0 % and 2.9 % (CI95% : [2.1, 5.1] % and [2.0, 5.9] %) and for Wramp>CP and Wramp>RCP 11.3 % and 11.6 % (CI95% : [8.0, 19.3] % and [8.2, 19.9] %). CP was higher than PORCP (bias 17 to 20 W, bias CI95% : [4, 29] to [6, 35] W, CCC = 0.52 to 0.67) and W' was higher than Wramp>CP (bias 1.5 to 6.2 kJ, bias CI95% : [-1.2, 4.3] to [4.2, 8.1] kJ, CCC = 0.48 to 0.74). Wramp>CP derived from the second modified SRS was higher than Wramp>CP derived from the SRS (+4.6 kJ, CI95% : [1, 8.2] kJ).

CONCLUSION: In trained triathletes, the modified SRS protocol provides good test-retest reliability for GET, RCP and VO₂peak. Using the existing corrections strategies, CP was higher than PORCP and W' was higher than Wramp>CP. Although the variability associated with W'ramp>CP is important, the modified SRS protocol may provide closer estimates for W'ramp>CP than the classical SRS protocol.

OPTIMAL CADENCE FOR OPTIMAL ENDURANCE CYCLING PERFORMANCE

OHAYON, E., CONSTANTINI, K., KADOSH, S.M., MARTINS, T.

TEL AVIV UNIVERSITY

INTRODUCTION: The concept of optimal cadence in cycling performance can be examined from both a metabolic and a biomechanical standpoint. Metabolic Optimal Cadence (MOC) refers to the cadence that minimizes metabolic demands, such as oxygen consumption (VO₂), thereby improving endurance performance. Biomechanical Optimal Cadence (BOC) can be assessed as improved neuromuscular efficiency measured via electromyograph (EMG), where total muscle excitation is minimized. The primary objective of this study was to investigate the possibility of predicting MOC from BOC.

METHODS: Each participant visited the lab twice. Visit 1 included a graded exercise test to determine maximal O₂ uptake (VO₂max) and the first ventilatory threshold (VT1). During visit 2, participants completed 35 minutes of cycling at a constant power output equivalent to 110% of VT1, where every five minutes cadence (60, 70, 80, 90, 100, 110, 120 rpm) was randomly changed. Participants were equipped with 13 EMG sensors on the quadriceps and hamstrings muscles, tibialis anterior, gastrocnemius, gluteus max and multifidi of the right side of the body. Additionally, they were connected to a metabolic system to allow continuous monitoring of metabolic variables. One minimum point was extracted from fitted parabolic

curves for VO₂ (i.e., MOC) and for muscles excitation and co-contraction (i.e., BOC) for each participant. Model II linear regression and Bland-Altman plots were performed to assess the relationship between MOC and BOC.

RESULTS: Fifteen highly trained triathletes and cyclists participated in this study (14 males; mean±SD; age: 24±5 years, height: 1.76±0.05 m, body mass: 66.8±5.1 kg, VO₂max: 65.9±8.3 mL/kg/min, training volume: 18±7 hours per week). They came from the fields of triathlon, road, cross country and track cycling (n=9,3,2,1 respectively). The preferred cadence reported by the participants was 88±9 rpm. As analysed from VO₂ data, MOC was 60±14 rpm. Conversely, EMGs provided greater BOC values (95±13 rpm for KE, 84±14 rpm for KF). The mean BOC leading to minimal KE-KF co-contraction was 91±7 rpm. For plantar flexors and for ankle co-contraction, BOC values were respectively 85±18 rpm 87±18 rpm. The relationship between MOC and KE showed fixed bias (35 rpm) with confidence interval (CI) for the intercept between 1.8-64.6 rpm. The relationship between MOC and KE-KF co-contraction showed both proportional bias (CI intercept: 38.2-73.7 rpm) and fixed bias (CI slope: 0.3-0.9). According to the Bland-Altman analysis, difference MOC and BOC were highly variable (CI: 1-71 rpm).

CONCLUSION: BOC values were on average greater than MOC values. Notwithstanding the fixed bias observed for KE, suggesting MOC may be predicted from KE EMGs (i.e., MOC = BOC – 35 rpm), the somewhat high variability observed in the Bland-Altman plots between MOC and BOC KE warrants further investigation.

SIMILAR PERFORMANCE AND MUSCLE ADAPTATIONS BETWEEN INTERVALS WITH AND WITHOUT BLOOD FLOW RESTRICTION IN WELL-TRAINED CYCLISTS

ZAMBOLIN, F., VIKMOEN, O., CUMMING, K.T., SKATTEBO, Ø., ØSTGAARD, H.N, ØFSTENG, S., HAMMARSTRÖM, D., HANSEN, J., RØNNESTAD, B.R., RAASTAD, T.

MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: Blood flow restriction (BFR) allows exercise at lower absolute intensity yet, showing similar or greater results compared with traditional training in non-trained individuals. However, since the effects in well-trained competitive athletes are unclear, the current study aims to compare the effect of an effort matched short HIIT microcycle performed with or without BFR, on indicators of endurance performance in well-trained cyclists.

METHODS: 17 well-trained cyclists (aged 31 ± 9 years, maximal oxygen uptake (VO₂max: 67±6mL/min/kg) were randomised in two groups performing a microcycle of five HIIT sessions (6 x 5 min intervals with 2.5 min of recovery) with (BFR group) or without (HIIT group) a cuff over the thighs occluding the limbs. An exercise cycling test was used to assess VO₂max, mean power output at 4 mmol/L blood lactate (LT4), and mean power output during 5-min maximal cycling (MPO5) and the percentage of maximal oxygen consumption used at LT4 (%VO₂max @LT4). Haemoglobin mass (HB) and blood volume (BV) were measured by CO rebreathing. Moreover, muscle biopsies on the vastus lateralis were used to evaluate muscle cross-sectional area (CSA), capillaries around fibre area (CAFA), citrate synthase (CS), Hydroxyacyl-Coenzyme A dehydrogenase (HADH), cytochrome c oxidase 4 (COX4), and αβ-Crystallin (CRYAB)

RESULTS: The BFR group trained at a lower power output compared to the HIIT group (177±3 W vs 307±8 W, respectively, p<0.01), but with no group differences in heart rate or rate of perceived exertion. Both groups significantly improved MPO5, with no significant changes in LT4, VO₂max, HB and BV. However, only HIIT improved significantly %VO₂max@LT4. Moreover, HIIT showed a significant reduction in CSA for type 2 muscle fibres compared with BFR whereas no significant changes were found in the other biomolecular indexes.

CONCLUSION: BFR applied during a 6-day microcycle provides similar but not greater physiological adaptations than traditional HIIT linked to exercise performance in well-trained cyclists. BFR achieved similar performance gains as the HIIT group with similar perceived effort and heart rate, but with 40% lower average power output during the training sessions. Moreover, despite HIIT having a significant reduction in CSA type 2 compared to BFR, no group differences were observed in capillarisation, CS, HADH, COX4, αβ-Crystalline (CRYAB) content. These results might be important for athletes who are seeking to promote positive adaptation in a relatively short period of time, or athletes who are recovering from injuries and want to obtain similar adaptation as HIIT with reduced mechanical stress. Future studies will be needed to ascertain if these adaptations can be maximized following consecutive intensified blocks and be of benefit to elite athletes with higher cardiorespiratory fitness and performance.

FAMILIARIZATION IS CRUCIAL FOR TESTING THE MAXIMAL RATE OF LACTATE ACCUMULATION

MEIXNER, B., SPERLICH, B.

JULIUS-MAXIMILIANS-UNIVERSITÄT WÜRZBURG

INTRODUCTION: Recently, the testing procedure for the maximal rate of capillary blood lactate accumulation following an all-out sprint test of 10 - 30 s has gained popularity. The metabolic implications of this parameter are based on simulations of human muscle energy metabolism described by the mathematical equations of Mader. While there is still a scarcity in the literature on this matter, the reliability of the testing procedure has been well studied.

Most of the studies describing good to excellent reliability in many modalities of the procedure include 2 or 3 trials. In studies involving 2 trials, reliability of subsequent trials is unknown as only one exists. Meanwhile, studies involving 3 trials have analyzed all three trials together. However, it is unknown if familiarization changes the results (i.e., what changes are caused by learning effects) and therefore the possible metabolic implications.

Therefore, the aim of this study was to determine differences in relevant variables (peak and mean power output, capillary lactate accumulation) between familiarization and subsequent trials.

METHODS: 50 cyclists performed a 15-s all-out sprint test in isokinetic mode at 130RPM on a Cyclus2 ergometer on three separate (T1, T2, T3) occasions. Capillary blood was sampled twice before and every minute (for 8 minutes) after the sprint to determine the difference between resting and peak post-exercise lactate values as maximal lactate accumulation.

Glycolytic contribution was calculated as the product of lactate accumulation, fat-free mass and the mechanical energy equivalent of lactate of 12J/kg FFM (Meixner et al. 2024). The fraction of glycolytic contribution to total work was also calculated. The One-way ANOVA was performed to determine differences in trials in peak and mean power output, capillary lactate accumulation, glycolytic contribution (Wgly) and percent of glycolytic contribution (%Wgly).

RESULTS: Peak and mean power output was significantly lower in T1 compared to T2 and T3. Capillary blood lactate accumulation was significantly higher in T1 compared to T2 and T3. Accordingly, Wgly and %Wgly also significantly decreased in T2 and T3. No differences were found between T2 and T3.

CONCLUSION: Several studies have shown that increased lactate accumulation and power output are intricately linked. Our results display a paradoxical behavior between T1 and subsequent trials: while lactate accumulation decreases, power output increases.

This is noteworthy as two relevant output components change in opposite directions and potentially obfuscate the relationship between power output and lactate accumulation. These findings highlight familiarization as a crucial element in this diagnostic procedure and we urge practitioners to include a familiarization trial in their practice.

HIGH CADENCE IN CYCLING – PHYSIOLOGICALLY OPTIMAL OR JUST A TREND?

CONSTANTINI, K., OHAYON, E., KADOSH, S.M., MARCUS, I., VIEIRA, T.M.

TEL AVIV UNIVERSITY

INTRODUCTION: There is a wide spread notion among coaches and athletes that cycling at a high cadence is advantageous for athletic performance. However, scientific data indicates that - at least metabolically - the "optimal" cadence is lower. Specifically, various physiological variables (e.g., heart rate (HR), O₂ uptake (VO₂), blood lactate concentration (BLA-)) have been shown to be lowest (i.e., physiologically advantageous) at cadences of 50-60 rpm, while cycling on a stationary ergometer – a condition that does not reflect real life cycling. Thus, this study aimed to comprehensively examine the effects of different cadences on metabolic, ventilatory and perceptual variables while riding on a motorized treadmill.

METHODS: Fifteen highly trained cyclists and triathletes (f=1; Mean±SD: age: 24±6 years; height: 1.76±0.05 m; weight: 66.9±5.1 kg) completed two exercise sessions: 1) maximal graded exercise test from which maximal O₂ uptake (VO₂max) and power output at the first ventilatory threshold (VT1), and 2) a 30-min submaximal bout at constant power output equivalent to 110% VT1. Every 5 minutes during the submaximal effort, subjects were instructed to change gears to match the target cadence (60, 70, 80, 90, 100 or 110 rpm, in a random order). HR and metabolic variables were continuously recorded, while rating of perceived exertion (RPE; 0-10 scale) and BLA- were obtained at the end of every stage. Mixed linear models were used to assess differences in physiological variables between cadences.

RESULTS: On Average, VO₂max was 65.9±8.3 ml/kg/min and power output at 110%VT1 was 235±46 watts. VO₂ was significantly (p<0.01) lower at 60 rpm (3127±546 l/min), and CO₂ production (VCO₂) was significantly (p<0.01) lower at both 60 and 70 rpm (2862±503 and 2878±503 l/min, respectively), compared to 90 rpm (VO₂: 3218±546; VCO₂: 2960±503 l/min). No other variables were different between 90 rpm and lower cadences. VO₂ and VCO₂ were significantly (p<0.01) higher at 100 rpm (3319±546 and 3085±503 l/min, respectively) and 110 rpm (3410±546 and 3226±503 l/min, respectively) compared to 90 rpm. At 110 rpm, minute ventilation (VE; 101.0±18.6 l/min), respiratory exchange ratio (RER; 0.95±0.02), %carbohydrates (CHO) oxidation (81.3±7.5 %), HR (155.9±15.6 beats/min), BLA- (2.9±1.2 mmol) and RPE (5.3±1.4) were significantly (p<0.01) higher than 90 rpm (VE: 88.6±18.6 l/min; RER: 0.92±0.02; CHO oxidation: 72.9±7.5 %; HR: 147.7±15.6 beats/min; BLA-: 2.0±1.2 mmol; RPE: 3.8±1.4).

CONCLUSION: This study is the first to examine physiological responses at different cadences while riding on a motorized treadmill, which more closely mimics real world cycling than a stationary ergometer. Our findings indicate that while riding at cadences >100 rpm is more taxing from a physiological and perceptual standpoint than lower cadences, these responses are similar at 60-90 rpm. Thus, using high cadences should be reconsidered as lower ones might be more beneficial, especially for endurance and metabolic efficiency.

COMPARISON OF MUSCLE ACTIVITY AND ENERGY EFFICIENCY IN CYCLING TRAINING WITH THREE-ROLLER SYSTEMS, FIXED-ROLLER TRAINERS, AND ON-ROAD TRAINING

OKADA, T., HORIMOTO, R., UDA, S., KAJIWARA, W., TAKEDA, M.

DOSHISHA UNIVERSITY

INTRODUCTION: The lateral tilt of the bicycle optimizes the direction of force on the pedals (1). This study aims to clarify which training device, fixed roller trainers (Fix) or three-roller systems (Roll), is closer to on-road training in terms of muscle activity, respiratory gas exchange, and kinematic analysis.

METHODS: A pilot study was conducted with one male athlete from the university triathlon team. The experiment involved three conditions: fixed roller (Fix), three-roller (Rol), and treadmill (Tre) simulating actual riding. The athlete pedaled at 75% of their maximal oxygen uptake ($\text{VO}_2 \text{ max}$) for 15 minutes in each condition. During the last 5 minutes of each exercise, external work, electromyography (EMG), respiratory gas, and bicycle and body tilt were measured. The work rate was measured using a power meter (Shimano, FC-R9200-P) attached to the athlete's own bicycle. Respiratory gas exchange was measured continuously during exercise. Kinematic data on bicycle and body tilt were collected using a Motion Capture System (BTS Bioengineering, Italy) and analyzed using specialized software. EMG was recorded using BTS FREEEMG (BTS Bioengineering, Italy) for eight muscles: latissimus dorsi (LD), upper rectus abdominis (RA), gluteus maximus (GMax), long head of the biceps femoris (BF), rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), and medial gastrocnemius (Gas).

RESULTS: The work rates for each exercise ranged from 207 W to 221 W, with Fix showing the highest ventilation volume (VE) [Fix: 98.9 ± 5.1 L/min, Rol: 90.0 ± 5.2 L/min, Tre: 92.9 ± 5.0 L/min]. VO_2 per body weight was lowest with Fix [Fix: 0.33 ± 0.02 L/min/kg, Rol: 0.35 ± 0.03 , Tre: 0.36 ± 0.03 ml/min/kg]. Regarding body and bicycle tilt angles, Fix exhibited the least bicycle sway compared to the other two conditions, with the greatest body sway. The angle A (the angle between the floor and the normal vector of the bicycle) for Fix was $93.6 \pm 0.4^\circ$, while Rol and Tre were $90.9 \pm 0.9^\circ$ and $90.9 \pm 1.1^\circ$, respectively. The angle F (the angle formed when the unit vectors of the sacrum and 7th cervical vertebra, and the bicycle's top tube unit vector are projected onto the floor) was smallest for Fix [Fix: $1.30 \pm 3.09^\circ$, Rol: $-0.19 \pm 1.27^\circ$, Tre: $2.12 \pm 1.62^\circ$].

In terms of muscle activity, GMax showed the highest activity during Tre [0.037mV], followed by Rol [0.026mV] and Fix [0.023mV]. For biceps femoris (BF), both Rol [0.134mV] and Tre [0.135mV] showed greater activity than Fix [0.127mV]. For RF, VM, and VL, Fix exhibited the highest muscle activity: [RF: 0.065mV (Fix), 0.056mV (Rol), 0.058mV (Tre)]; [VM: 0.106mV (Fix), 0.087mV (Rol), 0.082mV (Tre)]; [VL: 0.127mV (Fix), 0.102mV (Rol), 0.102mV (Tre)].

CONCLUSION: The results indicated that muscle activity and bicycle and body tilt differed among the three conditions, suggesting that energy efficiency may vary due to these differences.

IMPACT OF CYCLING STRATEGIES ON MUSCLE ACTIVITY AND ENERGY METABOLISM IN COMPETITIVE CYCLING

RYOJI, H., OKADA, T., NAKANO, H., UDA, S., KAJIWARA, W., TAKEDA, M.

DOSHISHA UNIVERSITY

INTRODUCTION: The superiority of variable-load intensity, in which the load intensity is changed during cycling exercise, over constant-load intensity has been pointed out (1). This study aimed to evaluate the effects of two different conditions—variable-load intensity, where the exercise intensity fluctuates, and constant-load intensity, where a steady intensity is maintained—on muscle activity and cardiorespiratory function.

METHODS: This study was positioned as a pilot study, with a single male university triathlete (maximum oxygen uptake: 58.5 ml/min/kg) as the participant. A cycling ergometer (Monark LC4) was used, and two different 30-minute cycling trials with different load conditions were conducted. The first condition was variable-load intensity, in which the exercise intensity was calculated based on an incremental exercise test performed beforehand, with alternating intensity levels at 95% and 105% of the OBLA threshold every five minutes. The second condition was constant-load intensity, where the participant cycled at the OBLA intensity. The total workload over the 30 minutes was set to be identical for both conditions. The pedaling cadence was set to match the participants' competition cadence.

RESULTS: During exercise, respiratory gas exchange parameters (AE-310s, Minato, Japan) were continuously monitored, blood lactate concentration (Lactate Pro2, Arkray, Japan) was measured every 2.5 minutes, and RPE was recorded every 5 minutes. Electromyography (EMG) (BTS EMG sensors, 1000 Hz) was continuously recorded throughout the entire cycling session. Muscle activity was measured in five muscles of one leg: the rectus femoris, vastus lateralis, biceps femoris long head, medial gastrocnemius, and tibialis anterior. The average oxygen uptake during the 30-minute cycling session was higher for the variable-load condition than for the constant-load condition (45.6 vs. 45.1 ml/min/kg). In the first five minutes, as well as between 10–15 minutes and 20–25 minutes, oxygen uptake was higher in the variable-load condition (39.8 vs. 38.9, 48.0 vs. 45.6, 49.6 vs. 47.4 ml/min/kg). However, in the intervals of 5–10 minutes, 15–20 minutes, and 25–30 minutes, oxygen uptake was lower in the variable-load condition (44.8 vs. 44.9, 44.7 vs. 45.6, 48.0 vs. 45.6, 47.0 vs. 48.2 ml/min/kg).

Regarding muscle activity, the average RMS value of the rectus femoris increased over time from 0.040 mV in the first five minutes after the start of exercise. In the final five minutes before exercise completion, the RMS value was higher in the variable-load condition (0.069 mV) than in the constant-load condition (0.053 mV).

CONCLUSION: These results suggest that the fluctuating intensity of variable-load cycling may induce physiological adaptations, allowing muscles to adapt to various intensities and maintain high muscle activity while minimizing oxygen consumption. In other words, variable-load intensity may lead to higher energy efficiency during cycling.

PHYSIOLOGICAL RESPONSES AND RESPIRATORY MUSCLE FATIGUE TO SUPRAMAXIMAL CYCLING EXERCISE ON POST-WARM-UP BREATHING THROUGH ADDITIONAL RESPIRATORY DEAD SPACE VOLUME MASK.

DANEK, N., HEBISZ, R., HEBISZ, P.

WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: In endurance sports, the frequent interval between the end of the warm-up and the start of the race leads to a loss of cardiorespiratory effects by, among other things, increasing the oxygen deficit during the initial stages of exercise. Therefore, it is worth looking for methods to sustain the effects of the warm-up. The factor that influences vasodilation of vessels and increases vascular blood flow is carbon dioxide, among others. A simple method to increase the arterialized blood CO₂ partial pressure (pCO₂) is to breathe through the additional respiratory dead space volume mask (POOPM). Therefore, it is possible that breathing through the POOPM during the interval between warm-up and intense exercise may increase oxygen uptake during exercise. We hypothesized that breathing through the POOPM during the interval between warm-up and 3-minute 110%P_{max} exercise would achieve, among other things, higher oxygen uptake (VO₂) during exercise. The purpose of this study was to compare acute physiological, biochemical and perceptual responses during supramaximal cycling exercise on post-warm-up breathing through by POOPM and without the device.

METHODS: Twelve cyclists (VO₂max: 57.5±6.1ml/kg/min) participated in the study. During 3 visits to the laboratory with a minimum break of 48 h, they participated in (1) an incremental test (IET) on a cycloergometer with respiratory gas analysis; (2) and (3) crossover sessions of a 110% of maximal power of IET (110%P_{max}), each lasting 3-min. Each of the 110%P_{max} tests was followed by a 15-min warm-up and an 8-min passive break. In the experimental condition (EC), immediately after the warm-up, a mask was used for 7-min with an increased tidal dead space volume of 1000ml (POOPM). In the control condition (CC), participants passive waiting for a test without POOPM. After a break, each performed a 3-min of 110%P_{max} test on a cycloergometer. During the entire test procedure, respiratory parameters were measured (excluding the POOPM breathing phase) in the same procedure as in the IET.

RESULTS: After a 3-min 110%P_{max} test preceded by POOPM mask breathing after warm-up, we observed a 6% increase in peak oxygen uptake (VO₂peak) (p<0.05) compared to CC (60.9 versus 57.8 ml/kg/min). VO₂mean was not significantly different between conditions. No differences were observed in the change in peak heart rate (HRpeak) where in EC was 195 u/min and in CC it was 193 u/min. There were also no statistically significant differences in lactate concentration after the 3-minute test, with 11.65 and 11.55 mmol/L in EC and CC, respectively. Rate of perceived exertion (RPE) did not significantly difference between conditions, while a statistically significant 4% higher inspiratory muscle strength was observed after the test in the EC condition (p<0.05).

CONCLUSION: Breathing through POOPM during the post-warm-up phase leads to higher peak oxygen uptake in 3-min supramaximal cycling exercise (100%P_{max}), with greater inspiratory muscle engagement and lower RPE.

ACUTE PHYSIOLOGICAL RESPONSES TO HEART RATE- AND CRITICAL POWER-BASED HIGH INTENSITY INTERVAL TRAINING

BONE, J., RICHARDS, D.L., GIBALA, M.J.

MCMASTER UNIVERSITY

INTRODUCTION: High intensity interval training (HIIT) is characterized by repeated bouts of relatively hard work interspersed with recovery periods, with bouts commonly prescribed at an intensity that elicits ≥80% of maximal heart rate (HR_{max}) [1, 2]. Exercise prescription based on “traditional” anchors such as HR_{max} can be associated with large interindividual response variability [3]. An alternative approach is to characterize intensity using metabolic thresholds, which demarcate intensity “domains” that reflect distinct profiles of physiological stress [4]. The application of metabolic thresholds such as critical power (CP) to prescribe HIIT, as commonly done in the training prescription for athletes, could reduce variability in physiological responses. We therefore examined whether an acute session of HIIT in which intensity was anchored to CP elicited lower variability in blood lactate (BLA-) accumulation as compared to a %HR_{max}-based approach.

METHODS: Healthy active adults (9 males and 10 females; 23±4 years) with a peak oxygen uptake (VO₂peak) of 46±7 ml·kg⁻¹·min⁻¹ were recruited. CP was initially determined based on three to five maximal, constant load tests [5]. Participants performed two familiarization visits before completing two experimental trials in a randomized, crossover, single-blind manner. Each trial involved a 5-min warmup followed by a 4x4-min HIIT session performed at a workload corresponding to CP+10% of work prime (CPHIIT) or one that elicited 80-90% HR_{max} (HRHIIT). Capillary BLA- samples were obtained at rest before exercise and immediately after the fourth bout. HR and rating of perceived exertion (RPE) were measured during each bout and expired gases were measured during the first and fourth bouts.

RESULTS: There was no difference in the variability in [BLA-] accumulation between CPHIIT and HRHIIT (1.33±1.13 vs 1.44±0.86 mM; p=0.75). Net [BLA-] accumulation was also not different (6.72±1.78 vs 6.13±1.71 mM, respectively, p=0.10). Workload was higher in CPHIIT vs HRHIIT (192±39 W vs 180±43 W; p=0.001). Mean exercise VO₂ was higher in CPHIIT vs HRHIIT (2.86±0.61 vs 2.72±0.65 L/min, p=0.002). CPHIIT elicited a higher mean (156±13 vs 153±10 beats/min, p<0.0001) and peak exercise HR (169±12 vs 166±9 beats/min, p<0.0001). RPE was also higher in CPHIIT vs HRHIIT (14±2 vs 13±2, p=0.003).

CONCLUSION: Anchoring exercise intensity to CP did not reduce variability in BLA- accumulation compared to a traditional, %HR_{max}-based approach. Participants, however, achieved a higher workload that elicited a greater cardiorespiratory and perceived stress during the CP- vs %HR_{max}-based trial, which could translate to divergent training-induced responses.

BIOMECHANICAL AND METABOLIC RESPONSES TO PEDALING CADENCE AND ROAD GRADIENT VARIATIONS DURING SUBMAXIMAL CYCLING: A 2x2 FACTORIAL STUDY

AMATORI, S., DELLANNA, S., BERNARDES A.G., AZZALI, G., LIBERALI, G., PRIVITERA, M., DI NOTO, L., BRIANDA, D., SISTI, D., ROCCHI, M.B.L., PERRONI, F., BALDARI, C., BUZZACHERA, C.F.

ECAMPUS UNIVERSITY

INTRODUCTION: In cycling, different pedaling cadences elicit distinct metabolic, neuromuscular, and biomechanical responses (Ahlquist et al., 1992; Broxterman et al., 2015). Pedaling cadence can vary considerably due to multiple factors, with road gradient playing a key role. However, research on the influence of road gradient on metabolic and biomechanical responses remains limited. To address this gap in the literature, we conducted a 2x2 factorial study to investigate the combined effects of pedaling cadence and road gradient on cyclists biomechanical and metabolic parameters during submaximal cycling.

METHODS: Twelve well-trained male cyclists (age: 29.2 ± 10.1 years, $\text{VO}_{2\text{max}}$: 60.3 ± 9.1 ml/kg/min) visited the laboratory on two separate occasions. During the first visit, they performed a ramp incremental exercise test (30 W/min) to determine power output at the first (WGET) and second (WRCP) ventilatory thresholds. On the second visit, participants completed, in a random order, four 5-min bouts at 100% WRCP in different conditions: flat low-cadence (0%, 55-60 rpm), flat high-cadence (0%, 90-95 rpm), uphill low-cadence (6.5%, 55-60 rpm), uphill high-cadence (6.5%, 90-95 rpm). Power, torque, cadence, heart rate, pulmonary gas exchange and ventilation data, biomechanical variables (i.e., crank-torque profile), and perceived exertion were recorded. A linear mixed-model analysis was used to compare conditions (high vs. low cadence; flat vs. uphill).

RESULTS: Pedaling cadence significantly influenced all measured biomechanical parameters. Specifically, in the low-cadence conditions, higher torque efficiency ($p < 0.001$) and pedaling smoothness ($p < 0.001$) were observed, along with a wider angular range of positive torque ($p = 0.001$). Additionally, the angle at which peak torque (T_{peak}) was expressed occurred earlier in both low-cadence ($p = 0.001$) and uphill ($p = 0.001$) conditions. Lower oxygen uptake (VO_2 ; $p = 0.027$), respiratory frequency ($p = 0.006$), and perceived exertion ($p = 0.025$) were also reported in low-cadence conditions compared to high cadence, irrespective of road gradient.

CONCLUSION: Our results confirm that pedaling cadence influences metabolic responses, with higher VO_2 and respiratory frequency observed in high-cadence conditions, irrespective of road gradient. Both cadence and road gradient affected the crank-torque profile, particularly the angle of T_{peak} , thereby influencing torque distribution throughout the pedal cycle. Our findings align with the assumption that training under specific conditions (uphill and level ground, low and high cadences) may induce distinct adaptations in cyclists (Bertucci et al., 2005). Moreover, since the work rate associated with intensity boundaries varies, this raises the question of whether training zones, commonly used for prescriptions in training programs, should be adapted for different cadences.

CP-AP27 Body Composition and Ageing

PHYSIOLOGICAL ADAPTATIONS AND TRAINING STRATEGIES IN THE TRANSITION FROM LIGHTWEIGHT TO HEAVYWEIGHT ROWING: A MULTI-YEAR CASE STUDY OF AN OLYMPIC FINALIST.

COLOSIO, A., COCQUYT, S., BOURGOIS, J.G., BOONE, G.

JEAN MONNET UNIVERSITY SAINT-ETIENNE

INTRODUCTION: Paris 2024 marked the final Olympic Games featuring lightweight rowing as a competitive category. In preparation for Los Angeles 2028, many elite lightweight rowers worldwide must transition to the heavyweight class to remain eligible for Olympic competition. This transition requires optimized training strategies and efficient body composition adjustments to maximize performance. This study reports the physiological adaptations and training practices over three years in a Belgian rower who successfully transitioned to the heavyweight category and placed fourth at the Paris 2024 Olympics after reaching the final in the lightweight event at Tokyo 2020.

METHODS: Physical testing was conducted at least once per year from April 2021 to June 2024 to monitor changes in physical and physiological variables during the weight transition. Assessments included anthropometric measurements, an incremental rowing test, power profiling, and maximal strength testing.

The training program over 145 weeks was analyzed to provide insight into training characteristics, including total volume, the relative contributions of rowing, alternative training, and strength training, as well as training intensity distribution (TID). The training period was divided into four phases corresponding to the years 2021, 2022, 2023, and 2024, and training characteristics were compared using a one-way analysis of variance (ANOVA) with post-hoc Tukey tests.

RESULTS: Body weight increased from 74.6 kg (fat-free mass: 72.1 kg) on April 21, 2021, to 81.8 kg (fat-free mass: 74.4 kg) on June 21, 2024, with the majority of changes occurring in the first year (2022: body weight 81.4 kg, fat-free mass 74.6 kg).

$\text{VO}_{2\text{peak}}$ increased from $5.65 \text{ L}\cdot\text{min}^{-1}$ ($75.74 \text{ mL}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$) to $6.06 \text{ L}\cdot\text{min}^{-1}$ ($74.08 \text{ mL}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$), while peak power output increased from 489 W to 508 W. Strength values for the squat and bench pull changed from 110 kg and 100 kg (2021) to 128 kg and 97 kg (2024), respectively.

The mean weekly training volume was 15 ± 4 hours, consisting of $53.3 \pm 26.6\%$ rowing, $26.4 \pm 6.6\%$ strength training, and $20.3 \pm 12.6\%$ alternative training. The training intensity distribution (TID) for rowing, based on heart rate zones, was 83.2% zone 1, 9.9% zone 2, and 6.7% zone 3. The proportion of zone 1 training increased significantly ($p < 0.05$) from 72.6% in 2021 to 89.3% in 2024, while the contributions of zones 2 and 3 decreased progressively each year ($p < 0.05$) up to Paris 2024.

CONCLUSION: This multi-year case study provides insights into the transition from lightweight to heavyweight rowing in an athlete who reached the Olympic finals in both Tokyo 2020 and Paris 2024. The data suggest that early-phase physical preparation is critical for a successful transition and can serve as a reference for coaches and sports scientists supporting athletes preparing for Los Angeles 2028.

ANTHROPOMETRIC PROFILES AND BODY COMPOSITION ASSESSMENT IN BULGARIAN BODYBUILDERS

KOLIMECHKOV, S., ZAYKOVA, D., PETROV, L.

KENSINGTON & CHELSEA GYMNASTICS ACADEMY

INTRODUCTION: Bodybuilding places a strong emphasis on achieving a balanced and aesthetically pleasing physique. This involves developing both size and proportion. Achieving a very low body fat percentage (BF%) is crucial to minimize the subcutaneous fat obscuring the underlying muscle definition, allowing for a more pronounced and impressive display of muscle volume and separation. The aim of this study was to compare anthropometric profiles of Bulgarian bodybuilders with classic bodybuilding parameters.

METHODS: This study included 11 bodybuilders with a mean age of 24.3 ± 4.3 years, who were practising bodybuilding for at least 6 years with a mean sport experience 8.19 ± 2.55 years, and an average of 10 hours per week. The height and body mass were measured preciously, and BMI was calculated. Arm, thigh, and calf circumferences were measured with the LufkinW606PM tape and compared to the 'ideal' standards for male bodybuilders developed by David Willoughby. The following skinfolds were measured: pectoral, triceps, axilla, suprailiac, abdomen, subscapular, thigh, and calf by using the Lange Skinfold Calliper. BF% was calculated based on the measured skinfolds by using Jackson & Pollock's 1976 and Katch & McArdle's 1973 equations for men. The percent muscle mass (MM%) was calculated by using the equations of Lee et al. Additionally, body fat percentage (BF%BIA) and muscle mass percentage (MM%BIA) were also measured by using BIA method with the Omron BF-511. The descriptive statistics test of distribution normality (Shapiro-Wilk), paired Student's t-test, and correlation and regression analyses were conducted with SPSS 19 (IBM, USA).

RESULTS: The average BF% (Katch & McArdle) was $8.2\% \pm 2.0$, which was within the reported BF% in the literature for male bodybuilders before competitions (6-10%). Height was 175.4 ± 6.2 cm, body mass was 81.3 ± 9.3 , and BMI of $26.4 \pm 1.7 \text{ kg/m}^2$. Regression equations with high correlation coefficient (0.997-1.000) for 'ideal' body circumference were obtained. Body mass, BMI, as well as the measured circumferences, except neck, did not differ significantly from the calculated 'ideal' measures for male bodybuilders. The individual BMI of some of the bodybuilders was above the normal limits provided by WHO due to the large MM% ($47.2 \pm 2.9\%$).

CONCLUSION: The anthropometric profiles of the bodybuilders in our study did not differ significantly from the 'ideal' standards published by Willoughby. Bodybuilders can apply the 'ideal' standards to compare and assess their body sizes. Our regression equations can be utilised to precisely calculate the published 'ideal' body circumferences for each individual. Although on a small number of participants, we also concluded that using the 3-skinfold equation of Katch & McArdle for calculating BF% provided the most consistent results compared to Jackson & Pollock's 7-skinfold and BIA Omron BF-511.

A MULTI-SPORT COMPARISON OF MUSCLE-TO-BONE RATIOS IN FEMALE COLLEGIATE ATHLETES

DONALD, D., JUCKETT, W., STANFORTH, P.

UNIVERSITY OF MINNESOTA; UNIVERSITY OF TEXAS AT AUSTIN

INTRODUCTION: The purpose of the present study was to compare the muscle-to-bone ratio (MBR) in National Collegiate Athletic Association (NCAA) Division I female athletes ($n=338$) to healthy, age-matched controls ($n=205$). In addition, to examine MBR in weight bearing and non-weight bearing sports.

METHODS: Total and regional lean mass (LM), fat mass (FM), and bone mineral content (BMC) were determined by dual X-ray absorptiometry (DXA). MBR was calculated by dividing LM by BMC. Female athletes were categorized by sport: basketball ($n=66$), diving ($n=17$), soccer ($n=69$), softball ($n=71$), swimming ($n=93$), and volleyball ($n=22$).

RESULTS: The controls were significantly ($P<0.001$) shorter (163.9 ± 6.6 vs. 171.4 ± 8.9 cm) and weighed less (61.7 ± 9.4 vs. 69.2 ± 10.3 kg) than female athletes. There were significant ($P<0.01$) differences between controls and female athletes for total LM (40.6 ± 5.5 vs. 48.8 ± 6.0 kg), FM (18.9 ± 5.6 vs. 17.7 ± 5.2 kg), and BMC (2.3 ± 0.3 vs. 2.9 ± 0.5 kg). Although there were significant differences in body composition between controls and female athletes, there was no difference in total MBR.

between controls and female athletes (17.3 ± 1.4 vs. 17.2 ± 1.9 , $P=0.38$). Regionally, controls had significantly higher trunk (27.9 ± 2.9 vs. 26.8 ± 4.3 , $P<0.001$) and leg MBR (16.7 ± 1.7 vs. 15.8 ± 2.0 , $P<0.001$) than female athletes but lower arm MBR (13.8 ± 1.7 vs. 14.5 ± 1.5 , $P<0.001$). Sport differences were noted as total MBR being significantly higher in swimming (19.0 ± 1.4) than basketball (15.4 ± 1.9), soccer (16.7 ± 1.2), softball (17.1 ± 1.2), and volleyball (16.5 ± 1.1). Total MBR was similar in swimming and diving (17.9 ± 1.3). The total MBR in basketball players was lower than the other sports examined. Arm MBR showed a similar trend with swimmers (15.4 ± 1.4) having a higher arm MBR than basketball (14.5 ± 1.5), soccer (13.8 ± 1.4), softball (14.0 ± 1.3), and volleyball (13.8 ± 1.4). Arm MBR was similar in swimming and diving (14.7 ± 1.7). Leg MBR was also higher in swimmers (17.6 ± 1.7) than basketball (14.2 ± 1.6), soccer (14.6 ± 1.2), softball (16.1 ± 1.5), and volleyball (14.7 ± 1.2). Leg MBR was similar in swimming and diving (17.0 ± 2.0).

CONCLUSION: When total MBRs in female athletes was compared to healthy controls there were no significant differences, however there were significant differences in regional MBRs. When female athletes were compared to each other by sport there were significant differences in both total and regional MBRs. Non-weight bearing sports such as diving and swimming had significantly higher total as well as regional MBRs than weight bearing sports such as basketball, volleyball, softball and soccer. The differences identified between sports in total as well as regional MBR may be a result of sport-specific training impacting the balance between muscle and bone. Findings of this study are important as they may provide insight into how training-induced body composition impacts the balance between the tissues which could inform strategies to mitigate discrepancies and prevent injury and optimize performance.

BODY COMPOSITION IN PROMISING YOUTH TENNIS PLAYERS - A PREDICTOR TO SUCCESS?

MOHR, P., EDEL, A., FERRAUTI, A.

RUHR UNIVERSITY BOCHUM

INTRODUCTION: In recent years, physical fitness and athletic anthropometrics are gaining relevance for elite tennis performance in men and women. Consequently, respective measurements should be taken at close intervals in childhood and adolescence. Bioelectrical impedance analysis (BIA) offers a practicable method for recording body composition. However, there is currently no evidence as to which body composition characteristics are associated with performance advantages in junior tennis. Therefore, the aim of the present study was (1.) to analyse body composition characteristics in a large sample of elite nationally ranked pre- and post-matured male and female tennis players and (2.) to calculate correlations between body composition and tennis performance (e.g. ranking position).

METHODS: In the present study, body mass (BM) and composition (percentage body fat [BF%] and skeletal muscle mass [SMM]) of 234 young squad tennis players were examined using BIA (InBody 770; InBody Co, Ltd. Seoul, Korea). Players were in the age groups u12 (11-12 years, $n=27$ male, $n=16$ female), u14 (13-14 years, $n=46$ male, $n=42$ female), u16 (15-16 years, $n=45$ male, $n=20$ female) or u18 (17-18 years, $n=24$ male, $n=14$ female). ANOVA and post-hoc t-tests (with α -correction according to Bonferroni) were used to analyse cross-sectional changes depending on age and gender. Pearson correlation was used to determine correlations between body composition components and tennis performance according to the national ranking position.

RESULTS: In boys, SMM increases significantly between age groups (u12: 18.1 ± 2.4 ; u14: 25.5 ± 6.6 ; u16: 33.2 ± 4.6 ; u18: 37.1 ± 3.9 kg) and was significantly correlated to the ranking position in u12 ($r=-0.414$, $p=0.032$) and u14 ($r=-0.436$, $p=0.002$). In girls SMM increases were less pronounced (u12: 18.6 ± 3.2 ; u14: 23.7 ± 3.2 ; u16: 26.6 ± 3.2 ; u18: 29.3 ± 2.9 kg) but also correlated to the ranking position in the age of u14 ($r=-0.317$, $p=0.041$) and u18 ($r=-0.579$, $p=0.030$). In boys, PBF (u12: 10.4 ± 4.2 ; u14: 10.5 ± 4.0 ; u16: 8.8 ± 3.2 ; u18: 8.0 ± 2.2 %) tend to decrease in u16 and u18 compared to u12 and u14 while in girls (u12: 13.2 ± 3.0 ; u14: 14.9 ± 5.2 ; u16: 18.1 ± 4.0 ; u18: 18.7 ± 4.5 %) PBF increased significantly between u14 and u16. In both sexes, no correlation between PBF and the ranking position was found.

CONCLUSION: The study showed that increased skeletal muscle mass positively correlates with the ranking position of elite young tennis players, particularly in pre-matured boys and in post-matured girls, while the percentage of body fat has no negative impact. It shows that skeletal muscle mass and biological age must be considered in talent identification, while in male adolescent tennis players muscle hypertrophy training beyond normal development is not primarily necessary for being successful. In adolescent females, a high fat-free mass is not primarily necessary, as long as there is a sufficient absolute skeletal muscle mass. Strength training instead of diet can be strongly recommended in older girls.

FROM FAT TO FACTS: NEW SKINFOLD-BASED REFERENCES FOR ASSESSING BODY FAT IN MALE AND FEMALE ADULTS

CAMPA, F., CORATELLA, G., PETRI, C., SPATARO, F., CHARRIER, D., CERULLO, G., BARONCINI, G., FARAONE, E., MARTINELLI, G., ORTENZI, L., SERAFINI, S., VACCARO, S., PINCELLA, M., IZZICUPO, P., PAOLI, A.

UNIVERSITY OF PADOVA: UNIVERSITA DEGLI STUDI DI PADOVA

INTRODUCTION: Anthropometric-based body fat assessment is typically performed using predictive equations. However, these equations, that are limited in the literature, provide estimates and can be prone to errors if not appropriately tailored to the target population. Monitoring raw anthropometric data, such as skinfold thicknesses that are directly related to body fat, offers a method to evaluate body fat without relying on predictive equations. The current multicentric, cross-sectional study aimed to provide new centile curves for the sum of skinfold thicknesses, specific to the general adult population, and to identify phases of significant change during adulthood.

METHODS: Stature, body mass, and eight skinfold thicknesses (i.e., triceps, biceps, subscapular, iliac crest, supraspinal, abdominal, thigh, and calf) were measured according to the International Society for the Advancement of Kinanthropome-

try (ISAK) protocol in 1,313 males and 1,194 females, all adults aged 18–65 years. Smoothed age- and sex-specific percentiles (3rd, 10th, 25th, 50th, 75th, 90th, and 97th) for the sum of eight skinfolds were generated. For both sexes, simple linear regressions of the dependent variable (sum of eight skinfolds) versus the explanatory variable (age) were performed to empirically investigate changes in the response variables slope and to test for potential breakpoints.

RESULTS: This study presented new centile curves for the sum of eight skinfolds, highlighting time-point phases of significant change. In males, skinfold thickness increased by 1.0 mm per year (95% confidence interval: 0.7–1.3) between 21.0 and 59.0 years ($p < 0.001$). In females, a pronounced increase of 3.8 mm per year (95% confidence interval: 0.3–7.3) was observed between 38.5 and 47.0 years ($p = 0.035$).

CONCLUSION: New reference values for assessing body fat using the sum of eight skinfold thicknesses are now available. Furthermore, specific age ranges with significant changes in subcutaneous adipose tissue have been identified for both male and female adults.

THE RELATIONSHIP BETWEEN THE PHYSICAL FITNESS TEST AND MOVEMENT-RELATED MEMORY ABILITY TEST IN ELDERLY WOMEN WITH REGULAR EXERCISE HABITS

NAKAZURU, A., KOIZUMI, K., SHIRAISHI, M., HOSHIKAWA, Y., TAKANO, M.

JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: Movement-related memory ability is important for maintaining independent living as it is related to activities of daily living. Thus, this study investigated the relationship between physical fitness and movement-related memory ability in elderly women in Japan through physical fitness tests and a simple dance-based motion memory ability test.

METHODS: Healthy women aged ≥ 65 years with regular exercise habits ($n=33$) were included. The measurements were conducted from September 2024 to February 2025. Physical characteristics such as height, weight, and body fat percentage were measured. Physical fitness tests included handgrip strength, seated forward bend stretch, and knee extension strength evaluations, and a 10-m obstacle walk. The movement-related memory ability test (MMAT) was conducted with a 30-s dance. The participants were asked to learn the dance in 3 min and then promptly tested. Since memory ability tends to decline with age, the participants were divided into the following groups to examine age-related differences: early (65–69 years, $n=9$), intermediate (70–74 years, $n=9$), and late (≥ 75 years, $n=15$). Data were analyzed using one-way analysis of variance and partial correlation analysis.

RESULTS: Regarding body composition, there were no significant age-related intergroup differences in body fat percentage, fat mass, or body mass index. However, there were significant differences in height, weight, lean body mass, and lean body mass/height ratio, with the early group having significantly higher values for height, weight, lean body mass, and lean body mass/height ratio compared with the late group (height: $p=0.012$, weight: $p=0.007$, lean body mass: $p=0.003$, lean body mass/height ratio: $p=0.012$). No significant age-related intergroup differences were found in the physical fitness tests. Significant intergroup differences were observed in MMAT scores, with the early group scoring significantly higher than the other two groups. Significant correlations were found between movement-related memory ability and age ($r=-0.408$, $p=0.018$), height ($r=0.384$, $p=0.027$), lean body mass ($r=0.346$, $p=0.048$), seated forward bend stretch ($r=0.368$, $p=0.035$), handgrip strength ($r=0.349$, $p=0.046$), 10-m obstacle walk ($r=-0.358$, $p=0.041$), seated forward bend stretch score ($r=0.345$, $p=0.049$), and 10-m obstacle walk score ($r=0.349$, $p=0.046$). When age was the controlled variable, no significant correlations were found between movement-related memory ability and the other variables.

CONCLUSION: MMAT showed significant positive correlations with height, lean body mass, and seated forward bend stretch, and negative correlations with age and 10-m obstacle walk performance. When controlling for age, no significant correlations were found, suggesting that age may be the primary MMAT-influencing factor. The observed relationships with seated forward bend stretch and the 10-m obstacle walk performance suggest that improving flexibility and walking ability could affect movement-related memory ability.

THE EFFECT OF E75 MODIFY EXERCISE PROGRAM ON MUSCLE MASS AND FLEXIBILITY IN THE ELDERLY

NHUSAWI, K., NEELAPAIJIT, N., CHANTASORN, N., KAESMAN, I.

SILPAKORN UNIVERSITY

INTRODUCTION: The modified E75 Exercise Program is adapted from the "Elderly Exercise Program For Hale 75 Years (E75)" developed by the Department of Health, Physical Activity for Health Division, Ministry of Public Health, Thailand. It is an exercise program aimed at enhancing muscle strength and brain function for elderly individuals, promoting physical health, an active lifestyle, and improved quality of life. The program strives to help seniors achieve an average life expectancy of 75 years with good health. The research objectives of this study included 1) to study the effects of E75 modify Exercise Program on Muscle mass and Flexibility in the Elderly 2) to compare the effects of E75 modify Exercise Program on body fat percentage and Flexibility in the Elderly within a control group and an experimental group and 3) to compare the effects of E75 modify Exercise Program on Muscle mass and Flexibility in the Elderly between the control group and the experimental group

METHODS: The samples were elderly people living in Nakhon Pathom Province whose age ranged from 60 to 70 years old. The sample of 26 people, which its size was calculated by G*power was divided into two groups, 13 people in the experimental group and 13 people in the control group. with E75 modify exercise program for . The E75 modify exercise programme is an exercise program that uses bodyweight exercises. The exercises are simple and can be performed anywhere without the any equipment. There are a total of 15 exercise poses included in the programThe researcher will de-

termine the appropriate intensity, frequency, and duration of the exercise to ensure it is safe for elderly individuals, incorporating a rhythm of 90-100 beats per minute using a metronome. The experimental group were trained 60 minute per day, 3 days per week, total 12 weeks. The instruments were the E75 modify exercise program, TANITA SC-330P body composition analyzer equipment, Chair Sit-and-Reach test. The statistics used to analyze data were Paired t-test and Independent t-test.

RESULTS: The results were found as follows:1. The results of comparison within the experimental group before training and after training found that the muscle mass were equal to Mean=38.83, SD=6.38 and Mean=38.99, SD=6.49 respectively, revealed no differences, but the Flexibility were equal to Mean=2.22, SD=4.03 and Mean=3.49, SD=3.19 respectively was significantly different at the .05 level.

2. The results of comparison within the control group before training and after training found that, it was found that the muscle mass, flexibility was consciously significant at the .05 level. 3. The results of comparison between the experimental group and the control group after training found that the muscle mass revealed no differences but flexibility was significantly different at the .05 level.

CONCLUSION: This research can be concluded that the muscle mass and flexibiity of the elderly can be improved by E75 exercise programme.

EXPLORING THE RATING OF PERCEIVED EXERTION OF THE FIRST REPETITION TO INDUCE POST-ACTIVATION PERFORMANCE ENHANCEMENT WITH ELASTIC BANDS: A PILOT STUDY

GENE-MORALES, J., MARTÍNEZ-FERNÁNDEZ, A., FERRARI, D., VILANOVA-ALAPONT, B., MARTIN-RIVERA, F., CHULVI-MEDRANO, I., JUESAS, A., SAEZ-BERLANGA, A., COLADO, J.C.

UNIVERSITY OF VALENCIA

INTRODUCTION: Jump and sprint performance are crucial in sports, however, limited research has investigated post-activation performance enhancement (PAPE) using a single set of a full-body elastic-band exercise. Moreover, the use of the rating of perceived exertion of the first repetition (RPE-1) as a method to quantify intensity remains largely underexplored.

This pilot study aimed to evaluate the PAPE effects of performing a single set of push-press with elastic bands, using the RPE-1 for intensity quantification. Additionally, the study examined the influence of participants' fitness level on PAPE. We hypothesized that the intervention would induce PAPE, regardless of the participants' fitness level.

METHODS: Twenty-four trained, healthy young adults (age 23 ± 3 years; height 178.83 ± 8.57 cm; weight 78.10 ± 12.27 kg) participated. Each participant completed both conditions in a randomized order on two non-consecutive days.

One condition included a conventional control warm-up, consisting of two laps around a basketball court at a light jog, followed by bodyweight and dynamic mobility exercises (10 repetitions of alternating front lunges, side squats in both directions, jumps with one-legged landings, and dynamic hip flexion-extension and abduction-adduction). Additionally, three sets of skipping for 5 seconds, each followed by a maximum-acceleration 5-m sprint, were performed. Finally, participants completed 5 squats, push-ups, and burpees.

The second condition included the same conventional warm-up, followed by a 3-minute rest period, after which participants performed a single set of 6 repetitions of the push-press with elastic bands at an RPE-1 of 6 out of 10 (corresponding approximately to 85% 1RM), executed with an intentionally maximal concentric velocity.

The assessed variables included jump height, measured via countermovement jump using force plates (Forcedecks 4000, Vald Performance, Vic, Australia) and 10- and 20-m sprint times, measured using photocells (Fitlight Trainer, Ontario, Canada).

A two-way mixed repeated-measures ANOVA was conducted with condition (control and push-press) and fitness level (low-strength, high-strength; based on the median jump height) as factors.

RESULTS: Less strong participants significantly improved their jump height by 7.93% ($p < 0.05$) following the push-press, while stronger participants showed no significant jump improvement. Both groups significantly improved in 10-m (5.70–8.07%) and 20-m (5.18–6.23%) sprints after the push-press intervention.

CONCLUSION: The push-press with elastic bands effectively induced PAPE, with greater benefits observed in less strong participants. These findings suggest that RPE-1 is a viable strategy for quantifying elastic-resistance exercise intensity and inducing PAPE.

THE EFFECTS OF RHYTHM JUMP TRAINING ON AGILITY AND JUMPING ABILITY IN JUNIOR HIGH SCHOOL SOCCER PLAYERS: A RANDOMIZED CONTROLLED TRIAL

TSUNEKAWA, N., WATANABE, H., KAWABATA, M., KATO, Y., MATSUBARA, T., MUROI, R., TAKAHIRA, N.
KITASATO UNIVERSITY GRADUATE SCHOOL

INTRODUCTION: Metronome-synchronized training utilizes rhythm perception and is suggested to enhance motor performance [1]. In soccer, precise synchronization of sensory and motor functions is crucial for optimal timing and coordination between the upper and lower limbs. Rhythm Jump Training (RJT) is a training method that incorporates auditory rhythms cues to enhance movement synchronization, potentially improving agility and jumping performance. However, its effectiveness in adolescent athletes remains unclear. This study aimed to clarify the effects of RJT on agility and jumping ability in junior high school soccer players through a randomized controlled trial.

METHODS: A randomized controlled trial was conducted with 25 male junior high school soccer players (age: 13.1 ± 0.2 years) who trained five days per week in their school club. Participants were randomly assigned to either the RJT group, which performed 30-minute rhythm jump training once per week for eight weeks, or the control group, which continued regular warm-up exercises without rhythmic training. To evaluate the effects of RJT on athletic performance, pre- and post-intervention assessments were conducted using the Pro-agility Test (PAT) to measure agility and the Reactive Strength Index (RSI) to assess jumping performance. A mixed-model two-way ANOVA was performed to analyze the effects of RJT, with group (RJT vs. Control) as the between-individual factor and time (pre vs. post) as the within-individual repeated factor. Additionally, age in months was included as a covariate to account for growth-related changes.

RESULTS: A total of 19 participants completed the study. No significant interaction effects were observed for the PAT ($p = 0.97$) or RSI ($p = 0.99$).

CONCLUSION: A previous study conducted with elementary school students demonstrated significant improvements in PAT, but no effect on RSI [2]. However, in this study, no significant improvements were observed in junior high school soccer players. This suggests that the intensity and frequency of RJT may have been insufficient for this age group. Additionally, RSI performance is highly dependent on maximum muscle strength [3], which may not be effectively enhanced through RJT. Future research should explore increased training intensity and frequency, as well as age-specific adaptations, to optimize the benefits of RJT in adolescent athletes.

THE IMPACT OF AGE ON PHYSICAL AND TECHNICAL SKILLS IN YOUNG FOOTBALLERS

CURZI, D., SILVESTRI, F., DI PINTO, G., COLOMBO, A., MARCELLI, L.
UNIVERSITY NICCOLO CUSANO

INTRODUCTION: Youth football performance depends on psychophysiological skills, but the relative age effect (RAE) often favors those born earlier in the year [1]. While physical fitness contributes significantly to technical performance, some studies [2] find no direct link. On the other hand, motor control has been highlighted as a good predicting factor of football-specific skills, with no regard for chronological age. However, age-based groupings are common, neglecting actual motor skills. Therefore, this study evaluates motor skill differences between adjacent age groups in a youth soccer academy, examining the development of physical and technical parameters.

METHODS: 170 male soccer players (aged 8-12) were divided into five groups based on chronological age. At the beginning of the regular season, participants underwent physical and technical tests, including: Counter Movement Jump with arm swing (CMJA) and without arms (CMJ); 15-meter linear sprint with (LSB) and without the ball (LS); 15-meter agility test with (ATB) and without the ball (AT); and a sit and reach test for flexibility (SeR). A non-parametric Kruskal-Wallis test was used to identify group differences at T0, with Mann-Whitney tests for post-hoc comparisons between adjacent age categories.

RESULTS: Kruskal-Wallis tests revealed significant differences across all age groups ($p \leq 0.01$). Post-hoc analysis comparing adjacent groups yielded interesting results. For the jump tests (CMJ vs. CMJA), significant differences were only observed between the 10- and 11-year-old groups ($p = 0.032$). However, when arm use was incorporated (CMJA), differences also emerged between the 8- and 9-year-old groups ($p = 0.045$). The linear sprint (LS, LSB) and agility test (AT, ATB) results showed similar trends. For tests without the ball (LS and AT), differences were found between the 8- and 9-year-old groups ($p \leq 0.010$) and the 11- and 12-year-old groups ($p < 0.01$). With the ball, differences were only present between the

10- and 11-year-old ($p < 0.01$) and 11- and 12-year-old groups ($p \leq 0.01$). Finally, the 9- and 10-year-old groups showed no significant differences across any of the tests.

CONCLUSION: For the CMJ tests, the increase between 10- and 11-year-olds likely reflects increased lower limb power, while the difference between 8- and 9-year-olds reveals a significant coordination improvement (CMJA). Differences in LS and AT between 8-9 and 11-12 year olds could be attributed to sensitive periods of speed development. However, with the ball, differences emerge only between 10-11 and 11-12 year olds, likely due to better ball control related to game experience. Finally, the lack of significant differences between 9- and 10-year-olds across all tests suggests similar characteristics, potentially justifying their practical grouping by age.

ANTHROPOMETRIC, PHYSIOLOGICAL, AND GENETIC DETERMINANTS OF CARDIORESPIRATORY FITNESS IN MALE YOUTH SOCCER PLAYERS: A CROSS-CULTURAL COMPARISON BETWEEN SAUDI ARABIA AND THE UK

STEBBINGS, G., EL ASHKER, S., ALKARSAH, K.R., SIMS, D.T., FAISAL, A.

MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: High cardiorespiratory fitness (CRF) is a key determinant of elite performance in soccer. In Saudi Arabia, the hosts of the FIFA 2034 World Cup, adult and youth soccer players demonstrated consistently lower CRF than international counterparts^{1,2} which could be attributed to genetic factors. The aim of this study was to compare CRF between elite youth Saudi and maturity-matched UK soccer players, and assess the cumulative genetic influences on CRF phenotype in elite youth Saudi soccer players.

METHODS: Anthropometric and CRF (measured VO_2max during Yo-Yo IRL1 using COSMED-K5) phenotypes were compared between post-peak height velocity (PHV) youth male soccer players from Saudi Arabia ($n=20$) and the UK ($n=23$). Subsequently, 98 Saudi players were genotyped for 6 SNPs (ACE, BDKRB2, NOS3, PRDM1, GRIN3A, KCNH8), using TaqMan PCR. Associations between genotypes and VO_2max from Yo-Yo IRL1 were assessed individually and as part of a total genotype score (TGS). A TGS of 100 represents a 'perfect' polygenic profile, and 0 the 'worst' possible profile for CRF. Independent t-tests were used to determine significant differences in anthropometric and CRF phenotypes of the post-PHV players from Saudi and UK. In the Saudi players, a one-way ANOVA was conducted to determine significant differences in anthropometric and CRF phenotypes between maturity offset groups and genotypes individually and as part of a TGS.

RESULTS: In comparison to post-PHV UK-based players, post-PHV Saudi players were smaller, lighter, younger and had a significantly lower VO_2max (0.09 ± 0.01 m; 11.0 ± 2.1 kg; 2 ± 0.3 years, 10.8 ± 3.3 mL·kg⁻¹·min⁻¹; $P < 0.001$ respectively) but there was no difference between groups for age at PHV ($P=1.00$). In the sub-group of Saudi players, age ($P=0.004$), height ($P < 0.001$), body mass ($P < 0.001$) and maturity offset ($P < 0.001$) differed between maturity groups. VO_2max was not significantly different ($P=0.183$) between maturity sub-groups for the Saudi players but there was a main effect of PRDM1 rs10499043 genotype on age ($P=0.016$), age at PHV ($P=0.007$) and VO_2max ($P=0.003$). TGS was significantly different between maturity groups ($P=0.029$), with the TGS for the pre-PHV group lower than circa-PHV (13 ± 5 , $P=0.031$).

CONCLUSION: Saudi elite youth male soccer players are smaller in size and possess inferior CRF compared to UK counterparts matched for maturity status. While this is likely explained by a lower training age of Saudi players, genetic factors are also important to consider. It is possible that PRDM1 TT homozygotes, achieved higher CRF via enhanced mitochondrial efficiency, oxygen transport and/or increased proportion of type I fibres. Interestingly, it appears that existing talent ID processes in Saudi reflect CRF polygenic profiles, as older and more mature players had higher TGS scores than younger players.

ANATOMICAL AND FUNCTIONAL CHARACTERISTICS OF ELITE CENTRAL AFRICAN YOUTH FOOTBALL PLAYERS: A COMPARATIVE STUDY WITH INTERNATIONAL PEERS

BOTTARI, A., BOCHICCHIO, G., RIZZO, M., SCARTON, A., POGLIAGHI, S.

UNIVERSITY OF VERONA

INTRODUCTION: Youth football performance is influenced by several anatomical and functional factors, which vary depending on age, ethnicity, and position played. While many studies have analyzed adult players, limited data exist on young, elite African footballers. This study compared the anthropometric and performance characteristics of elite Central African U15 and U17 football players with international peers.

METHODS: Data were collected during the 2022 International Challenge Cup (Rabat, Morocco) from 162 players (126 Central African; 36 international). Anthropometric measurements included height, weight, and body fat percentage. At the same time, performance tests assessed lower limb power (Squat Jump, Countermovement Jump, Drop Jump), sprint speed (10m and 20m), and aerobic capacity (Yo-Yo IRI test). ANOVA was used to analyze differences across age groups, ethnicities, and field positions.

RESULTS: International players had higher body weight (66.17 ± 10.25 kg vs. 61.5 ± 8.3 kg, $p=0.041$) and body fat percentage ($11.5 \pm 2.1\%$ vs. $U15=6.8 \pm 1.2\%$, $U17=7.1 \pm 1.5\%$, $p < 0.001$) compared to Central Africans. U15 Central Africans exhibited superior jump performance (SJ: 42.5 ± 4.3 cm; CMJ: 45.2 ± 4.8 cm) compared to U17 ($p=0.032$) and international players ($p=0.003$). Sprint times showed no significant differences, while U17 Central Africans had a higher VO_2max (56.3 ± 5.2 ml/min/kg) than international players (52.8 ± 4.6 ml/min/kg, $p=0.040$).

CONCLUSION: Central African youth players demonstrated superior lower limb power and aerobic capacity than their international peers, with lower body fat percentages observed in the U15 and U17 categories. These findings contribute to the scarce literature on African youth football and may guide training and talent development programs for young athletes in the region.

COMPARISON OF FUNCTIONAL AND TRADITIONAL STRENGTH AND POWER TRAINING ON U19-TRAINED MALE FOOTBALL PLAYERS

ENGBERG TREU LASSEN, L.
AALBORG UNIVERSITY

INTRODUCTION: Functional strength training is thought to develop the neuromuscular system controlling muscle force and dynamically stabilize the kinetic chain during functional movements in a coordinated sequence, while traditional strength training has its benefits in improving maximum strength in an isolated muscle or specific muscle groups.

METHODS: The current study compared the effects of functional versus traditional strength training on physical and technical parameters in U19-trained male football players. A quantitative randomized controlled trial design was used. Thirty-three participants were recruited and randomly divided into a functional training group (FTG; $n = 11$), a traditional training group (TTG; $n = 11$), and a control group (CG; $n = 11$). The intervention groups were trained for eight weeks, with additional off-season football training (two weekly sessions) in the first four weeks of the intervention.

RESULTS: A significant ($p = 0.05$) decrease in time in the Loughborough soccer shooting test (LSST-time) was observed between the FTG ($p = 0.031$) and TTG ($p = 0.003$) compared with the CG, and an increase in body weight was observed between the FTG and CG ($p = 0.002$).

CONCLUSION: Both training methods improved the LSST-time performance during the off-season period. Furthermore, both training methods can maintain components considered important in football performance during the off-season period, ensuring that players are better prepared for the upcoming pre-season period.

SMALL-SIDED GAMES WITH STOP-BALL RULE: ANALYSIS OF SOME EXTERNAL LOAD PARAMETERS IN YOUNG SOCCER PLAYERS

TROTTA, N., SANNICANDRO, I.
UNIVERSITY OF FOGGIA

INTRODUCTION: Small-sided games (SSGs) are currently one of the most common drills used and have been progressively growing in amateur and professional soccer teams [1]. SSGs are used to increase the technical skills and physical abilities of soccer players [2].

During SSGs, the manipulation of pitch size, number of players per team, goalkeeper presence and technical rules modulate the soccer-specific demands depending the aims of each training session [3]. Among these variables pitch size is most frequently used, as larger vs smaller configurations affect soccer players behavior [4].

The purpose of this study is to investigate the effects of two fields of different sizes for SSGs-stop ball (SB) on some parameters of high intensity in Under-15 soccer players.

METHODS: Ten young soccer players (age: 13.8 ± 0.42 years; stature: 168.8 ± 6.21 cm; body mass: 55 ± 7.07 kg) voluntarily participated in this study. During the training interventions, the SSGs-SB were based on 4-a-side team format, without goalkeeper, and were performed on 20×25 m ($62.5 \text{ m}^2 \cdot \text{player}$) and 30×38 m ($142.5 \text{ m}^2 \cdot \text{player}$) fields. In both exercises the protocol consisted of 4x3 min, followed by 2 min of passive recovery. The training sessions, conducted in two different days, were performed on the same artificial grass field and time (16:30-18:00 pm) with the same outside temperature (22°C).

During sessions, the players were monitored using global positioning system (GPS) devices at 18.18 Hz (GPEXE® SYSTEM, EXELIO srl, Udine, Italy). Total distance covered (TD), high speed running distance 13-18 km/h (HSRD), sprint running distance >18 km/h (SRD), peak speed, distance in acceleration (ACC) $>2.5 \text{ m/s}^2$ and deceleration (DEC) $<-2.5 \text{ m/s}^2$ were measured. The significance level has been set to $p < 0.05$ and effect size (ES) was calculated.

RESULTS: Large SSGs-SB (30×38 m) have determined higher significantly values than smaller field for HSRD (317.41 ± 63.82 m vs 248.05 ± 61.56 m; $p < 0.05$; ES: 1.10), SRD (84.77 ± 30.28 m vs 54.37 ± 29.17 m; $p < 0.05$; ES: 1.02) and peak speed (23.36 ± 0.93 km/h vs 21.64 ± 1.19 km/h; $p < 0.001$; ES: 1.62); instead, small SSGs-SB (20×25 m) have produced greater outcomes and statistically significance for distance covered both in ACC $>2.5 \text{ m/s}^2$ (22.36 ± 7.58 m vs 12.82 ± 3.17 m; $p < 0.001$, ES: 1.77) and DEC $<-2.5 \text{ m/s}^2$ (33.47 ± 6.86 m vs 24.55 ± 6.77 m; $p < 0.05$; ES: 1.39). No significant differences haven't been found for TD (1568.14 ± 122.37 m vs 1592.81 ± 136.15 m).

CONCLUSION: Large SSGs-SB have generated a significant increase on external load monitored, while lower dimensions have affected mechanical variables. Finally, it is recommended implementing high intensity exercises in order to promote lower non-contact muscle injury risk [5]. This results can contribute some methodological advises to practitioners and fitness soccer coach that must schedule SSGs during season.

REACTION SPEED PERFORMANCE IN SOCCER PLAYERS: A CROSS-SECTIONAL STUDY FROM U13 TO PROFESSIONAL LEVELS

PALUDO, A., TAMASIOS, D.1, PARPA, K.2, MICHAELIDES, M.2, SHIMI, A.1,3, CHRISTOU, M.1,4, AVRAAMIDES, M.N.1,3
UNIVERSITY OF CYPRUS

INTRODUCTION: Reaction speed is a key factor in soccer, influencing players' ability to anticipate actions. Its development can be influenced by age, cognitive-motor maturation, training exposure and competitive level. The study aims to investigate the reaction-speed performance across U13 to U17, professional and semi-professional soccer players, using a light training task.

METHODS: A total of 159 soccer players participated in the study, categorized into U13 (n=23), U14 (n=17), U15 (n=26); U16 (n=18), U17 (n=18), semi-professional (n= 23) and professional (n=34) groups. Each player completed a single session of a reaction-speed task using the Speedpad application (Mentis VR Ltd), a Virtual Reality light training task. The task presented an array of nine circular discs and players were required to hit with their hands as fast as possible, each disc whose outline changed to red. The number of correct responses to target discs in a 1-minute session was considered the player's reaction-speed score. One-way ANOVA was used to compare the groups, and Tukey post-hoc to identify significant differences across groups.

RESULTS: Reaction speed performance was lower in U13 (62.7 ± 10.3 points) and U14 (63.5 ± 8.87 points) players compared to the other groups ($F=6.90$, $p<.001$). No significant differences were observed among U15 (75.0 ± 7.01 points), U16 ($n=72.9 \pm 10.0$), U17 (74.6 ± 12.6 points), semi-professional (75.3 ± 10.1 points), and professional (74.3 ± 10.3 points) players, indicating that reaction speed stabilizes from U15 forward.

CONCLUSION: This study demonstrated that reaction speed improves up to U13-U14 and stabilizes across older age groups, including semi-professional and professional players. The lower performance in U13 and U14 may reflect ongoing neuromuscular development, maturation and training exposure. The lack of differences from U15 onwards suggests reaction speed plateaus with accumulated experience. These findings emphasize the need for targeted reaction-speed training from childhood to early adolescence to achieve maximum cognitive-motor development. Future research should explore advanced training methods, such as virtual reality-based drills, to further refine reaction speed in elite soccer players.

CAN INCREASED WEEKLY PLYOMETRIC TRAINING FREQUENCY ENHANCE PERFORMANCE AND MITIGATE MUSCLE SORENESS IN YOUTH SOCCER?

TRAPLETTI, M., FORMENTI, D., MORAN, J., MERATI, G., ESPOSITO, F., TRECROCI, A.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Neuromuscular adaptations and performance gains can be achieved across different plyometric training (PT) frequencies assuming the total training volume remains equal (1). However, distributing the training load across more frequent weekly sessions may assist young soccer players in reducing their perceived internal load, thereby fostering recovery, and enhancing training sustainability (2). This study aims to investigate the effects of volume-matched PT with different weekly frequency distributions on physical performance and muscle soreness in adolescent soccer players.

METHODS: Thirty-four sub-elite adolescent soccer players were allocated into two groups: the PLYO-1 group underwent one PT session per week, while the PLYO-3 underwent volume-matched PT distributed over three sessions per week. The 9-week experimental program included nine plyometric exercises, starting with a weekly volume of ~55-foot contacts and increasing by 10% each week. The 7-point Likert scale was employed to assess the perceived muscle soreness before and after each PT session. All players were tested for countermovement horizontal (CMHJ) and vertical (CMVJ) jumps, 10-m sprint and change of direction (COD) performance using the modified 505 test (505mod). A two-way ANOVA for repeated measures analyzed simple and main effects between PLYO-3 and PLYO-1, with Cohen's d (d) effect size to quantify the magnitude of each difference.

RESULTS: After the 9-week experimental period, both groups exhibited significant improvements in CMHJ distance ($p < 0.001$; $d = -0.55$) and CMVJ variables (jump height and modified reactive strength index) ($p < 0.001$; $d = -0.34$ and $d = -0.33$), and 505mod time (COD deficit) performance ($p < 0.001$, $d = 1.09$). However, no improvements were observed in the 10-m sprint time performance for PLYO-1 and PLYO-3 ($p > 0.911$, $d = -0.12$). The changes in perceived muscle soreness were significantly lower for PLYO-3 compared with PLYO-1 ($p < 0.001$, Cohen's $d = 1.04$) throughout the experimental period.

CONCLUSION: Implementing a high-frequency PT regimen (three sessions per week) with a progressive 10% increase in weekly foot contacts can optimize weekly load distribution and enhance overall athletic readiness in youth soccer. Therefore, employing PT interventions with weekly volume-matched but conducted at different frequencies can help maintain or even improve jump and COD performance, while impacting muscle soreness differently.

THE RELATIONSHIP BETWEEN FITNESS CAPACITIES AND THE MAXIMAL INTENSITY PERIODS IN YOUTH SOCCER MATCH-PLAY

LEE, M., SINGH, S., YUSOF, M., TAN, F.

SPORT DEVELOPMENT GROUP, SPORT SINGAPORE

INTRODUCTION: Soccer is a high-intensity intermittent sport that demands a combination of technical skill, tactical awareness, and fitness to compete successfully. During periods of match-play, players are at times required to perform at very high intensities - termed the maximal intensity periods (MIPs), which can significantly impact match outcomes (Weaving et al., 2022). Thus, the development of fitness to perform in these intense periods may underpin the capacity to sustain high output during the MIPs. Till date, most studies examining the relationship between fitness and match-running output have mainly focused on the volume of match outputs (total distance, total high-speed distance etc.). However, studies have shown large variability lies within these volume-based metrics, which is further compounded by variability shown between playing positions (Carling et al., 2016). The use of intensity-based metrics by normalizing to playing minutes may provide a more reliable expression of match intensities with lower variability (<10% CV) between matches and positions (Thoseby et al., 2022). This study seeks to examine the relationship between fitness status and the maximal intensity periods in a cohort of male youth competitive footballers.

METHODS: 32 male youth players (age = 14.1 ± 0.8 years, height = 162.8 ± 8.3 cm, body mass = 50.4 ± 9.6 kg) were observed during the in-season period. Fitness capacities were assessed using the 5-m acceleration time and maximal sprinting speed (MSS) derived from a 40-m sprint test, vertical jump (VJ) test and the Yo-Yo Intermittent Recovery Test Level 1 (YYIRT 1). MIPs were tracked using a moving-average technique applied to the speed, acceleration and PlayerLoad across 10 different durations (1-10 mins) in matches played within four weeks of the fitness tests. Mixed linear models were used to determine the relationship between fitness capacities and the peak-match intensities by converting the t statistics from the models to effect sizes (ES) correlations (r).

RESULTS: There were no clear relationship between 5-m, MSS, VJ or YYIRT 1 with the rolling averages of MIP of total distance (m.min⁻¹), high-speed distance (> 14.4km.h⁻¹), acceleration (m.s⁻²), and PlayerLoad (au.min⁻¹) ($r = 0.02$ to 0.16).

CONCLUSION: There is little association between a youth footballer's fitness status and the ability to perform during MIPs in matches. Practitioners should evaluate fitness and match intensities metrics separately and avoid postulating an effect between these two constructs. Both measures can be assessed based on their variability to identify meaningful changes in individual player's fitness and match outputs.

THE EFFECTS OF SOFT AND DEEP TISSUE MASSAGE ON LOWER EXTREMITY OXYGENATION RATES ASSESSED USING IS-CHAEMIC PRECONDITIONING

GORDON, D., GERNIGON, M., MOLONEY, S., WILLMOTT, A., BERNARD, P., PHILIPS, D.

ANGLIA RUSKIN UNIVERSITY

INTRODUCTION: Soft and deep tissue massage are routine approaches utilised both in the rehabilitation and recovery processes of performance and recreational athletes, with therapeutic benefits purported to be increased blood flow and oxygenation rates. However, the evidence remains contradictory. Therefore, the purpose of this preliminary study was to examine the impact of both soft and deep tissue massage on consequent muscle oxygenation levels.

METHODS: Following local institutional ethics approval, 10 recreationally active participants (7 males, 3 females) volunteered (mean $\pm$ SD: age 21 ± 2 , body mass 67.8 ± 11.2 kg, height 175.3 ± 9.2 cm). All participants were assessed using the ankle-to-brachial index for suitability to undergo blood flow occlusion. For all conditions, the participant lay supine on a massage bench, where muscle oxygenation was recorded throughout using NIRS sampling at 10 Hz, across the mid-point of rectus-femoris. An occlusion cuff (20 cm width) was placed midway between ASIS and mid-patella. Following 7 min in the rested state (REST), muscle blood flow was regulated using occlusive and reperfusion phases of 7 min using 80% of the individualised limb occlusion pressure. Immediately followed by 7 min of SOFT then DEEP tissue massage, which were proceeded by a second occlusive-reperfusion phase.

RESULTS: There was a significant difference ($P < 0.01$, effect size (ES) = 2.03; 95% CI 3.01 - 0.88 between minimum ($66.43 \pm 12.13\%$) and maximum ($88.24 \pm 9.12\%$) tissue saturation index (TSI) values when comparing REST to SOFT following reperfusion. For DEEP, when comparing to REST for minimum to maximum responses ($82.34 \pm 6.84\%$), a large ES: 1.51; 95% CI 2.54 - 0.55; ($P < 0.01$) was also observed. Oxyhaemoglobin (O2Hb) increased from a minimum [baseline value] at REST of

26.63 ± 18.38% to a maximum of 91.53 ± 37.65% following SOFT; ES = 2.19; 95% CI 3.19 – 1.01; (P< 0.01), while for DEEP there was an increase of 201.6% in O2Hb: ES = 3.19; 95% CI 1.77 – 4.35; (P< 0.01).

CONCLUSION: These data tentatively suggest that both soft and deep tissue massage increased O2 availability at the muscle, as reflected in the increases for both TSI and O2Hb. It is probable that vasodilation, possibly linked to the nitric oxide cascade influenced by the pressure applied and thermoregulatory responses are the primary candidates attributable. Caution should be applied to these findings as both procedures occurred subsequent to each other, potentially explaining the mixed results across conditions.

JOINT PREDICTION OF ENERGY EXPENDITURE DURING INCREMENTAL LOAD EXERCISE IN COLLEGE STUDENTS USING MULTI-SOURCE HETEROGENEOUS DATA AND DYNAMIC TIME SERIES ANALYSIS

SONG, Y., ZHEN, W., RUI, Z., ZHIMO, J., BINGNAN, G.

CAPITAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORTS

INTRODUCTION: Energy Expenditure (EE), a key indicator reflecting exercise intensity and volume, has been widely researched in public health and sports training. Accurate monitoring of EE is crucial in physiology, health management, and exercise prescription design. Consequently, accurately predicting or estimating energy expenditure using simple, easy-to-measure indicators combined with artificial intelligence (AI) algorithms has become a critical direction in energy consumption research. Building on previous research, this study integrates heart rate and acceleration data from incremental load exercises, constructing multiple dynamic time series prediction models. The model with the best fit was selected based on performance evaluation metrics, providing a theoretical reference for future energy expenditure prediction studies.

METHODS: Twenty-five college students participated as subjects, undergoing an incremental load exercise test on a treadmill. Data collection comprised exercise load metrics and heart rate readings captured by accelerometers, with energy expenditure predictions made using dynamic time-series models (e.g., LSTM, BiLSTM, TCN, GRU, CNN+LSTM). Model performance was evaluated using metrics such as RMSE, R², and Bias, with prediction consistency further assessed through Bland-Altman plots.

RESULTS: The LSTM model achieved the lowest RMSE (0.2423) and Bias (0.1060), indicating its high accuracy and consistency in predicting energy expenditure. It also displayed the highest R² value (0.9255), demonstrating its strong ability to interpret the data. The TCN model also performed well, with an RMSE of 0.2710, an R² of 0.9068, and the lowest Bias (0.0216) among the models. The low Bias value indicates that TCN offers a reduced systematic error in predictions compared to other models. TCN's ability to capture long-term contextual information through its convolutional structure helped it mitigate biases effectively. BiLSTM, GRU, and CNN+LSTM showed moderate performance. Overall, LSTM and TCN were the top-performing models.

CONCLUSION: In this study, we developed an EE model for incremental loading exercise by utilizing acceleration and heart rate data, comparing the predictive performance of multiple time series models, including LSTM, BiLSTM, GRU, TCN, and CNN+LSTM. Through evaluation metrics such as RMSE, R², and Bias, along with Bland-Altman plots to assess prediction consistency, we identified LSTM and TCN as the most accurate and stable models for EE prediction. Our findings underscore the effectiveness of time series-based algorithms in capturing dynamic patterns in incremental loading exercise. Moreover, incorporating joint internal (heart rate) and external (acceleration) metrics as input features proves effective in reflecting exercise intensity. This approach suggests that the integration of multiple metrics enhances the accuracy of EE estimation, providing a reliable means for quantifying exercise load and calculating exercise intensity.

BIOFEEDBACK IN ATHLETIC PERFORMANCE: A SYSTEMATIC REVIEW

TIAN, H., DINGDING, C., DENG, W., GUOPING, Q., JUN, Z., QIANG, Y.

NANJING SPORT INSTITUTE

INTRODUCTION: Biofeedback technologies are increasingly applied in sports science to optimize neuromuscular control and psychophysiological adaptation [1-3]. Current research demonstrates methodological inconsistencies in efficacy assessments across athlete populations, particularly regarding long-term outcomes and modality-specific mechanisms.

METHODS: This systematic review aims at evaluating biomechanical pathways and proposes evidence-based training through multilevel data synthesis. Following PRISMA guidelines, Web of Science, PubMed, and SPORTDiscus were systematically searched. 32 studies (2019–2024) were analyzed from using search terms: ("biofeedback" OR "neurofeedback") AND ("athletic performance" OR "sport*"). Dual-blind AMSTAR2 assessments excluded studies scoring <22% on methodological rigor (κ=0.81). Data extraction categorized outcomes by European College of Sport Science biofeedback taxonomy: physiological (HRV/EMG), biomechanical (kinematic), and neurocognitive (EEG).

RESULTS: HRV biofeedback demonstrated moderate effects on endurance performance (d=0.62–1.15) and stress resilience, while EMG interventions improved strength output variability by 18–27% in power sports. Neurocognitive protocols enhanced decision-making accuracy (p<0.05, ES=0.89) but showed conflicting results in motor learning retention between RCTs and non-randomized trials. Biomechanical feedback reduced injury-risk movement patterns (Cohen's f²=0.31) yet exhibited limited transfer to competition contexts.

CONCLUSION: Theoretical integration of psychophysiological adaptation models clarifies biofeedback's task-specific efficacy. Practitioners should prioritize multimodal protocols combining HRV and kinematic feedback for compound adapta-

tions. Limitations include heterogeneity in outcome measures and underrepresentation of female athletes (18% of samples).

AORTIC IMPEDANCE DURING MODERATE-INTENSITY HANDGRIP EXERCISE: A TIME-RESOLVED PHASE-CONTRAST MRI STUDY

MARINA, F., DAISUKE, H., TSUBASA, T., JUN, S., TARUMI, T.

NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY

INTRODUCTION: Resistance exercise increases afterload on the left ventricle during stroke volume ejection. While afterload is traditionally assessed using total peripheral resistance (TPR), this measure overlooks the pulsatile nature of the cardiovascular system. Aortic input impedance, which reflects the dynamic pressure-flow relation at the ventricular-vascular interface, may offer a more accurate and comprehensive assessment of the afterload. This study aimed to evaluate aortic input impedance during moderate-intensity rhythmic handgrip exercise (RHE) in young, healthy men and women. We hypothesized that RHE would increase characteristic impedance (Z_c), a key pulsatile component of aortic input impedance, and that this increase would correlate with left ventricular workload.

METHODS: Fifteen healthy young adults (6 women, 24 ± 3 years) participated in the study. Aortic flow and pressure were measured simultaneously at rest and during RHE at 40% of maximum voluntary contraction using time-resolved phase-contrast magnetic resonance imaging (PC-MRI) and a generalized transfer function method, respectively. Aortic input impedance was derived from frequency-domain analysis of aortic flow and pressure waveforms. Z_c was calculated as the mean impedance modulus between the 3rd and 8th harmonics of heart rate. Left ventricular workload was assessed using the augmentation index (Alx) and tension-time index (TTI) derived from the aortic pressure waveform.

RESULTS: During RHE, heart rate and mean arterial pressure increased significantly ($p < 0.001$), while stroke volume showed a trend of decrease (74 ± 16 to 71 ± 18 mL, $p = 0.084$). Cardiac output (4.56 ± 0.80 to 5.12 ± 0.97 L/min, $p = 0.011$), TPR (17.70 ± 2.51 to 19.72 ± 4.10 L/min/mmHg, $p = 0.033$), and Alx (-1.19 ± 11.73 to $4.86 \pm 12.72\%$, $p = 0.045$) increased significantly. Z_c also increased significantly during RHE compared to rest (480 ± 94 to 602 ± 215 dyne/cm³/s, $p = 0.033$). While TPR was not associated with TTI ($r = 0.402$, $p = 0.138$), changes in Z_c during RHE correlated with increased TTI ($r = 0.598$, $p = 0.018$).

CONCLUSION: These findings indicate that cardiac afterload increases during moderate-intensity handgrip exercise, as reflected by both TPR and aortic Z_c . However, the association between cardiac afterload and workload was observed only for Z_c . This suggests that aortic input impedance is a more relevant marker of left ventricular workload during resistance exercise than TPR.

ANALYSIS OF THE WAKE-SLEEP CYCLE IN ESPORTS ATHLETES AND ITS RELATIONSHIP WITH REACTION TIME

ESTEVE, A., SANZ-MILONE, V., SILVA, A., DE MELLO, M.T.

UNIVERSIDADE ESTADUAL DE CAMPINAS

INTRODUCTION: The eSports has attained a significant level of professionalism [1]. The main strengths of an eSports athlete are hand-eye coordination and reaction time [2]. Studies indicate that the lifestyle of electronic eSports athletes can be considered unhealthy, even of those athletes with high engagement and commitment to the eSport [3]. Sleep is directly responsible for interfering with reaction time, and poor sleep quality directly leads to increased reaction times [4]. Therefore, the aim of this study is to evaluate the wake-sleep rhythm of professional eSports players and their reaction times.

METHODS: 27 professional players from a traditional eSports team in São Paulo were evaluated. The athletes used the actigraph for 10 consecutive days and performed three reaction tests during the period, upon waking up, upon starting training and at the end of training, in addition, the players sleep regularity was also analyzed.

RESULTS: The eSports players have poor sleep quality, with low total sleep time (6:39 hours) and efficiency (83.70%), as well as a high number of wake after sleep onset (47 minutes), regarding sleep regularity 7 players were considered irregular sleepers with an average score of 67.72 ± 5.37 , while the 7 regular sleepers had an average score of 90.37 ± 1.17 . There was an association between the sleep time of players who slept more and reaction time, in which athletes with longer total sleep time showed greater accuracy in reaction tests, in addition, players with better sleep regularity showed faster reaction times.

CONCLUSION: We can conclude that the players had low general sleep quality and athletes with longer total sleep time and better sleep regularity are those who performed better during the reaction tests.

BLOOD BIOMARKERS AND WINGATE TEST PERFORMANCE IN LATVIAN YOUTH ATHLETES: DESIGN AND PRE-SEASON ASSESSMENT

JUSTAMENTE, I., ZOLOVS, M., REIHMANE, D.

RĪGA STRADIŅŠ UNIVERSITĀTE

INTRODUCTION: Nowadays youth athletes experience high physical workload due to increasing number of competitive matches, including participation among older age groups. Proper monitoring of youth athletes throughout the season are of importance to ensure optimal development, recovery, and injury prevention. To evaluate the health of Latvian youth athletes project within National Research Programme Sport (IMRSportsLV; Nr. VPP-IZM-Sports-2023/1-0001) has been initiated. This project aims to develop research methods and guidelines for evaluation of physical and mental health of youth athletes across the season.

METHODS: Pre-season testing of 12–18-year-old athletes began in fall 2024, evaluating physical fitness (aerobic and anaerobic capacity), movement quality (Functional Movement Screen, Y-Balance Test), anthropometry (BMI, waist circumference, bioimpedance), blood biomarkers and questionnaires of burn out, well-being, and competition anxiety. This abstract focuses on some baseline measures. So far fasting blood samples have been collected from 112 athletes (48 females, 54 males; age 15.5 ± 3.07). Anaerobic performance has been estimated using the Wingate 30-second maximal power test on a Cyclus2 veloergometer for 77 athletes (29 females and 48 males, age 15.9 ± 1.6), who did not report bodily pain or discomfort. Follow-up assessments in mid- and end-season will be performed to track changes over time.

RESULTS: When compared to reference values pre-season assessments showed insufficient vitamin D levels in 60% of youth athletes with varied magnitude (severe: 8.55 ± 1.91 ng/mL, $n=2$; moderate: 16.22 ± 2.86 ng/mL, $n=15$; mild: 24.31 ± 2.98 ng/mL, $n=51$). Low ferritin was observed in 13 athletes (5.78 ± 1.3 ng/mL), while 9 had decreased hemoglobin (116.44 ± 2.40 g/L). Elevated glucose levels were detected in 3 athletes (6.79 ± 1.77 mmol/L). Lipid profile analysis showed low HDL in 5 athletes (0.96 ± 0.019 mmol/L) and elevated LDL in 9 (3.28 ± 0.22 mmol/L). Baseline testosterone-to-cortisol ratio was 0.004 ± 0.002 in females and 0.062 ± 0.025 in males ($p < 0.001$). Wingate test results showed that female relative peak anaerobic power (8.35 ± 0.93 W/kg) and relative anaerobic capacity (6.88 ± 0.73 W/kg) was significantly lower ($p < 0.001$) than for males (10.88 ± 1.21 W/kg and 8.84 ± 0.87 W/kg, respectively). There was no correlation between blood biomarkers and anaerobic performance when adjusted for sex.

CONCLUSION: Pre-season results show that notable number of athletes have low ferritin and hemoglobin levels. Furthermore, vitamin D insufficiency among youth athletes is highly prevalent. Hormonal analysis revealed sex-based differences in testosterone-to-cortisol ratios, while Wingate test results showed notable differences in anaerobic power and capacity between males and females. These findings highlight the need for continuous monitoring of youth athletes and such interventions as supplementation of vital micronutrients for optimal physical health and performance.

CAFFEINE OR SODIUM BICARBONATE INGESTED 180-90 MINUTES PRIOR TO TESTING DID NOT AFFECT REPETITIONS, RATING OF PERCEIVED EXERTION OR ELECTROMYOGRAPHY

SHEA, A., WILLIAMS, M., BARRETT, C., LAWSON, E., MAJOR, C.P., SQUIRES, K., SQUIRES, M., BEHM, D.G.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Caffeine supplementation has gained renewed interest since its removal from the World Anti-Doping Agency's prohibited substances list in 2004[1]. Research suggests caffeine as a supplement for high-intensity physical tasks[2] and it may enhance force production and endurance[3,4]. Similarly, sodium bicarbonate has been shown to enhance high-intensity exercise performance[5]. This study aimed to assess the efficacy of an acute caffeine and sodium bicarbonate supplementation on leg extension and chest press resistance training performance.

METHODS: Fourteen resistance-trained individuals (≥ 6 months of training, daily caffeine consumers) ingested caffeine, sodium bicarbonate or a placebo at 120, 90, and 60 minutes before testing. Participants performed six sets of chest press or knee extension at a 12-repetition maximum (12RM) load with 60-second rest intervals. Electromyography (EMG) of the rectus femoris and triceps brachii, movement velocity, time under tension, and blood lactate levels were recorded. Heart rate and rate of perceived exertion (RPE) were measured after each set.

RESULTS: Chest press repetitions significantly differed between conditions ($F(2,20)=4.35$, $p=0.027$, $\eta^2=0.303$, $OP=0.686$). Although the highest repetitions were observed following sodium bicarbonate supplementation (7.42 ; $95\%CI: 6.8-7.9$), post-hoc tests could not specify a significant difference. No significant effects were found for knee extension repetitions. There were no significant main effects or interactions for EMG activity or RPE in either exercise. Caffeine significantly increased diastolic blood pressure compared to sodium bicarbonate and placebo (79.2 mmHg; $95\%CI: 74.6-83.7$ vs. 72.7 mmHg; $95\%CI: 67.5-77.9$ and 74.5 mmHg; $95\%CI: 71.7-77.3$). Blood lactate, systolic blood pressure, and extracellular water-to-total body water (ECW/TBW) ratio increased pre- to post-test across all conditions. A significant time x sex interaction ($F(1,9)=5.46$, $p=0.04$, $\eta^2=0.378$, $OP=0.55$) showed both males and females experienced an increase in extracellular water/total body water (ECW/TBW). All conditions led to significant ECW/TBW increases ($F(2,18)=16.49$, $p=0.001$, $\eta^2=0.647$, $OP=0.977$) with no differences between supplement groups.

CONCLUSION: The overall findings of this study found that caffeine increased diastolic blood pressure but had no apparent effects on repetition performance while sodium bicarbonate supplementation improved chest press performance. Although there were no obvious benefits for knee extension, both supplements caused an increase in blood lactate and EWC/TBW ratio.

DOES SLEEP PATTERN AFFECT RESISTANCE TRAINING-INDUCED MUSCLE HYPERTROPHY?

CANOY, L., SANZO, K., DIMICELI, S., MUNDOK, E., RAUCCI, J., CARY, P., YAMEEN, N., SEUNATH, D., CLARK, L., SHINE, T., SMALL, J., KOUREMENOS, K., ALIAS, T., UGRINOWITSCH, C., DE SOUZA, E.O.

THE UNIVERSITY OF TAMPA

INTRODUCTION: Anecdotal evidence suggests that sleep is a significant part of the training process due to its function in skeletal muscle recovery and adaptation. Thus, comparing short- and regular-sleepers (i.e., <360 min and > 360 min per night, respectively) resistance training (RT) -induced muscle hypertrophy may provide empirical evidence for such a claim. In addition, we tested if high RT volume would overcome allegedly lower muscle hypertrophy in short sleepers. Thus, our study aimed to determine if total sleep time, number of awake periods during the night, and differences in RT volume may affect RT-induced muscle hypertrophy.

METHODS: Twenty-five sedentary college students (20 females and 5 males) volunteered to participate in the study (mean $\pm$ standard deviation [SD]—age: 20.0 ± 2.0 years, body mass: 61.6 ± 18.9 kg). Total sleep time (TST) and wake after sleep onset (WASO) were assessed over seven days at pre-training via wrist-worn actigraphy. The sum of anterior thigh muscle thickness (Σ MT) (i.e., rectus femoris and vastus intermedius) at 40% and 60% of femur length was assessed pre- and post-training by researchers blinded to the training protocol. Classification of participants into short- and regular-sleepers was performed non-randomly at post-training for blinding purposes (i.e., a non-randomized controlled trial). Participants' lower limbs were randomly assigned to low- and high-RT volume conditions (1 set vs. 3 sets per exercise [leg press and knee extension], respectively—i.e., within-subject design) and trained for eight weeks, twice a week, under the supervision of researchers blinded to sleep patterns. General linear models were used to compare changes in MT from pre- to post-training and delta change in VL thickness between the low- and high-RT volume limbs.

RESULTS: Means and SD for TST and WASO were 442.0 ± 63.4 min and 32.3 ± 2.32 times per night, respectively. As our sample had only 3 short and 22 regular sleepers, TST and WASO were modeled as covariates instead of a fixed effect. Covariates TST and WASO did not change the interpretation of our findings, and they were removed from the statistical models. The lower-volume limb presented a significant increase in the Σ MT from pre- to post-training (7.99 ± 0.29 and 8.77 ± 0.25 cm: $p=0.05$, respectively). In contrast, the high-volume limb presented a trend (8.16 ± 0.29 and 8.82 ± 0.24 cm: $p=0.09$, respectively). The comparison of the delta change in Σ MT between the low- and high-volume limbs showed that the former had significantly higher anterior thigh hypertrophy than the latter ($p=0.001$).

CONCLUSION: College students with no previous experience in RT demonstrate sleep patterns that do not appear to affect RT-induced anterior thigh hypertrophy. However, our data suggest that a low RT volume is more beneficial than a high volume for this cohort.

THE RELATIONSHIP BETWEEN EMGT AND ENERGY METABOLISM RESPONSE DURING INCREMENTAL EXERCISE

NAKANO, H., WAKO, K., SHUNYA, U., KEISUKE, O., RYOJI, H., MASAKI, T.

DOSHISHA UNIVERSITY

INTRODUCTION: The relationship between Electromyographic thresholds (EMGT1 as the first increased point and EMGT2 as the second increased point) and cardiorespiratory and blood lactate response have still not been fully understood. The purpose of this study was to evaluate the relationship between EMGTs and cardiorespiratory and blood lactate response during an incremental exercise test on a bicycle ergometer.

METHODS: Sixteen adult male subjects (25.6 ± 9.3 years) with exercise habits were subjected to incremental exercise test on a bicycle ergometer. The workload at the beginning of the exercise was set at 30 watts (constant at 60 rpm), and the workload was increased by 30 watts every 2 minutes. Wireless electromyography (EMG, Sports sensing, Japan) sensors were attached to the vastus lateralis muscles, and EMG was recorded during exercise. Exhaled gas exchange was measured with an exhaled gas analyzer (Minato, AE-310s, Japan). Blood lactate concentration (Arkley, Lactate pro 2, Japan) was measured before the start of the exercise, every 2 minutes during the exercise, and immediately after the end of the exercise.

The EMGTs were determined by visual inspection, using the first (EMGT1) and second (EMGT2) points at which the magnitude of the EMGTs began to increase sharply. Two EMGTs (EMGT1 and EMGT2) were detected.

VT was defined as the time when VE started to increase sharply.

LT was defined as the time when blood lactate levels start to increase significantly.

RCT was defined as the time when $P_{\text{et}}\text{CO}_2$ started to decrease from its peak.

OBLA was defined as the time when the blood lactate concentration exceeded 4 mmol.

Significant level of Pearson's correlation coefficients were assessed among these variables.

RESULTS: EMGT1 and EMGT2 were detected in the vastus lateralis muscles of 15 subjects. Good correlations were observed between VT, LT and EMGT1: VT and LT ($r=0.69$, $p<0.05$), EMGT1 and VT ($r=0.65$, $p<0.05$), EMGT1 and LT ($r=0.71$, $p<0.05$).

And also better correlations were observed between RCT, OBLA and EMGT2: RCT and OBLA ($r=0.77$, $p<0.05$), EMGT2 and RCT ($r=0.83$, $p<0.05$), EMGT2 and OBLA ($r=0.78$, $p<0.05$).

CONCLUSION: A good correlation can be observed between the EMGT2 and RCT, OBLA.

RCT (Respiratory Compensation Threshold) and OBLA (Onset of Blood Lactate Accumulation)

CP-AP33 Hockey, Ice Hockey and Warm-up

SCORING, SAVING, AND STAYING OUT OF THE BOX: STATISTICAL DETERMINANTS OF SUCCESS IN ICE HOCKEY TOP DIVISION WORLD CHAMPIONSHIPS

AYTAÇ, T.

BASKENT UNIVERSITY

INTRODUCTION: The International Ice Hockey Federation (IIHF) World Championships are among the most prestigious international ice hockey tournaments, with success determined by a combination of offensive, defensive, and strategic metrics. Understanding the factors that drive success in these championships is crucial for teams seeking to improve their competitive edge. Previous research has explored individual performance factors in ice hockey, but there has been limited systematic investigation into the determinants of medal-winning teams at the international level.

METHODS: This study applies Bayesian Ridge Regression and Ordinal Logistic Regression to analyze data from the IIHF World Championships (2010–2024) for both men's and women's tournaments. A comprehensive dataset was compiled, including key performance indicators such as goals scored, assists, penalty minutes, shots on goal, save percentage, and player age metrics. Teams were categorized into four groups—gold medalists, silver medalists, bronze medalists, and non-medalists—allowing for a more granular analysis of success factors. Multinomial logistic and ordinal regression models were employed to assess the relationship between team statistics and medal rankings.

RESULTS: Results indicate that offensive performance metrics, such as goals per game ($\beta = 0.825$, $p < 0.01$) and assists per game ($\beta = 0.789$, $p < 0.01$), were the strongest predictors of gold medal success in men's hockey, while save percentage ($\beta = 0.005$, $p < 0.01$) and shooting efficiency ($\beta = 0.689$, $p < 0.05$) played a more significant role in women's hockey. The effect of penalty minutes per game (PIM/GP) was found to be negatively correlated with success in men's hockey (-0.0565 , $p < 0.05$) and women's hockey (-0.0406 , $p < 0.05$).

CONCLUSION: In men's hockey, offensive metrics such as Goals per Game and Assists per Game were dominant predictors for winning gold medals, whereas Save Percentage was more important for securing silver and bronze medals. In women's hockey, shot efficiency (Shot Percentage, Shots per Game) had the strongest impact on winning gold, while Penalty Minutes per Game (PIM/GP) showed a moderate correlation with medal success. These findings highlight the distinct determinants of success in men's and women's tournaments. The results emphasize the importance of offensive efficiency in men's hockey and a balanced approach between offensive and defensive metrics in women's hockey. Additionally, minimizing penalties could improve team success, as aggressive playstyles do not necessarily lead to better outcomes.

RELATIVE AGE IN SWEDISH ICE HOCKEY: DIFFERENTIATING RELATIVE AND ABSOLUTE REPRESENTATION TO REVEAL HIDDEN BIASES IN JUNIOR AND ADULT ELITE TEAMS.

RIETZ, M., NIKLASSON, E., LINDHOLM, O., LIND, J., JOHNSON, D.M., LUNDBERG, T.R.

KAROLINSKA INSTITUTET

INTRODUCTION: The relative age effect (RAE) describes an overrepresentation of athletes born early in a chronological selection year. In this report, the dynamics of the RAE in ice hockey were described by analysing the distributions of relative age (RA) across junior and adult elite selections in a large Swedish cohort.

METHODS: This retrospective, longitudinal study was conducted using birth dates collected from a cohort of players attending certified Swedish ice hockey high schools between 1998 and 2017 ($n=2363$). First, RA was defined as a numeric variable ranging from 0 to 0.99, along with the quarterly terms of the birth year (Q1 – Q4). Data on player selection to the Swedish national U16 team and the National Hockey League (NHL) were retrieved from open databases. Next, RA in the cohort was compared to the general Swedish population using birth data from Statistics Sweden (1), covering the number of children born per month between January 1, 1982, and December 31, 1998. Finally, distributions and group-based differences of RA across elite teams were visualised and described, and generalized logistic regression models were used to compute RA-associated selection probabilities adjusted for relevant confounders.

RESULTS: Individuals with a higher RA were overrepresented in Swedish ice hockey programmes. In detail, 36.7% vs. 13.2% of the included players in the sample were born in Q1 and Q4, respectively, compared to 26.1% (Q1) and 21.7% (Q4) in the Swedish national reference.

Key differences in the absolute distribution of players and relative selection probabilities across RA were observed. Players born in Q1 were about twice as likely to reach the U16 national team than late-born players (Q4), corresponding to absolute numbers of 169 (19.5%) and 32 (10.3%) players, respectively. Consequently, numeric RA was identified as a significant predictor of U16 selection in a regression model ($P < 0.01$). In contrast, 44 (5.1%) born in Q1 and 25 (8.0%) players born in Q4 were selected for the NHL, suggesting trends favouring late-born players. However, in a regression model, numeric RA was not a significant predictor of reaching the NHL ($P = 0.21$).

CONCLUSION: Early-born players are overrepresented in certified Swedish high school programmes, and they are more likely to be selected for the U16 national team. Considering adult success, RA was not identified as an important predictor of NHL selection, and the overrepresentation of early-born players here may be due to earlier selection biases.

THE RELATIONSHIP BETWEEN ANTHROPOMETRICS, ON-ICE, AND OFF-ICE PERFORMANCE IN SLOVAK NATIONAL ICE HOCKEY TEAMS ACROSS DIFFERENT UNDER-18 AGE CATEGORIES

KOVÁČ, M., LOPATA, P., VAJDA, M., KABÁT, M., SURÁN, T., DÚBRAVSKÝ, R., KRUPA, F.

NATIONAL SPORT CENTER OF SLOVAKIA

INTRODUCTION: The relationship between anthropometric characteristics and both on-ice and off-ice performance in ice hockey players over 18 years of age is well-documented (Potteiger et al., 2010; Peterson et al., 2015; Runner et al., 2016). However, these characteristics have not been thoroughly examined across different age categories of players under eighteen. The purpose of this study was to analyze differences in anthropometric characteristics, on-ice, and off-ice performance and to investigate potential relationships among these factors in Slovak National Hockey Teams in the U15, U17, and U18 categories.

METHODS: A total of 120 male members of the Slovak National Hockey Team participated in this study, including players from the U15 ($n = 44$; age 14.8 ± 0.24 years), U17 ($n = 34$; age 16.7 ± 0.34 years), and U18 ($n = 42$; age 17.6 ± 0.48 years) categories. First, body height (BH), body composition, and two off-ice tests—squat jump (SJ) and countermovement jump (CMJ) were performed. Subsequently, on-ice testing in full hockey gear was conducted, consisting of a 40m forward sprint (40FS), a 40m backward sprint (40BS), an agility test with the puck to the left (AGL) and right (AGR), and six 40m shuttle sprints (60SS). Standardized warm-up protocols, tailored separately for on-ice and off-ice measurements, were conducted before each testing session. All testing procedures took place on the same day.

RESULTS: U18 players had significantly greater BH ($p < 0.01$), body weight ($p < 0.01$), and muscle mass ($p < 0.01$) compared to U17 players. However, no significant differences were observed between U18 and U17 players in either on-ice or off-ice performance. Except for BH, U17 and U18 players showed significantly higher values across all measured variables compared to U15 players ($p < 0.01$). A significant relationship was observed between SJ and 60SS (U18, $r = -0.695$, $p < 0.001$; U17, $r = -0.727$, $p < 0.001$), 40FS (U18, $r = -0.851$, $p < 0.001$; U17, $r = -0.686$, $p < 0.001$), and 40BS (U18, $r = -0.552$, $p < 0.001$). Similarly, CMJ correlated with 60SS (U18, $r = -0.672$, $p < 0.001$; U17, $r = -0.657$, $p < 0.001$), 40FS (U18, $r = -0.808$, $p < 0.001$; U17, $r = -0.650$, $p < 0.001$), and 40BS (U18, $r = -0.515$, $p < 0.01$). No significant relationships were found in the U15 category.

CONCLUSION: The results of this study suggest that natural physiological differences between age groups (U15 vs. U17 and U18) may account for the observed disparities in performance and anthropometric characteristics. While relationships between on-ice and off-ice performance were evident in U17 and U18 players, no correlations were found in U15 players. This lack of correlation in U15 players may be attributed to limited training experience with jumping exercises and/or lower levels of strength and power development.

BILATERAL ASYMMETRIES IN ECCENTRIC KNEE-FLEXOR STRENGTH AND THEIR IMPACT ON CHANGE OF DIRECTION AND DECELERATION ABILITY IN FEMALE FIELD HOCKEY PLAYERS : A PILOT STUDY

BAHDUR, K., DA SILVA, Y.

LUNEX

INTRODUCTION: Eccentric knee-flexor strength is a critical determinant of deceleration and change of direction (COD) performance in field hockey. Given the sports unilateral demands and potential for muscular imbalances, this study investigates the relationship between bilateral asymmetries in eccentric knee-flexor strength and COD ability in female field hockey athletes.

METHODS: Thirteen female field hockey players (mean $\pm$ SD age: 28.3 ± 9.3 years; mean $\pm$ SD body mass: 62.1 ± 7.6 kg) underwent eccentric knee-flexor strength testing using an instrumented Nordic hamstring device (NordBord, Vald Performance). Bilateral asymmetries were quantified based on peak torque and strength normalized to body mass (N/kg). COD performance was assessed using the 505 test (dominant and non-dominant plant foot trials), while deceleration ability was measured via distance to stop and time to stop using GPS-based tracking. Normal distribution was assessed for all variables using the Kolmogorov Smirnov Test. Pearson's product moment correlation coefficients was used for normally distributed variables and non-parametric method Spearman's rank correlation was used for non-normally distributed variables.

RESULTS: Bilateral asymmetry in eccentric strength ranged from 1% to 21%, with five athletes exceeding 10% imbalance. Sprint performance (10m, 15m, and 30m splits) was negatively correlated with higher strength asymmetries ($r = 0.615$ – 0.598 , $p < 0.05$). 505 COD performance was negatively correlated with higher strength asymmetries ($r = -0.42$, $p < 0.05$). Acceleration and deceleration characteristics were strongly correlated, with athletes displaying greater acceleration rates also requiring more significant braking adaptations ($r = 0.846$, $p < 0.001$).

CONCLUSION: Athletes with greater bilateral asymmetries in eccentric knee-flexor strength exhibited reduced COD efficiency, slower sprint times, and altered deceleration mechanics. These findings emphasize the need for individualized

training strategies to improve bilateral strength symmetry, sprint acceleration, COD performance, and braking ability in female field hockey players. Further research should investigate whether targeted eccentric strength interventions can reduce these asymmetries and improve COD efficiency.

UNILATERAL VERTICAL FOOT-ANKLE REACTIVE STRENGTH INDEX: A NEUROMUSCULAR READINESS INDICATOR FOR PLYOMETRIC ACTIVITIES IN FLOORBALL PLAYERS ACROSS AGE GROUPS, PLAYING POSITIONS AND LEVELS

VECBERZA, L., PLAKANE, L.

UNIVERSITY OF LATVIA

INTRODUCTION: The reactive strength index (RSI) is a key assessment of lower limb neuromuscular efficiency, whereas kinetic variables provide in-depth information into an individuals jumping performance [1]. High-intensity movements impose a significant mechanical load on the ankle joint [2]; therefore, unilateral RSI can more accurately reflect an athletes single-limb readiness for plyometric activities and the potential risk of ankle-complex injury. This study aimed to indicate floorball players unilateral RSI as a readiness indicator for plyometric activities and compare metrics across age groups, playing positions, and levels.

METHODS: Seventy-six male floorball players (age: 18.9 ± 3.9 years; height: 180.0 ± 7.1 cm; body mass: 76.1 ± 9.9 kg; body mass index: 23.4 ± 2.5) from the three highest and first league teams (grouped as follows: U17: $n = 29$, U20: $n = 23$, 20+ years: $n = 24$) performed a unilateral foot-ankle 10/5 rebound jump test on an infrared contact grid (MuscleLab, Norway). Jumping strategy-based metrics, including jump height (JH), contact time (CT), flight time (FT), vertical stiffness (Kvert), average power (AP), and RSI, were determined and used for correlational analysis. For the jump strategy, standardised z-scores were calculated; however, for the readiness, t-scores as RSI benchmarks were used. However, a one-way ANOVA test was used to compare age groups and eta squared (η^2) to determine effect size, but an independent t-test and Cohen's d for playing position and level. All test results were statistically significant if $p < .05$.

RESULTS: Significant differences in RSI, JH, and FT were indicated among age groups ($p < .05$, $\eta^2 = .111$ to $.133$), but no differences in CT. RSI is significantly higher in U20 than U17 ($p = .014$), but U17 showed shorter CT than U20 and the 20+ group ($p < .05$). Higher-league athletes had higher RSI, JH, FT, and AP compared to the first league ($p < .001$), but no differences by playing position. Unilateral RSI was negatively associated with Kvert ($r = -.49$, $p < .05$) in the U20 group. Twelve athletes had good RSI, while twelve showed poor RSI, indicating unpreparedness for plyometric activities. Twenty-seven athletes showed short CT with low JH jumping strategy, mostly from U17, while longer CT with higher JH was mostly utilised in the U20 group ($n = 10$).

CONCLUSION: Athletes with poor RSI have low reactive strength capabilities and are unprepared for moderate to high-intensity plyometric activities, where low AP and JH indicate a need for strength development. These findings indicate that unilateral RSI from rebound jumps is a key dynamic performance indicator and a useful data-driven tool to assess an athlete's readiness, providing coaches with athlete-centred monitoring and appropriate training decision-making.

INVESTIGATING THE DYNAMICS OF EYE-HAND COORDINATION IN FIRST-PERSON SHOOTER VIDEO GAMES

SCIARRA, D., COCO, M.I.

SAPIENZA UNIVERSITY

Introduction:

Eye-hand coordination is critical in many daily tasks and essential in sporting contexts, directly relating to performance outcomes (1). This topic has been central in research on traditional sports, such as soccer (2) or basketball (3). However, newer gaming-related sports (e-sports) are rapidly emerging, involving sensorimotor control and the coordination of various cognitive processes, such as attention and memory (4). These skills are currently understudied. This work addresses this gap by examining the learning patterns underlying eye-hand coordination and performance in video games, focusing on the interplay of different cognitive functions.

Methods:

Twenty non-professional males ($M = 28.2$; $SD = 2.57$) and females ($M = 26.1$; $SD = 3.22$) played eight different first-person shooter video games (e.g., shooting fixed or moving targets, decision-making, memory, audio-spatial tasks, etc.) drawn from the "Aimlab" platform. Participants eye movements were tracked using "EyeLink 1000", while their hand responses were concurrently collected through "Weblink", a screen recording software. Each game was repeated four times (4 repetitions x 8 games, totalling approximately 1 hour of gameplay).

Results:

The analysis focused on three of the eight video games: "gridShot" (fixed targets), "flickShot" (object tracking), and "decisionShot" (colour-based action selection), all involving rapid target selection. Using linear mixed-effects models with a by-subject random effect, we predicted the duration of the final fixation before clicking on a target as a function of a performance metric (integrating shot frequency, hit/miss rates, and reaction time) across the four repetitions. Overall, performance linearly improved across sessions in all games. Importantly, each game exhibited distinct patterns of overt attention time-locked-to-hand responses. "gridShot" showed a progressively linear increase in fixation duration over sessions, while "flickShot" showed the opposite trend. In "decisionShot," fixation duration displayed a non-linear dynamic, reaching an individual-specific maximum threshold that optimised performance.

Discussion:

To the best of our knowledge, this study is the first to demonstrate that the duration of target fixation before a hand response does not linearly predict performance in these types of video games. This finding contrasts with the "quiet eye" concept often described in traditional sports, where a linear relationship between overt attention and performance is typically observed. Future work will investigate whether this type of learning can enhance relevant cognitive functions and whether expertise influences eye-hand coordination strategies.

THE INFLUENCE OF QIGONG ON THE BALANCE CAPABILITIES OF PRACTITIONERS

ANGELOV, V.

NATIONAL SPORTS ACADEMY

INTRODUCTION: According to various authors, the systematic practice of qigong exercises has a beneficial effect on health, reducing stress, improving balance, and more. The aim of this study is to prove the positive effect of warming up with qigong exercises on balance capabilities. The object of the study is to compare the warm-up effects between two different types of exercises: qigong and basic gymnastics.

METHODS: Thirty-two students from different sports, between 20-25 years old, 16 males and 16 females, participated in the study. The balance assessment was conducted with the help of a stabilometric force platform. The Flamingo test in four conditions was used: eyes open and eyes closed with balancing on the left and right leg. Testing before and after two types of warm-ups was performed: with qigong exercises and with basic gymnastics exercises. A statistical processing of the results by descriptive analysis, Shapiro-Wilk Test, and Paired-Samples t Test was done. The effect size was calculated. Most of the differences observed in the center of gravity deviation during the balance tests were statistically significant, except for those with the left leg pre- and post-, and the right leg with eyes closed pre- and post- warm-up with basic gymnastics.

RESULTS: The mean center of gravity deviation pre- and post- the two types of warm-ups was established. When using qigong exercises, the following results were found: for right leg 7.7 ± 1.8 vs 5.7 ± 1.4 cm, for right leg with eyes closed 12.1 ± 4.2 vs 9.3 ± 3.2 cm, for left leg 8 ± 2.1 vs 6.1 ± 1.6 cm and for left leg with eyes closed 12.2 ± 4.4 vs 9.2 ± 3.2 cm. The results recorded from applying a warm-up with basic gymnastics were 5.9 ± 2.0 vs 7.0 ± 2.0 cm for right leg, 9.5 ± 3.1 vs 9.6 ± 3.0 cm for right leg with eyes closed, 6.5 ± 1.8 vs 6.8 ± 1.8 cm for left leg and 9.4 ± 2.2 vs 11.2 ± 3.5 cm for left leg with eyes closed, respectively. The calculated differences showed that qigong exercises led to a decrease in this indicator for all variables: for right leg by 2 cm, for right leg with eyes closed by 2.8 cm, for left leg by 1.9 cm, and for left leg with eyes closed by 3 cm. The use of basic gymnastics exercises produced the opposite effect, as evidenced by the negative differences recorded: -1.08 cm, -0.09 cm, -0.38 cm, and -1.85 cm for right leg, right leg with eyes closed, left leg and left leg with eyes closed, respectively. The calculated large and very large effect size with values of 1.17, 1.15, 0.99 and 1.4 for the four conditions confirms the good influence of qigong on balance capabilities. The effect size of using basic gymnastics was negative with calculated values of -0.57, -0.04, -0.17, and -0.58.

CONCLUSION: On the basis of the results obtained, it can be firmly concluded that a warm-up using qigong exercises positively influences balance capabilities. This type of warm-up favours the performance of balance exercises and has a place in the training programs. Warming up with qigong is preferable to basic gymnastics when working up to balance exercises.

PERCUSSIVE MASSAGE DOES NOT REDUCE ECCENTRIC AND CONCENTRIC TORQUE DECLINE DURING AND AFTER FATIGUING ECCENTRIC KNEE EXTENSIONS

HEINKE, L., RAPPELT, L., ZEMKE, J.A., FREIWALD, J., LEGERLOTZ, K., BAUMGART, C.

UNIVERSITY OF WUPPERTAL

INTRODUCTION: Percussive massage is commonly used to enhance performance and recovery. Pre-exercise applications verifiably improve ROM and flexibility, while post-exercise use may help to reduce DOMS [1]. However, its acute effects on performance indicators remain unclear, with studies reporting both performance benefits [2] and drawbacks [3]. This study examined the effects of intra-set percussive massage on torque decline during isokinetic eccentric and concentric contractions in a fatiguing exercise protocol, compared to a placebo treatment.

METHODS: This study used a randomized crossover design, with participants completing one familiarization and two testing sessions. A total of 20 healthy, physically active individuals ($f = 2$, $m = 18$; age: 25.5 ± 2.2 years; height: 178.9 ± 8.8 cm; weight: 79.3 ± 12.8 kg) were included. The primary outcome was the isokinetic knee extensor peak torque ($60^\circ/\text{s}$) measured concentric (PRE and POST) as well as during an eccentric fatiguing protocol. The protocol consisted of 5 sets of 15 maximal eccentric leg extensions on an isokinetic dynamometer ($60^\circ/\text{s}$), with 3 min intra-set breaks. During these breaks, participants received either 3 minutes of percussive massage (40 Hz) targeting the vastus medialis, vastus lateralis, and rectus femoris, or a placebo "light therapy" using a conventional laser pointer.

RESULTS: Test-retest reliability (ICC 2.1) for the initial concentric and eccentric torque values were (ICC(2,1) = 0.74, 95% confidence interval (CI) [0.55; 0.86]) and (ICC(2,1) = 0.73, 95% confidence interval (CI) [0.53; 0.85]), respectively. For concentric torque, no significant intervention $\times$ time interaction was observed. However, a significant time effect was found ($F(1,39) = 15.54$, $p = .0003$, $\eta^2 = .032$ [small]), indicating a torque decline in both interventions. For eccentric torque, a significant intervention $\times$ time interaction was detected ($F(2.28,89.08) = 4.30$, $p = .013$, $\eta^2 = .004$ [trivial]), along with significant intra-set fatigue effects ($F(2.28,89.08) = 4.30$, $p = .013$, $\eta^2 = .004$ [trivial]), showing a torque decline within sets in both interventions. Additionally, a significant main effect of time ($F(1,39) = 13.64$, $p = .0006$, $\eta^2 = .011$ [small]) indicated a decline in eccentric torque from PRE to POST in both interventions.

CONCLUSION: The comparison of percussive massage with a physiologically irrelevant "light therapy" placebo intervention in this study suggests that intra-exercise percussive massage has no impact on maximum strength parameters. These findings have practical implications for recreational exercisers, coaches, and athletes, indicating that incorporating percussive massage during workouts does not enhance performance. As a result, its use should be critically evaluated to ensure efficient exercise time management.

RECOGNITION OF VOLLEYBALL SETTING TACTICS USING BIOLOGICAL MOTION

CHANG, C., LIU, Y.T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Volleyball players ability to observe the setters movements and predict the sets direction and tactics is critical for improving blocking success. This relies on players sensitivity to movement cues and is closely associated with specialized training. Studies have shown that experienced players detect movement cues earlier and over a broader range [1]. Using biological motion created by dynamic point-light displays, observers can focus on the relative movements of the setter's body segments without viewing the ball's trajectory. This approach enables the examination of observers' visual discrimination sensitivity to setting movements. The purpose of this study was to investigate differences in recognizing various setting tactics among individuals with different levels of volleyball proficiency.

METHODS: This study recruited 90 collegiate Division A, 84 Division B volleyball players, and 81 individuals without volleyball training. Using Simi Motion software, 17 markers were placed on specific body parts (toes, ankles, knees, hips, shoulders, elbows, wrists, fifth metacarpals, and head) of 6 Division A players (3 males) to record movements during 3 successful setting scenarios: A quick, an outside set (position 4), and a back-row attack (position 6). Wolfram Mathematica was used to create 18 dynamic point-light videos randomly ordered and embedded in Google Forms. Participants were briefed on the experiment and watched the videos on their phones in a quiet environment, completing the task within 10 minutes. A one-sample, one-tailed t-test determined whether the correct rates of each group exceeded the random guessing probability of 0.33. One-way analysis of variance (ANOVA) compared correct rates among the three groups. The significance level was set at $\alpha = .05$.

RESULTS: The results showed that correct rates for all three groups were significantly higher than the random guessing probability of 0.33 ($ps < .001$). ANOVA indicated significant differences in correct rates among the three groups ($p < .001$). Post hoc comparisons revealed that Division A players significantly outperformed Division B and untrained individuals, while Division B players scored higher than untrained individuals ($ps < .05$).

CONCLUSION: This study found significant differences in recognizing volleyball-setting tactics using dynamic point-light displays among individuals with different skill levels. Division A players excelled in identifying setting motion cues, likely due to their extensive volleyball experience and training. Division B players demonstrated higher visual discrimination abilities than untrained individuals, but their performance was still lower than that of Division A players, likely due to less exposure to standard setting skills. These findings suggest that professional sports skills are influenced by physical performance and perceptual abilities specific to sports scenarios.

WHERE DO YOU LOOK WHEN HITTING A SOFTBALL OFF A TEE?

CHEN, Y., LIU, Y.T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Striking a ball off the tee-stand is commonly used as the batting practice in softball. When striking a ball off the tee, the visual focus is often on the ball; while hitting a ball from a pitch, the visual focus is on the coming ball. The

batter needs to perceive the pitching event and swing at the ball when the ball enters the home plate based on the speed of the ball. Therefore, the visual focus should be on the direction of the incoming ball to perceive the distance that affords the swing time based on the ball speed. This study examined the performance of fast softball batters striking softballs off the tee under different visual focuses.

METHODS: 4 active collegiate Division I female softball players performed the tee strikes under 4 visual focus conditions. The visual focus was on the ball for the regular tee strike (T); the other 3 visual focuses were at right (R), right-front (RF), and directly in front (F) of the player at a distance (4.5m) to simulate 70 km/h pitching speed and 0.23 s of swing time. Players performed 5 trials in each condition, and the order of conditions was randomly assigned. 3-D kinematics of the ball and the bat's tip were captured using 2 high-speed cameras and the Simi Motion software. Based on the bat-ball speed change after the hit, the hitting results were classified into 3 groups: miss, decrease, and increase. A Chi-square test of independence was performed on the classification of batting results and the visual focus conditions. In addition, (T F) and (R RF) were further grouped, and the independent sample t-test was performed for each player. The significant level was set to $\alpha=.05$.

RESULTS: The chi-square test result was significant, $p=.014$. R and RF had a positive association with the number of misses, with a standardized residual of 3.184. There were individual differences in the t-test results: 2 batters at the T and F conditions performed significantly greater than that at the R and RF conditions, $ps < .05$, and one of the batters swing-and-missed all trials at the R and RF conditions; the other two batters did not reach significant difference between conditions, $ps > .3$.

CONCLUSION: This study provides preliminary observations of the effect of visual focus on the softball tee strike performance. Overall, when the visual focus is not on the ball at the tee or in front of the simulated position of the ball, the probability of swing-and-miss increases. When focusing on the part unrelated to the hitting situation, half of the hitters' performance was significantly affected. Striking the ball on the tee does not simulate the dynamic hitting situation, and the perception-and-action coupling is also different from the actual striking situation. In addition to increasing the sample size for future research, we suggest that if tee strikes are unavoidable due to equipment and resource issues, the visual focus should be placed at an appropriate distance in front to simulate the pitching situation.

WHEN DEFENDERS CLOSE IN: PERFORMANCE AND ADAPTION IN THREE-POINT JUMP SHOTS

CHEN, Y., LIU, Y.T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: In basketball, the presence of a defender forces shooters to adjust their movements, such as modifying shooting trajectories and shortening movement time. These adjustments are strategies to avoid blocking, but they often come at the cost of reduced stability and shooting success. Most prior research has focused on the impact of static defensive distances or the presence of defenders on jump shot performance, while the dynamic interaction between shooters and defenders remains underexplored. This study investigates how varying defensive starting distances and actions (hands-up or hands-down) dynamically influence shooters' movements and performance.

METHODS: Eight female division 1 collegiate basketball players made sixty 3-point jump shots at the 45-degree angle under 3 defensive starting distances (5.75m, 4.75m, 3.75m), each with hands-up or hands-down defensive actions. Video-based kinematics analysis was used with Simi Motion analysis software. 3-D data of the shooter's right hip was used to determine the preparation and shooting phases as well as the air time. 3-D data of the ball was used to derive the ball release heights, angles, and velocity. In addition, 2-D data from the defender's left hip was used to calculate the kinematics of the defender's displacement. Shooting results were recorded manually. Shooters' data were analyzed using two-way repeated measures ANOVA to examine the interactions between defensive distance and action. The relation between the shooter's preparation time and defender displacement was examined using Pearson's correlation analysis.

RESULTS: The shorter defensive distance (3.75m) significantly reduced preparation and shooting times but increased air time and ball release angle, ultimately decreasing shooting accuracy ($ps < .05$). Defensive actions (hand-up or hand-down) and the interaction effect did not show any significant result. Six participants showed significantly positive correlations ranging from 0.78 to 0.92 between the preparation time and defender's displacement ($ps < .05$). The other two shooters showed no significant correlation ($ps > .1$).

CONCLUSION: The study shows that the shooting motion adjusts according to the defenders movement among different starting distances. The shooting movement time decreased as the initial defensive distance shortened. The shooter also increases the release angle and air time to avoid being blocked at the closest distance. These adaptations, however, reduced shooting accuracy. The results of correlation analysis indicate that most shooters spent more time in the preparation phase when defenders were further away. Future research should investigate defensive distances shorter than 3.75m and possibly the minimum shooting preparation time.

INFLUENCE OF PELVIC BELT-EQUIPPED GARMENT ON BALANCE AND MUSCLE SYNERGIES DURING SINGLE LEG LANDING

BENIO, K., AOI, N., TAKASHI, K.

KOBE UNIVERSITY

INTRODUCTION: Landing stability is essential for preventing lower limb injuries. Pelvic belts reduce landing impact by limiting lumbar motion and enhancing hip energy absorption (1), and they improve Y-balance performance and dynamic stability (2). Moreover, lumbar compression may increase intra-abdominal pressure, enhance trunk stiffness and reduce

muscle activity (3). Thus, pelvic belts may improve landing stability while reducing trunk effort. However, because landing requires coordinated trunk and lower limb activation, decreased trunk activity might alter lower limb strategies, though this remains unclear. This study examined how wearing a pelvic belt-equipped garment (PBG) affects balance and muscle synergies during single leg landing (SLL). Muscle synergy analysis quantifies coordinated activation patterns among multiple muscles. We hypothesized that PBG would reduce trunk muscle weightings in synergies while also modifying lower limb muscle weightings.

METHODS: Eleven male athletes (age: 20 ± 1 years; height: 1.70 ± 0.03 m; body weight: 62 ± 7 kg) participated in sports at least three times per week and performed SLL under two conditions, one with PBG and the other without PBG (CON). During each trial, surface electromyography was recorded from 10 trunk and lower limb muscles, and ground reaction forces were measured at 1000 Hz. Non-negative matrix factorization was performed to the electromyography data from toe-off to 5 seconds after toe-off. We compared differences in synergy weightings and center of pressure (CoP) sway between conditions using paired t-tests. CoP sway was quantified over the 5 seconds following landing by total path length, rectangular area, and mean velocity.

RESULTS: CoP sway tended to be higher in PBG than in CON ($p < 0.08$). Three muscle synergies were extracted. Synergy 1 was related to absorbing landing impact. Synergy 2, mainly activates immediately after landing, was associated with postural recovery. Synergy 3 was associated with maintaining single leg balance. In Synergy 2, the external oblique weighting was lower in PBG than in CON ($p = 0.02$), and modulation of lower limb weightings was also observed, as the weightings for the ankle plantar flexors and knee extensors were higher in PBG ($p < 0.07$). No significant differences were found in overall synergy activation between the two conditions.

CONCLUSION: PBG increased CoP sway and modulated Synergy 2 weightings. Modulation of Synergy 2 weightings may reflect PBG support to the external oblique and a landing strategy that pushes off the ground using the ankle and knee. Within the postural recovery synergy, we concluded that PBG not only reduced the external oblique weighting but also increased the weightings of the ankle plantar flexors and knee extensors.

MECHANISMS OF PREMOTOR CORTEX IMPACT ON MOTOR CORTEX OUTPUT: A STUDY OF NEUROPHYSIOLOGICAL CONNECTIVITY WITH TRANSCRANIAL MAGNETIC STIMULATION

ALLAHVERDLOO, E., CHIU, L., OFARRELL, A., DANCAUSE, N., NEVA, J.
UNIVERSITY OF MONTREAL

INTRODUCTION: Connectivity between the premotor (PMC) and primary motor (M1) cortices is critical for coordinated voluntary movement. Interactions between these areas, both within and across hemispheres, have been extensively studied in non-human primates with invasive stimulation techniques. In human studies, distinct subregions, including the dorsal (PMd) and ventral (PMv) areas, may exert time and region-specific influences on M1 output, however the precise mechanisms remain poorly understood. To address this gap, we systematically assessed the neurophysiological connectivity between PMd/PMv and M1 using transcranial magnetic stimulation (TMS).

METHODS: Thirty right-handed adults (15 females, aged 18–39) were recruited. T1-weighted MRI scans guided TMS coil placement (Brainsight) over PMd, PMv, and M1. Individualized M1 “hotspots” were identified to evoke ~1 mV motor-evoked potentials (MEPs) in the contralateral first dorsal interosseous muscle. For the first assessment with dual-site TMS, a conditioning stimulus (CS) was delivered over the non-dominant PMd, PMv, or M1, followed by a test stimulus (TS) over the dominant M1 “hotspot” at inter-stimulus intervals (ISIs) of 0 ms, 10 ms, and 50 ms. Interhemispheric inhibition (IHI) was quantified by comparing MEP amplitudes from CS+TS trials to TS-alone trials, calculating an IHI ratio where lower values indicate greater inhibition. For the second assessment and to evaluate transcallosal inhibition, the ipsilateral silent period (iSP) was measured by stimulating each site at 150% of resting motor threshold during a 50% maximum voluntary contraction of the FDI. iSP magnitude was calculated as the percent decrease in EMG amplitude from a pre-stimulus baseline, and iSP onset was defined as the latency from the TMS pulse to the first drop in EMG below baseline.

RESULTS: IHI was strongest at 0 ms for all sites. PMd consistently inhibited M1 across all ISIs with 0ms having the strongest inhibition, whereas PMv showed more variable inhibition with nearly no inhibition at 10 ms and little inhibition at 50 ms. The iSP results showed robust inhibition from all sites, with M1 producing the largest magnitude (~45%) and the shortest onset latency. Although PMd (35%) and PMv (~25%) also induced significant iSP, yet to a lesser extent than M1. By integrating measures of both IHI and iSP, this study provides a more comprehensive view of the temporal and regional dynamics underlying PMC–M1 connectivity.

CONCLUSION: Our findings highlight that PMd and PMv differentially modulate M1 excitability via distinct pathways. Early (0 ms) inhibition likely reflects subcortical or reticular circuits, while longer intervals (10 ms and 50 ms) may involve callosal or higher order corticocortical connections. Understanding the temporal and regional dynamics of interhemispheric connectivity with M1 could benefit targeted neuromodulation strategies or tailored rehabilitation to optimize motor recovery following stroke.

EFFECTS OF DUAL-TASKING ON GAIT PARAMETERS AND CORTICAL ACTIVATION IN OLDER ADULTS ACROSS DIFFERENT WALKING CONDITIONS

DREWES, C., WOLLESEN, B.

UNIVERSITY OF HAMBURG; GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Performing a motor and a cognitive task simultaneously (dual tasking, DT) is essential in daily life but often leads to cognitive-motor interference (CMI), in older adults. With increasing age, walking requires more cognitive control. In addition, different walking conditions (e.g. barefoot, minimal and conventional footwear) can influence gait parameters (I). This study investigates how DT affects motor and cognitive performance and prefrontal cortex (PFC) activity across different walking conditions.

METHODS: Eighteen older adults (69.5 $\pm$ 4.4 years; n = 8 barefoot, n = 4 Leguano, n = 6 control) completed four conditions: 1 - baseline, 2 - visual discrimination task (ST visual), 3 - single task walking (ST walking), and 4 - a motor-cognitive dual task (DT visual: responding to peripheral visual stimuli). Gait was assessed using Optojump Next (speed, step length, double support time, cadence). Cognitive performance was assessed by reaction time and response accuracy, while PFC activity was measured based on HbO2 concentration using near-infrared spectroscopy (fNIRS). A general linear model (GLM) with repeated measures was used to analyse differences in gait parameters, HbO2 concentration, reaction times, and response accuracy across task conditions (ST walking, DT visual), with walking condition (barefoot, minimal footwear, control) and sex as between-subject factors, and age as a covariate. Group differences were examined using a multivariate GLM.

RESULTS: Motor performance revealed no significant differences between ST walking and DT visual ($p > 0.05$). However, the three walking conditions differed significantly in motor performance ($F(16,18) = 2.437$; $p = 0.036$; $\eta_p^2 = 0.684$), with significant differences observed for gait speed and step length (control group > barefoot group; $p < 0.01$) as well as for double support time (barefoot group > control group; $p < 0.05$). Cognitive performance declined under DT conditions, indicated by significantly reduced response accuracy ($F(1,10) = 124.734$; $p < 0.001$; $\eta_p^2 = 0.926$). Furthermore, walking condition significantly affected changes in reaction time from ST visual to DT visual ($F(2,9) = 4.614$; $p = 0.042$; $\eta_p^2 = 0.506$), with a decrease in the control group ($p < 0.05$) and an increase observed in the barefoot and Leguano shoe groups ($p > 0.05$). PFC activation varied across walking conditions and was highest during ST walking (barefoot, leguano) and DT visual (control), but did not show significant differences.

CONCLUSION: The findings indicate that older adults prioritise motor performance under DT conditions, leading to a decline in cognitive performance. Moreover, the influence of walking conditions on both motor and cognitive outcomes highlights the role of footwear in dual-task scenarios. However, due to the small sample size, further studies are required.

AN ACCELEROMETER-BASED SINGLE-ARM DYNAMIC STABILITY TEST FOR THE ASSESSMENT OF THE SENSORIMOTOR CONTROL OF THE SHOULDER

PICERNO, P., IULIANO, E., BRAVI, M., SANTACATERINA, F., PEŠOVIC, U., MARTÍNEZ MÉNDEZ, R., GARCÍA RAMOS, A., MARTINS VIEIRA, T.

UNIVERSITY OF SASSARI

INTRODUCTION: Myers introduced the Single-Arm Dynamic Stability (SADS) test to assess the sensorimotor control of the shoulder by analysing the sway of the centre of pressure of the supporting hand during a one-handed push up position on a force platform [1]. However, in the SADS test, stability does not depend solely on the shoulder muscles due to other support points, load modulation is limited to part of the body mass, and the closed-chain configuration weakly reflects the shoulder injury patterns. Aim of this research was to address such limitations by designing and validating a variation of the SADS test as performed in an Open Kinetic Chain (SADS-OKC) with the subject lying supine while holding a dumbbell still in one hand with the extended arm.

METHODS: The dumbbell was assumed as the endpoint of an inverted pendulum linked at shoulder level while its sway was measured using a triaxial accelerometer, applying the same stability parameters typically used for standing balance assessments with a waist-mounted accelerometer [2]. SADS-OKC test was performed by 20 healthy subjects (16 males and 4 females aged 23 ± 2 years) in two sessions of day1 and in one session of day2. Each session was performed with both arms and consisted of three randomised trials with 15%, 25% and 35% of a reference load (RL) determined as the mass measured by a scale placed under the hands while maintaining a quadruped position (five attempts). Based on previous studies on SADS test, test duration was set to 30 s but stability parameters were also computed over the first 20 s. Stereophotogrammetry was used to detect any elbow or wrist motion that could invalidate the pendulum assumption. ICC analysis assessed intra- and inter-day reliability of time- and frequency-domain stabilometric parameters. Spearman's rank correlation analysed the relationship between load variations and stability parameters.

RESULTS: Both elbow and wrist flexion never exceed 2° during all trials. Average RL was 28.3 ± 5.5 kg (2.2% CV). ICC analysis revealed that the SADS-OKC test at 15% RL exhibited the highest intra- and inter-day reliability for both sides and test durations, while reliability decreased at higher loads. Specifically, Jerk and swayArea exhibited good to excellent intra-day reliability ($ICC = 0.866 - 0.947$) and moderate to good inter-day reliability ($ICC = 0.707 - 0.766$). All other stabilometric parameters showed moderate or moderate-to-good reliability. Overall, swayFreq, F50, F95, CF and FD appeared to be moderately affected by load increase ($0.4 < p < 0.59$).

CONCLUSION: The SADS-OKC test, as performed with 15% of RL for either 20 or 30 s, has proven to produce a set of reliable stabilometric parameters that may be related to the neuromuscular control of the shoulder. Further studies should investigate whether any of these parameters can also identify deficits in the neuromuscular control of the shoulder in clinical populations. TOWARD THE DEVELOPMENT OF A MOVEMENT QUALITY ASSESSMENT FOR ATHLETES: A MODIFIED DELPHI APPROACH

WIJEKULASURIYA, G., WOODS, C., KITTEL, A., LARKIN, P.

VICTORIA UNIVERSITY

INTRODUCTION: Assessing athletic motor skill in talent development environments helps practitioners identify developmental gaps in individuals and groups (1). Movement quality assessments can be used to assess athletic motor skills, with some measures of movement quality associated with certain physical fitness attributes (2,3). However, these assessments have been developed with varied academic rigour and none have been developed to assess movement quality that may associate with multiple fitness attributes (4). This study aimed to draw upon previous research and the experiential knowledge of discipline experts to design a movement quality assessment that may associate with physical fitness attributes.

METHODS: Academics (n=5), strength and conditioning coaches (n=18) and physiotherapists (n=1) with five years of experience assessing movement quality within athletic populations were recruited via personalised email and social media. Participants completed three stages of online surveys designed to establish expert consensus about the structure of a novel movement quality assessment using a modified Delphi approach. Participants rated their agreement with each component of the assessment using a 9-point (Stage 1) or 5-point (Stage 2 and 3) Likert scale with consensus defined as 70% agreement to a component of the assessment.

RESULTS: Consensus was reached for the instructions to use, movements within the assessment and scoring system and criteria of the movement quality assessment. The novel movement quality assessment included the active straight leg raise, shoulder mobility test, squat, push up, triple hop and lateral bound. Each movement was scored out of five with a maximum composite score of 45 achievable.

CONCLUSION: A novel movement quality assessment was developed for athletes using high academic rigour. The assessment includes movements assessed with scoring criteria that could associate with various physical fitness attributes. Hence, this assessment may be more useful for practitioners assessing athletic motor skills within talent development environments than current assessments.

WHOLE-BODY MUSCLE SYNERGY ANALYSIS DURING THROWING MOTION IN YOUNG CHILDREN

MURAKAMI, T., KUSAFUKA, A., OKEGAWA, T., YAMASAKI, D., SAKAKIBARA, Y., HAKARIYA, N., KANEKO, N., SASAKI, A., NAKAZAWA, K.

THE UNIVERSITY OF TOKYO

INTRODUCTION: Throwing is a fundamental skill in sports such as baseball and handball requiring coordinated activation of muscle throughout the body. Muscle synergy analysis enables a quantitative approach to evaluating muscle coordination. Despite its importance, the mechanisms underlying whole-body coordination during throwing, particularly its development across different stages of growth, remain unclear. Therefore, this study aimed to investigate the development of whole-body coordination during throwing in children at different developmental stages by examining muscle synergies.

METHODS: Eleven preschoolers (3–6 years old) and nine primary school children (7–9 years old) participated in this study. Each participants performed 8 to 13 throws toward a net located 2 meters away, with instructions to throw balls as fast as possible. Ball and body movements were captured using high-speed cameras. Electromyographic (EMG) activities were recorded from the 16 muscles across the dominant upper limb, bilateral trunk and lower limbs, including the pectoralis major, middle deltoid, infraspinatus, middle trapezius, rectus abdominis, erector spinae, rectus femoris, biceps femoris, tibialis anterior, and soleus. Ball speed was defined as the magnitude of the velocity vector at the moment of ball release. Muscle synergy analysis was conducted using non-negative matrix factorization (NMF), with the number of synergies determined as the minimum number required to achieve a variance accounted for (VAF) >90%. Synergies from each group were clustered using the k-means, and cluster consistency was compared based on cosine similarity. Clusters with cosine similarity exceeding 0.8 were considered common synergies.

RESULTS: The average ball speed in preschool children (22.1 ± 6.1 km/h) was significantly lower than that in primary school children (33.6 ± 10.7 km/h) ($p < 0.05$). The number of muscle synergies in preschoolers (5.5 ± 0.82) was fewer than that in primary school children (6.3 ± 1.41) ($p < 0.05$). No significant correlation was observed between the number of muscle synergies and ball speed. K-means clustering identified eight muscle synergy clusters in preschool group and nine in primary

school group. Of these, six clusters were common between the two groups, while two clusters were unique to preschoolers and three were unique to primary school children.

CONCLUSION: Ball speed increases significantly from preschool to primary school age. Our findings suggest that this increase is not solely due to the natural increase in muscle strength with growth but may also be related to changes in muscle synergies, indicating the maturation of motor control. The disappearance of preschooler-specific muscle synergies and the acquisition of new, refined synergies enable more efficient coordination of force generation and transfer across the entire body. This highlights the importance of whole-body coordination and neuromuscular adaptation in the motor skill development.

CP-BM12 Running Biomechanics

THE RELATIONSHIP BETWEEN BODY COMPOSITION, LOWER EXTREMITY BIOMECHANICS AND RUNNING ECONOMY IN RECREATIONAL FEMALE RUNNERS

SENINGTON, B., MANDERS, R., SUJAK, J.

UNIVERSITY OF SURREY

INTRODUCTION: The influence of anthropometry and running biomechanics on running economy in recreational female runners is unclear, with previous investigations on this topic involving small homogeneous groups of runners and only examining a limited set of anthropometric or biomechanical measurements [1]. As such, this study aims to investigate the relationships between anthropometry and lower extremity biomechanics with running economy within a homogenous sample of female runners.

METHODS: Twenty-six female recreational runners (age 34.7 ± 9.4 yrs), performed a standardised incremental running protocol on a force-sensing treadmill (4-minute stages at 8km/h, 10km/h, and 12km/h). During the final minute of each stage ground contact time (GCT), flight time, stride length (SL), stride frequency (SF), leg stiffness and vertical oscillation (VO) were collected and compared to respiratory gases to determine the submaximal (<1.00 respiratory exchange ratio) locomotory cost (LEc) of running. Whole body and segmental anthropometry were also obtained using dual-energy x-ray absorptiometry and correlated to LEc.

RESULTS: Absolute LEc (ABSLEc) was positively associated with 8 out of 9 anthropometric variables in the first two stages of the running protocol and 7 out of 9 during the final stage. Only SL and VO out of the six biomechanical variables were positively associated with ABSLEc at 8 and 10km/h, respectively. Relative LEc (RELLEc) was positively correlated with body mass (BM) and height during the first stage. SL showed significant correlations with RELLEc at 8km/h ($R=0.401$; $P=0.03$). At faster velocities, significant positive and negative correlations were identified between GCT ($R=0.542$ (10km/h); $R=0.451$ (12km/h) and SF ($R=-0.545$ (10km/h); $R=-0.407$ (12km/h), respectively. Backward multiple linear regression analysis revealed four anthropometric measures (BM, bone mass, leg fat mass, and fat-free mass), plus VO at 12km/h, explained most variance in ABSLEc ($R^2=0.742$ (8km/h); $R^2=0.704$ (10km/h); $R^2=0.433$ (12km/h). In addition, regression analysis suggested that BM, height, and SL explained variance in RELLEc at a slower velocity ($R^2=0.162$, (8km/h). At faster running speeds, combined effect of GCT and SF explained a small variation in RELLEc ($R^2=0.137$, (10km/h); $R^2=0.075$, (12km/h).

CONCLUSION: This study presents novel evidence that anthropometric and body composition factors explain a substantial proportion of the variance in running economy compared to running biomechanics alone among recreational female runners, maintaining a slim physique, minimising GCT, and increasing SF result in a lower LEc. These findings indicate that coaches and practitioners working with female recreational runners should optimise individual anthropometrics beneficial for running, while concurrently addressing specific spatiotemporal variables to enhance running economy, and distance running performance.

RELATIONSHIP BETWEEN MEDIAL LONGITUDINAL ARCH AND GROUND REACTION FORCES IN LONG-DISTANCE RUNNERS DURING RUNNING

IRIGUCHI, K., NOZU, S., TOGASHI, I., AOYAGI, M., UCHINO, S., TAKAZAWA, Y.

JUTENDO UNIVERSITY

INTRODUCTION: The incidence of running disorders is as high as 79.3%, highlighting the importance of examining the factors that contribute to their development. During running, the vertical ground reaction force (vGRF) can reach two to three times the body weight, putting significant stress on the lower extremities. In particular, a higher peak value of vertical ground reaction force, Vertical Instantaneous Loading Rate (VILR), and Vertical Average Loading Rate (VALR) have been reported to be associated with running disorders. Moreover, some studies have reported that differences in foot arch morphology, such as flat feet or high arches, may lead to abnormal movement of the lower leg and foot during running. This abnormal movement may affect the ground reaction force during ground contact. However, few studies have reported on the interactive effects of arch height and ground reaction forces during running. Therefore, the purpose of this study was to examine the relationship between foot arch morphology and ground reaction forces in runners.

METHODS: Twenty-one male university long-distance runners (age: 19.6 ± 1.2 years, height: 172.9 ± 5.1 cm, weight: 58.5 ± 4.2 kg) participated in this study. The morphology of the foot arch was evaluated using the Arch Height Index (AHI), which was calculated by dividing the height from the floor to the dorsum of the foot at 50% of the foot length in a seated position by the length from the heel to the first metatarsophalangeal (MTP) joint. Ground reaction forces during running were measured with a force plate. Participants were instructed to run at a speed of 18 km/h. Ground reaction forces data were sampled at 1000 Hz, smoothed using a low-pass filter with a cutoff frequency of 35 Hz, and normalized to body weight. We calculated the initial peak value, maximum peak value, force product, VILR, and VALR during the stance phase of running. Pearson correlation analysis was performed to examine the association between AHI and the ground reaction forces in each direction (vertical, braking, medial/lateral). The significance level was set at less than 5%.

RESULTS: A significant positive correlation was found between AHI and the vertical ground reaction force

(maximum peak value: $r = 0.45$, $p < 0.05$; initial peak value: $r = 0.68$, $p < 0.01$; VILR: $r = 0.59$, $p < 0.01$; VALR: $r = 0.53$, $p < 0.05$).

CONCLUSION: In male long-distance runners, a higher foot arch may be associated with a greater initial and maximum peak value, VILR, and VALR of vertical ground reaction force during running.

COMPARISON OF MULTI-SEGMENTAL FOOT KINETICS BETWEEN NEUTRAL FOOT AND HIGHLY PRONATED FOOT IN NON-REARFOOT STRIKE RUNNERS

NAKATSUGAWA, T., EZAWA, Y., MARUYAMA, T.

INSTITUTE OF SCIENCE TOKYO

INTRODUCTION: Foot posture is a risk factor for running-related injuries (RRIs). In a case-control study, the odds of RRIs were 20 times higher for highly pronated foot than for neutral foot [1]. Although differences in foot kinetics according to foot posture may be a contributing factor, it is unclear whether foot kinetics differ between the neutral and highly pronated foot during running. The purpose of the present study was to compare multi-segmental foot kinetics during running between neutral foot and highly pronated foot groups.

METHODS: Nine females running with mid- and forefoot strike participated in this study. Foot posture was evaluated using the Foot Posture Index (FPI) [2]. Total score ranges from -12 to +12. Four participants were classified as neutral foot (0 to +5) and five participants were classified as highly pronated foot (+10 to +12) according to the FPI score. Participants were attached to reflective markers and plantar pressure sensor and asked to run at $3.3 \text{ m/s} \pm 10\%$ on a 10-m runway. We synchronously collected plantar pressure, ground reaction force, and kinematics including shank, rear-, and forefoot during the running task. Ankle and midfoot moments were calculated from distal to proximal using the Newton-Euler equation. Joint power was calculated as the scalar product of the joint moment and angular velocity. Joint work was calculated as the time integration of the joint power. Independent t-test or Mann-Whitney U test was used to compare peak moment, peak power (positive and negative), and work (positive and negative) in sagittal plane at ankle and midfoot between two groups ($\alpha = 0.05$).

RESULTS: The FPI scores of the neutral foot and the highly pronated foot groups were 0.5 ± 0.6 and 10.4 ± 0.5 , respectively. There were no differences in demographics, running speed, and stance time between groups. The neutral foot showed significantly larger peak positive power and negative work at ankle compared to the highly pronated foot ($8.77 \pm 2.26 \text{ W/kg}$ vs. $5.99 \pm 1.00 \text{ W/kg}$; $p = 0.04$, $-0.50 \pm 0.13 \text{ J/kg}$ vs. $-0.31 \pm 0.11 \text{ J/kg}$; $p = 0.05$).

CONCLUSION: The neutral foot demonstrated large power absorption and efficient power generation at ankle. The neutral foot showed a greater peak dorsiflexion angle at ankle than the pronated foot during gait [3]. Thus, the increase of dorsiflexion angular velocity in the neutral foot appears to result in large negative work. The large positive power in the neutral foot could be explained by the increase of plantarflexion angular velocity at rearfoot. The neutral foot has a higher arch stiffness than the pronated foot [4], which could promote efficient propulsive force generation at ankle by elevating the arch immediately. This study emphasizes the need to consider changes in foot kinetics associated with foot posture.

DISTRIBUTION OF THIGH MUSCLE ACTIVITY DURING SPRINTING IN MALE SPRINTERS USING T2-WEIGHTED MAGNETIC RESONANCE IMAGING

ARAI, H., SUGA, T.1,2, TERADA, M.2,3, KUSAGAWA, Y.2,3, KUROKI, K.1, ENDO, Y.1, UMEDA, M.3,4, ISAKA, T.1,2

RITSUMEIKAN UNIVERSITY

INTRODUCTION: Sprint performance is enhanced when the body's muscular system functions as an integrated unit, with particular emphasis on the lower limb muscles that drive the sprinting action. Therefore, it is essential to evaluate lower limb muscle activity during sprinting. Surface electromyography has been widely used to measure lower limb muscle activities during sprinting (Kuitunen et al. 2002, Kakehata et al. 2022); however, this technique is limited by its inability to measure deep muscle activities and distinguish between muscle crosstalk. To address these limitations, T2-weighted magnetic resonance imaging (MRI) can be used as an alternative method for assessing lower limb muscle activity during

sprinting (Yoshimoto et al. 2022). This study aimed to determine the distribution of thigh muscle activity during sprinting using T2-weighted MRI.

METHODS: Twelve male sprinters (age: 20.3 ± 1.5 years, body height: 173.8 ± 6.0 cm, body mass: 66.9 ± 4.8 kg, 100-m personal best time: 10.89 ± 0.39 sec) completed a repeated sprint protocol consisting of three 60-m sprints, each performed at maximal effort, with 2-min rest intervals. Before and after the sprint protocol, 15 axial T2-weighted images, covering a total of 30 cm of the thigh (i.e., 15 cm proximal and distal to the mid-thigh), were acquired using a 3T MRI system. The distribution of thigh muscle activity was assessed based on pre-post changes in T2 values for 13 thigh muscles, and site-specific differences in the T2 value changes within each muscle. A paired t-test and one-way repeated ANOVA with a Bonferroni post-hoc test were conducted to determine the pre-post changes and site-specific differences.

RESULTS: T2 values significantly increased in the rectus femoris, sartorius, adductor longus, adductor magnus, gracilis, semimembranosus, semitendinosus, and both the long and short heads of the biceps femoris after the sprint protocol (corrected $P < 0.05$). Site-specific differences were observed, with a greater increase in T2 in the proximal region of the long head of the biceps femoris compared to the middle and distal regions ($P < 0.05$). In contrast, T2 values increased more in the middle and distal regions of the semitendinosus than in its proximal region ($P < 0.05$). T2 changes were significantly higher in the middle region of the semimembranosus than in the distal region ($P < 0.001$).

CONCLUSION: Our findings indicate that sprinting induces non-uniform muscle activation in the thigh, with certain regions demonstrating greater involvement. Notably, the site-specific differences observed in the hamstrings indicate varying regional muscle engagement. These results highlight the importance of evaluating both whole-muscle and regional activation patterns using T2, providing valuable insights for enhancing sprint performance and preventing sports injuries.

ANALYSIS OF THE TEMPORAL PATTERN OF NEUROMUSCULAR ACTIVATION DERIVED FROM THE FLOATING HEEL RUNNING TECHNIQUE

PÉREZ MALETZKI, J., MARTÍN-RUIZ, J., ALARCON-JIMENEZ, J., VILLARÓN-CASALES, C., GÁMEZ-PAYÁ, J.
UNIVERSIDAD EUROPEA DE VALENCIA

INTRODUCTION: Running is one of the most practiced sports activities worldwide today. The rise and popularization of this sport have led to an increase in the incidence of injuries resulting from its practice. Injury mechanisms include poor running technique (1) or excessive impact during foot strike (2).

To address the challenge of injuries, various products have been introduced to the market. Specifically, floating heel running shoes (FBR concept) have been seen as a solution to help runners avoid heel strikes and reduce vertical impact (3). Additionally, this concept has proven effective in the injury recovery process (4). These shoes have the structure of conventional sneakers, with the main characteristic being that they lack a heel and do not have a midsole in the rear part of the shoe.

Surface EMG measures muscle action during movement. It has been observed that with heel strike running technique (RFS), muscle activity occurs after contact, whereas with forefoot strike (FFS), it occurs before contact (5). This shows that the muscle contraction scenario seen in FFS presents advantages over RFS.

The objective of this study is to analyse the temporal pattern of muscle activation derived from the floating heel running technique.

METHODS: The study sample consisted of 16 runners who are accustomed to running with floating heel shoes. An analysis of surface muscle electrical activity (sEMG) was conducted on the lateral gastrocnemius (GNL) and medial gastrocnemius (GNM) muscles following the SEINAM guidelines (Surface Electromyography for the Non-invasive Assessment of Muscles). The sEMG measurement system was synchronized with an accelerometer to detect ground contact (Gwalk BTS). Additionally, an analysis of the foot strike pattern was performed using a high-speed camera (240Hz) in the sagittal plane (6). The variables analysed were the timing of muscle activation relative to ground contact and the foot strike pattern during running.

RESULTS: The results showed that all runners run with a midfoot strike technique. Additionally, the same temporal activation pattern of the GNL and GNM was observed in all participants. They all activated the calf muscles before ground contact.

CONCLUSION: The results of this study confirm that the running technique associated with floating heel shoes promotes a midfoot strike technique, similar to findings in previous studies (3). Regarding muscle activation, the temporal activation pattern obtained is similar to the activation pattern of the forefoot strike technique (5). This temporal activation scenario is considered positive for the protection of the runners muscle-tendon unit.

RELATIONSHIP BETWEEN THE ACCELERATION PERFORMANCE AND GROUND REACTION FORCES DURING THE SPRINTING START IN SOCCER PLAYERS

YAMAZAKI, Y., HIBI, T., HATA, K., ISHIKAWA, M., KANOSUE, K., YANAGIYA, T.

JUNTENDO UNIVERSITY

INTRODUCTION: In soccer matches, sprinting ability is crucial for competitive performance. Indeed, competitive soccer teams exhibit longer high-intensity running distances during matches¹). Moreover, as most sprinting performed by soccer players during a match are less than 20-m²), sprinting acceleration performance is particularly important. The ability to accelerate during sprinting would be related to the amount of force exerted at the start of the sprinting. Therefore, this study aimed to clarify the relationship between the sprinting acceleration performance and ground reaction force (GRF) during the sprinting start in soccer players.

METHODS: Sixty-three soccer players performed a maximal-effort 10-m sprinting from a standing split-stance position. Sprinting time, speed, and horizontal force were recorded using a motorized towing device without load. Acceleration was obtained by differentiating the speed with respect to time, while power was calculated as the product of speed and horizontal force. In addition, GRFs data during the standing start and the first step after the start were recorded from force plates embedded in the runway. Then, the relationships between each variables—10-m sprinting time, peak speed, peak horizontal force, peak acceleration and peak power—and the GRFs of the front and rear leg at the start, as well as those during the first step, were determined using Pearson's Partial Correlations.

RESULTS: The results of the relationship between sprinting time and GRF indicated a weak negative correlation between peak vertical GRF of the rear leg at the start and sprinting time ($r = -0.41$, $p < 0.001$), as well as a moderate negative correlation between peak anteroposterior GRF and sprinting time ($r = -0.56$, $p < 0.001$). Furthermore, a moderate positive correlation was observed between peak vertical GRF of the rear leg at the start and peak acceleration ($r = 0.53$, $p < 0.001$), as well as a strong positive correlation between peak anteroposterior GRF and peak acceleration ($r = 0.70$, $p < 0.001$). Additionally, a weak negative correlation was found between the peak vertical GRF of the front leg at the start and the sprinting time ($r = -0.33$, $p = 0.009$). However, neither sprinting time nor peak acceleration showed a significant correlation with the GRFs of the first step after the start.

CONCLUSION: The findings of this study suggest that acquiring GRFs with the rear leg during the sprinting start is crucial for enhancing sprinting acceleration performance. Adjustments in kinematics, such as the forward lean angle of the body³), may contribute to the acquisition of greater GRFs.

In conclusion, sprinting acceleration performance in soccer players was particularly associated with the magnitude of the GRFs exerted by the rear leg at the start.

INTERLIMB COORDINATION PATTERN DURING RUNNING WHILE TURNING

DEWOLF, A., MESQUITA, R.

UNIVERSITÉ CATHOLIQUE DE LOUVAIN

INTRODUCTION: During human running gait, the left and right limbs exhibit mirror-symmetric kinematic and neuromuscular patterns, with each limb executing the same movement sequence shifted by 50% of the gait cycle. However, when running along a curve, the limbs are forced to operate somewhat independently, to properly redirect the center of mass laterally. Therefore, the neuromuscular control of each limb must present specific and shared patterns.

METHODS: In this study, we investigated the organization of the neuromuscular control of running using surface electromyography (EMG) of 14 bilateral muscles in 11 participants at different speeds on a straight line (SLR) and on circular curves with a 6 m curvature. We extracted muscle synergies from the EMG envelopes of the left and right limbs separately using non-negative matrix factorization, decomposing the data into a linear combination of muscle weight vectors (W, spatial parameters) and activation coefficients (C, temporal parameters). The similarity index between W and C of the right and left limb, based on their scalar product normalized to the Euclidean norm¹, was then compared across speed and radius of curvature.

RESULTS: Four synergies accounted for more than 90% of the total EMG variance in all tested conditions. As compared to SLR, greater differences were observed between the neuromuscular patterns (both W and C) of both limbs when running along a curve. In particular, patterns 1, 2 and 4, occurring at the braking and propulsive parts of stance and at the end of the swing phase respectively, showed specific limb adaptations, whereas pattern 3, initiating the swing, was shared by both limbs at all running conditions. Such differences can be related to the distinct functional roles of the limb to accommodate lateral forces. Indeed, the inner limb primarily managed lateral redirection of the body, with greater muscular contribution of the hip muscles to accommodate the greater lateral forces².

CONCLUSION: Our findings align with research on split-belt treadmill walking, where each leg is subjected to different belt speeds, leading to distinct neuromuscular responses³. Identifying both left-right common and specific neuromuscular patterns provides key insights into the adaptive strategies during curved running. This knowledge can contribute to refining training and rehabilitation strategies, particularly for athletes and individuals recovering from locomotor impairments.

SPRING-MASS MODEL OF THE LOWER LIMB USING AN INERTIAL SENSOR-BASED APPROACH

FRÈRE, J., BELLETERRE, E.

UNIVERSITÉ GRENOBLE-ALPES

INTRODUCTION: During running, the lower limb behaves like a spring-mass system bouncing on the ground. Lower limb stiffness (kleg) and vertical stiffness (kvert) describe its mechanical response and the centre of mass (CoM) vertical oscillations during ground contact. Although a sine-wave-based method exists (1), data collection requires bulky, expensive equipment, limiting its use in natural conditions. With wearable sensors, such as inertial measurement unit (IMU) now validated for biomechanical assessment (2-3), in-run measurements in ecological settings have become feasible. This study aimed to validate an IMU-based method for estimating spring-mass model parameters, hypothesising comparable results to reference methods using ground reaction force (GRF) or sine-wave modelling (SINE).

METHODS: Eleven participants (3 women and 8 men, 1.76 ± 0.10 m, 69 ± 7 kg) completed a running test on an instrumented treadmill (Zebis FDM-TDM System, Zebis Medical GmbH, Germany). Each participant performed, in a randomised order, 9 trials combining three running speeds (10, 12, and 14 km·h⁻¹) and 3 stride frequencies (100, 110, and 90% of the self-selected frequency) for 120 seconds. Simultaneously, each participant wore three IMUs (Movella DOT, Movella, Henderson, NV, USA) placed on the sacrum and bilaterally on the lateral side of the shank. Contact and aerial times were obtained from the treadmill (TDM; reference) and used to compute the spring-mass model parameters (kleg; kvert; Δz : vertical displacement of the CoM; ΔL : lower limb shortening) from the SINE approach (1). At each stance, the vertical ground reaction force was estimated based on the weighted sum of the vertical accelerations from the IMUs as proposed by (2). From these estimated vertical force traces, contact and aerial times were calculated. Therefore, two spring-mass models were computed from the IMUs data (IMU-GRF and IMU-SINE). Bland-Altman comparative analyses were conducted for comparison between both devices (TDM and IMU) across all running trials.

RESULTS: The IMU-GRF vs. TDM-SINE comparison showed a bias of 2.58 ± 6.78 kN/m and -0.76 ± 2.88 kN/m for kvert and kleg, respectively. The bias was -0.72 ± 1.99 cm and 2.08 ± 3.72 cm for Δz and ΔL , respectively. The IMU-SINE vs. TDM-SINE comparison showed a bias of -4.17 ± 4.82 kN/m and -1.76 ± 2.04 kN/m for kvert and kleg, respectively. The bias was 0.92 ± 1.16 cm and 2.36 ± 2.92 cm for Δz and ΔL , respectively.

CONCLUSION: Based on these results, IMU-based spring-mass model seemed suitable to assess the mechanical behaviour of the lower limb during running. More specifically, the IMU-GRF approach seemed to provide better results compared to IMU-SINE. While this wearable approach enables the ecological analysis of running, future studies should investigate its validity in conditions involving slopes.

SURFACE EMG FEATURES IN UNILATERAL AND BILATERAL ECCENTRIC MOVEMENT PATTERNS IN COMPARISON

YOU, Y., HIROSE, N., SUGIMOTO, D.

WASEDA UNIVERSITY

INTRODUCTION: Eccentric training, which involves muscle lengthening under load, enhances athletic performance and prevents injuries. While most interventions focus on bilateral exercises, unilateral movements are crucial in real-life activities, aiding balance, coordination, and rehabilitation. However, differences in muscle activation between unilateral and bilateral exercises remain unclear. Therefore, the current study investigated these variations to guide training and rehabilitation programs.

METHODS: A cross-sectional laboratory-controlled design was used. Twenty-five male participants performed four self-weighted eccentric tasks: single- and double-leg Nordic hamstring exercise (NHE-S/NHE-D) and eccentric leg extension (ELE-S/ELE-D). Electromyographic (EMG) data were collected using the Delsys Trigno Wireless system (Delsys Inc., Natick, MA, USA) from dominant side muscle groups: rectus abdominis (DRA), lumbar erector spinae (L3ES), multifidus (L5MF), biceps femoris long head (BFlh), semitendinosus (ST) at mid (50%) and distal (30%) regions, and gluteus maximus (Gmax). EMG parameters included RMS (normalized to MVIC), mean frequency (MF), waveform length (WAV), and tension index (TI). A Mann-Whitney U test was used to analyze EMG features across four tasks. ($P < 0.05$).

RESULTS: The BFlh and Gmax exhibited significantly higher RMS values during unilateral tasks compared to bilateral tasks ($P < 0.001$). While the ST showed no significant difference in the NHE, it demonstrated higher RMS values during ELE-S ($P < 0.01$). In terms of trunk muscle (DRA, L3ES, L5MF) responses, most of them showed no significant differences in activation, except for the DRA during NHE-S exhibited increased RMS ($P = 0.01$). The lumbar muscles (L3ES, L5MF) had significantly higher activation levels compared to the DRA ($P < 0.01$, all comparisons), with the L5MF displaying higher levels of MF and TI than the L3ES during ELE ($P < 0.01$, all comparisons). Regarding regional patterns, MF values consistently followed the hierarchy: BFlh50 > ST50 > ST30 > BFlh30 ($P < 0.05$). The RMS of ST50 exceeded that of BFlh50 only during NHE-D ($P = 0.02$), and ST50 demonstrated greater WAV and TI compared to ST30 during NHE ($P < 0.05$, all comparisons). These differences in inter-muscle comparisons were consistent across both unilateral and bilateral patterns.

CONCLUSION: Unilateral eccentric training elicited greater activation in BFlh and Gmax than bilateral training, while ST showed increased activation only in ELE. Trunk muscle activation remained largely unchanged, except for higher DRA activation in NHE-S. L5MF exhibited greater fatigue and tension than L3ES in ELE, and muscle fatigue patterns followed a consistent ranking (BFlh50 > ST50 > ST30 > BFlh30). These findings suggest that unilateral training can enhance hamstring activation and may be valuable for athletic performance, rehabilitation, and injury prevention.

RATE CODING OF FDI MOTOR UNITS DURING FINGER FLEXION AND PINCH TASKS

HU, N., CABRAL, H.V., POURREZA, E., DESMONS, M., INGLIS, J.G., NEGRO, F.

UNIVERSITY OF BRESCIA

INTRODUCTION: The force output produced during muscle contraction is modulated by activating different numbers of motor units (i.e., recruitment) and modulating their discharge rates (i.e., rate coding) [1]. However, there is still limited knowledge regarding how rate coding modulation across force levels differs between isolated and synergistic muscle contractions. In this study, we examined the first dorsal interosseous (FDI) motor unit (MU) discharge rates across three submaximal force levels during isolated finger flexion and synergistic pinch task.

METHODS: Eight healthy adults sat in front of a custom-made manipulandum with their right arm and wrist stabilised and their index finger and thumb fixed to adjustable supports attached to load cells. After performing maximum voluntary isometric contractions (MVC), subjects were asked to perform submaximal contractions at different target forces (10%, 20%, and 30% MVC). Subjects followed trapezoidal feedback with a ramp up phase from 0% MVC to the target force at 3% MVC/s, keep at the target force for 30 s (plateau), and a ramp down phase from the target force to 0% MVC at 3% MVC/s. Each force level was repeated for two conditions: isometric finger flexion and pinch. During the tasks, high-density surface electromyograms (HDsEMG) were recorded from the FDI muscle. MU spike trains were decomposed from HDsEMG signals [2] and matched between 10% and 20% MVC (10-20%), as well as between 20% and 30% MVC (20-30%). MU matching was achieved by reapplying the MU separation vectors [3]. The mean discharge rate (MDR) during recruitment (up), plateau, and de-recruitment (down) phases was calculated and compared using linear mixed models, with force level and task as fixed effects and subject as random effects. The analyses were carried out separately per matching conditions (10-20% and 20-30%).

RESULTS: A total of 586 matched MUs were identified across subjects. In both the 10-20% and 20-30% matching conditions, MDR during plateau phase increased at higher force levels ($p < 0.001$) and was higher in the pinch task compared to the isolated finger flexion ($p < 0.001$). No significant changes were observed in recruitment or de-recruitment phase. Additionally, no significant interaction was found between force level and task in all phases.

CONCLUSION: By reapplying MU separation vectors in the concatenated decomposed files, it was possible to track motor units across force levels and analyse their mean discharge behaviour. Our results confirmed that FDI MU discharge rate increased with force level, but this increase did not depend on whether the task involved isolated or synergistic contraction. Interestingly, pinch task required higher MU discharge rates than isolated finger flexion, revealing a task-dependent modulation in rate coding.

THERE ARE NO DIFFERENCES IN RETICULOSPINAL TRACT EXCITABILITY ACROSS ISOMETRIC, CONCENTRIC AND ECCENTRIC MUSCLE ACTIONS AT THE SAME ABSOLUTE FORCE OUTPUT

ANDRUSHKO, J., HAIGNEY, E., ATKINSON, E., ANSDELL, P., VITORIO, R., THOMAS, K., GOODALL, S., HOWATSON, G., ANGIUS, L., KIDGELL, D.J., SPILLANE, P., SQUIRES, E.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: Human movement involves a dynamic interplay of isometric, concentric, and eccentric muscle actions. There is a need to understand the contribution of the reticulospinal tract (RST) to human movement control during different muscle actions. This research aimed to determine the excitability of the RST during isometric, concentric and eccentric muscle actions.

METHODS: Fourteen neurologically intact participants (Age: 26 ± 7 years; Sex: 3 female, 11 male; Stature: 176 ± 8 cm; Mass: 78.5 ± 10.9 kg) performed isometric, concentric, and eccentric muscle actions with the biceps brachii. Participants performed a submaximal contraction at 25% of their isometric maximum voluntary contraction (MVC) during all muscle actions. Neurophysiological electrical stimulations to indirectly measure RST excitability consisted of conditioned (startling auditory stimulus of ≥ 110 dB) and unconditioned (no auditory stimulus) cervicomedullary motor evoked potentials (CMEPs).

RESULTS: Larger conditioned CMEP responses compared to unconditioned CMEPs were observed for all muscle actions ($p = 0.008$). However, no differences in RST excitability, inferred from the difference between conditioned and unconditioned CMEP responses, were observed across the three muscle actions ($p = 0.319$).

CONCLUSION: These results suggest that across isometric, concentric, and eccentric muscle actions, there are no differences in RST excitability whilst performing a submaximal contraction at 25% of their isometric MVC. It could therefore be inferred from this that RST input to motoneurons is not different between isometric, concentric, and eccentric muscle actions of the biceps brachii at relatively low contraction intensities.

ACUTE AND PROLONGED HIGH-ALTITUDE EXPOSURES ALTER INDICES OF AXONAL EXCITABILITY

DEBENHAM, M., HA, P., MCNEIL, C.

UNIVERSITY OF BRITISH COLUMBIA

INTRODUCTION: Hypobaric hypoxia experienced at high altitude may influence the neuromuscular propagation of action potentials, as evidenced by changes to the maximal compound muscle action potential. However, equivocal findings highlight the need for more comprehensive evaluations of the effect of high altitude on neuromuscular propagation. This study used an automated threshold-tracking paradigm known as the TROND protocol¹ to assess multiple measures of axonal excitability at sea level (SL; 350 m) as well as after acute (AH; 1-2 days) and chronic (CH; 5-6 days) exposure to high altitude (3800 m).

METHODS: In 13 healthy, young participants (5 females; 27.0 ± 3.4 years), axonal excitability was assessed by repeatedly stimulating the median nerve with various currents, pulse widths, and conditioning pulses. Evoked responses were recorded from the right abductor pollicis brevis (APB) using surface electromyography. Five examinations were completed: (i) the stimulus-response curve; (ii) the strength-duration time constant (SDTC); (iii) the threshold electrotonus to depolarizing and hyperpolarizing conditioning currents (TEd and TEh, respectively); (iv) the current-voltage (I/V) relationship; (v) the recovery cycle after supramaximal activation

RESULTS: Compared to SL, resting I/V slope (AH: 122% SL, CH: 111% SL), TEh (AH: 124% SL, CH: 117% SL), and relative refractory period (AH: 137% SL, CH: 123% SL) were greater for AH and CH ($p < 0.05$). Resting I/V slope was also greater for AH than CH ($p < 0.05$). Superexcitability for AH (126% SL) was greater than both SL and CH ($p < 0.05$), while there was no difference between SL and CH (103% SL). The slope of the stimulus-response curve for CH (120% SL) was greater than SL and AH, with AH (102% SL) not different to SL. The SDTC, TEd, and subexcitability were unchanged across sessions ($p > 0.05$).

CONCLUSION: Our findings demonstrate that motor axons innervating the APB became less hyperpolarized and moved closer to threshold with exposure to high altitude for 1-6 days. Differences between AH and CH for resting I/V slope and superexcitability indicate acclimatization of some indices of axonal excitability, with a return towards the control state (i.e., SL). In contrast, the slope of the stimulus-response curve required more than 1-2 days of exposure to high altitude before an adaptation occurred. These alterations to motor axons should be investigated further, and axonal excitability should be accounted for when evaluating the effects of high altitude on cortical and motoneuronal excitability.

THIGH MUSCLE ACTIVATION PATTERNS DURING UNILATERAL AND BILATERAL LEG PRESS EXERCISE VARIATIONS

OLIVA, V., BANOVIC, M.

COMENIUS UNIVERSITY IN BRATISLAVA, FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: The leg press is a multi-joint exercise primarily engaging quadriceps, hamstrings and gluteal muscles simultaneously in a complex manner (1). The widespread applicability of the exercise is explained by the simplicity of its technique since it is a guided movement (2). At the same time, it has substantial transfer to functional movements such as walking, squatting, running, or jumping (2,3). Therefore, the exercise is frequently included in any training or rehabilitation program regardless of age or training goal for strengthening the lower limbs (2,4,5,6). Myoelectric muscle activity during leg press exercises is a critical area of study in resistance training, as it provides insights into muscle activation patterns and their implications for strength training and rehabilitation (7). The objective of this study was to compare the myoelectric activity of thigh muscles during unilateral and bilateral leg press exercise variations in resistance-trained men.

METHODS: Ten young college resistance-trained men (age 23.46 ± 1.66 years, height 181.7 ± 5.17 cm, weight 83.65 ± 7.51 kg) performed maximal voluntary isometric contraction (MVIC) during unilateral (UL) and bilateral (BL) leg press exercise at a 90-degree knee angle. Surface electromyography (Delsys EMG Trigno Wireless Research System) was used to assess muscle activation pattern and integrated myoelectric activity (iEMG) of m. vastus medialis (VM), m. vastus lateralis (VL) and m. biceps femoris (BF). A non-parametric Wilcoxon t-test was used to measure differences in iEMG of VM, VL and BF between UL and BL leg press exercise. The level of significance was set at $\alpha = 0.05$ for all statistical analyses.

RESULTS: The iEMG of the VM was significantly higher in BL compared to UL leg press exercise ($p=0.01$). The BL leg press exercise variation generated significantly greater VL activity than the UL variation ($p=0.02$). There was no significant difference in myoelectric activity of the BF between the two leg press exercise variations. For BL and UL leg press exercise variations, the greatest muscle activation was for the VM, followed by the VL, and the BF.

CONCLUSION: The results indicated that BL leg press was more effective in VM and VL muscle activation. The UL leg press exercise was as effective as the BL leg press exercise in BF muscle activation. When the objective is to activate the VM muscle, unilateral and bilateral leg press exercise variations can be used, because both are equally effective in greatest VM muscle activation. The study was supported by grant VEGA no. 1/0415/23 and by the Slovak Research and Development Agency no. APVV-21-0164.

INTER-INDIVIDUAL DIFFERENCE AND RELATIONSHIP WITH MOTOR FUNCTION AND MUSCLE MORPHOLOGY IN MOTOR UNIT NUMBER OF ABDUCTOR POLLICIS BREVIS MUSCLE IN HEALTHY MIDDLE-AGED MALES AND FEMALES

WATANABE, K., IGAWA, K., TAKEDA, R., NOTO, Y.

CHUKYO UNIVERSITY

INTRODUCTION: The number of motor units (MUs) decreases with aging and this accelerate from 40-50s. This anatomical characteristic would be a crucial biomarker for age-related muscle dysfunctions because MU numbers should contribute to both motor functions and muscle morphology. However, MU number has been mainly measured in patients with neurological diseases, and its inter-individual variability and the associations between MU number and muscle functions and/or muscle morphology have not been investigated in healthy subjects. We aimed to investigate the inter-individual variability of MU number and its associations with motor function and muscle morphology in middle-aged healthy males and females.

METHODS: The participants were 93 healthy middle-aged males and females (40s: $n=59$, 50s: $n=29$, 60s: $n=5$). The maximal voluntary contraction pinch force (MVC) and muscle thickness of abductor pollicis brevis muscle measured by ultrasonography (MT). MU number was estimated from a detailed electrical stimulation-electromyographic response curve by MScanFit-2 for abductor pollicis brevis muscle (MUNE). Inter-individual variability of MVC, MT, and MUNE were quantified by coefficient variation (CoV). Relationships between MVC, MT, and MUNE were quantified by the Spearmans rank correlation coefficient.

RESULTS: MVC, MT, and MUNE were 9.7 ± 2.5 kg, 0.4 ± 0.1 cm, and 107.6 ± 28.7 and their CoV were 25.3%, 28.4%, and 26.7%, respectively. A significant correlation between MVC and MT was detected ($r = 0.334$, $p = 0.001$). There were no significant correlations with MUNE in MVC and MT ($p > 0.05$).

CONCLUSION: In healthy middle-aged populations, MU number has similar amount of inter-individual variability with those of motor function and muscle morphology and is a biomarker independent of motor function or muscle morphology.

THE EFFECTS OF ONLINE VS. OFFLINE APPLICATION OF TRANSCRANIAL DIRECT CURRENT STIMULATION IN AN ISOMETRIC ENDURANCE TEST OF THE QUADRICEPS MUSCLES

WINOKUR, S., BURKHART, T., CHEN, J.L.

UNIVERSITY OF TORONTO

INTRODUCTION: A novel approach to improve athletic performance is the use of Transcranial Direct Current Stimulation (tDCS). tDCS can induce neuronal excitability changes through the application of weak subthreshold direct current to the brain. The ability of tDCS to modulate cortical excitability could be harnessed to mitigate the effects of central fatigue in the context of muscular endurance exercises. Through the application of tDCS, output from the primary motor cortex (M1) can remain elevated, which may prolong time to fatigue (TTF). However, while some prior studies have found tDCS to improve TTF, other studies have not. Reasons could relate to the timing of tDCS application and, controlling for individual differences in electric fields generated by tDCS. Thus, this study aims to evaluate different tDCS application protocols and their

effects on TTF. The study protocols are different in 1) the time of tDCS application, and 2) whether a personalized tDCS dosage is applied versus a generic dosage. It is hypothesized that the individualized condition will lead to the longest TTF. EMG data was also collected from the quadriceps to help confirm the effect of tDCS on neuromuscular fatigue.

METHODS: To date, 8 strength trained varsity athletes have been tested who have completed 4 testing sessions, in a within subject design (data collection is ongoing with a target of 15). Participants first received an MRI scan that was used for current flow modelling to determine individualized current intensities at M1. Each of the following sessions began with 3 maximal voluntary isometric contraction leg extensions using a biodex dynamometer. Participants then received one of the following 4 conditions per session: (1) sham tDCS, (2) offline (priming), (3) online, and (4) individualized online tDCS, all with the anode over M1 and cathode over Fp2. Offline tDCS consisted of 6 minutes of stimulation at 2mA prior to a TTF leg extension at a 90-degree angle, at 20% of peak torque. Online tDCS followed the same protocol but occurred during the TTF task. Individualized tDCS also occurred online, but with a personalized current intensity. Rate of perceived exertion (RPE) was collected every 30 seconds and mean power frequency (MnPF) (data analysis is ongoing), calculated from the surface EMG, was also collected as subjective and objective measures of fatigue, respectively.

RESULTS: Preliminary results suggest that there was a trend toward a significant effect of stimulation condition on TTF [$F(3,21)=2.670$, $p=0.074$, $\eta^2 = 0.276$]. Data from 5 of the 8 participants tested support the hypothesis; the individualized condition led to the longest TTF. The stimulation condition had no significant influence on the slope of RPE increase during the TTF task [$F(3,21)=0.785$, $p=0.516$, $\eta^2 = 0.101$].

CONCLUSION: These findings will help to inform future studies on the optimal tDCS application protocol that can be used to mitigate central fatigue and improve endurance performance.

EFFECTS OF ACUTE PASSIVE BLOOD FLOW RESTRICTION ON MOTOR UNIT RECRUITMENT THRESHOLD AND DISCHARGE RATE

KURZ, E., BARTELS, T., NEGRO, F., PRÖGER, S., SCHWESIG, R., DELANK, K.S., VALLI, G.

MARTIN-LUTHER-UNIVERSITY HALLE-WITTENBERG

INTRODUCTION: Periods of mechanical unloading following injury or surgery lead to neuromuscular deconditioning and altered motor control. Passive blood flow restriction (BFR), applied without movement, has been shown to reduce muscle atrophy and strength loss. However, its effects on motor unit (MU) properties remain unclear. This study investigated changes in MU properties before and after a passive BFR intervention.

METHODS: Eighteen male handball players (age: 18-28 years, BMI: 21-30 kg/m²) participated in the study, where vastus lateralis activity was recorded using a 64-channel High-Density surface EMG (HDsEMG) grid before and after a 5-minute passive BFR intervention at 80% arterial occlusion pressure. Isometric ramp contractions at 20, 30, and 40% maximal voluntary contraction (MVC) were performed before BFR and at 20% immediately after BFR. HDsEMG signals recorded before BFR were decomposed (1) to analyse MU recruitment threshold (RT), derecruitment threshold (DERT), and discharge rates (DR). Analyses were performed in Python with the openhdemg V0.1.1 library (2). Identified MUs were tracked post-BFR using individual MU filters (3). Effects on MU properties were assessed using linear mixed models.

RESULTS: MVC values did not change as a result of the BFR intervention (from 732 ± 153 N to 738 ± 147 N, $t=-0.54$, $p=0.59$, $d=-0.13$). Relative MU RT and DERT for MUs tracked across the contractions performed at 20% MVC before and after BFR did not differ (from 12.2 ± 0.8 % to 12.1 ± 0.8 %, $p=0.94$ for RT; from 11.9 ± 0.6 % to 11.2 ± 0.6 %, $p=0.31$ for DERT). Similarly, the MU DR measured during the steady-state phase did not change after BFR (from 9.1 ± 0.3 pps to 9.5 ± 0.3 pps, $p=0.06$). For MUs tracked across contractions performed at 30 (15 MUs) or 40% (12 MUs) MVC before BFR and at 20% MVC after BFR, relative MU RT and DERT were reduced after BFR (from 23.3 ± 0.5 % to 17.7 ± 0.5 %, $p<0.001$ for RT; from 20.8 ± 1.0 % to 15.0 ± 1.0 %, $p<0.001$ for DERT). MU DR measured during the steady-state phase decreased after BFR (from 10.7 ± 0.5 pps to 8.1 ± 0.5 pps, $p<0.001$).

CONCLUSION: This study analysed the effects of a passive BFR intervention on MU properties of exactly the same MUs non-invasively. Hence, additional recruited MUs (MUs that were unrecruited before BFR) remain unconsidered. Although only a small number of MUs were detected showing a reduced RT, these results provide direct evidence that a preceding passive BFR changes the excitability, particularly of the same MUs.

ACUTE EFFECTS OF OXYGEN ADMINISTRATION ON NEUROMUSCULAR FATIGUE IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE PATIENTS WITH CHRONIC RESPIRATORY FAILURE AND LONG-TERM OXYGEN THERAPY

SPINELLO, L., SIMONELLI, C., SALVI, B., VITACCA, M., VENTURELLI, M., PANERONI, M.

UNIVERSITY OF VERONA

INTRODUCTION: Patients with chronic obstructive pulmonary disease (COPD) and chronic respiratory failure (CRF) experience exaggerated neuromuscular fatigue (NMF). Reduced muscle oxygen availability leads to increased metabolite production, exacerbating peripheral component of NMF, while chronic hypoxemia leads to exacerbation of central components of NMF. Oxygen therapy can correct hypoxemia, enhance aerobic metabolism, and reduce ventilatory effort. However, its effects on NMF development in COPD remain unclear.

This cross-sectional study hypothesizes that NMF is sensitive to changes in the inspired oxygen fraction (FiO₂). The aim was to evaluate whether different levels of FiO₂ (%) influence NMF development in COPD patients with CRF.

METHODS: Twenty patients (81% male, age 72 ± 6 YRS, BMI 25 ± 6 , FEV1 $34.5 \pm 10.9\%$, FEV1/FVC 39.6 ± 9.3 , RV $206.5 \pm 53.1\%$) completed three intermittent isometric quadriceps tests at 80% of the time to exhaustion at 30% of maximal voluntary contraction (MVC). Tests were performed under three different FiO₂ conditions using a Venturi mask®: A) 21%, B) 31%, and C) 60%. NMF was assessed through changes in MVC, voluntary activation (VA), and quadriceps potentiated twitch force (Q_{tw,pot}) following exercise. Oxygen saturation (SpO₂) was monitored throughout.

RESULTS: The mean test duration was 739.6 ± 260.1 seconds. Changes in MVC were $-27.6 \pm 9.5\%$, $-24.4 \pm 7.8\%$, and $-22.0 \pm 7.1\%$ for conditions A, B, and C, respectively ($P=0.023$), with significant differences observed between A-B ($P=0.043$) and A-C ($P=0.035$). $\Delta Q_{tw,pot}$ showed changes of $-31.1 \pm 14.3\%$, $-31.3 \pm 16.7\%$, and $-26.7 \pm 16.1\%$ for conditions A, B, and C, respectively ($P=0.019$), with differences between A-C ($P=0.023$) and B-C ($P=0.014$). VA decreased similarly across conditions: A $-3.9 \pm 4.1\%$, B $-2.7 \pm 3.0\%$, and C $-2.2 \pm 3.9\%$ ($P=0.211$).

SpO₂ remained stable during the tests but differed significantly between conditions: A) $88.7 \pm 4.2\%$, B) $95.8 \pm 2.7\%$, and C) $98.5 \pm 1.5\%$ ($P < 0.001$).

CONCLUSION: The progressive changes in the MVC suggest that the acute oxygen administration reduces neuromuscular fatigue development in COPD patients with CRF. Indeed, this result was primarily determined by greater responses on the peripheral component of NMF.

BILATERAL LIMB DEFICIT IN DORSIFLEXION: INVESTIGATING FORCE PRODUCTION, MOTOR UNIT DISCHARGES, AND OFF-DIRECTION FORCES

VARVARIOTIS, N., AMIRIDIS, I., SAHINIS, C., KELLIS, E., HOLOBAR, A.

ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: The bilateral limb deficit (BLD) refers to the reduced maximal force production observed during bilateral contractions compared to the sum of unilateral contractions. This phenomenon occurs across various movement types (isometric and dynamic), with its magnitude ranging from 11% to 36.7% in explosive contractions(1). Identifying BLD is essential, as it may reflect neuromuscular control limitations affecting force production (2). The aim of the present study to investigate the effect of motor unit discharge characteristics and off-direction forces on force production during unilateral and bilateral rapid contractions.

METHODS: Eighteen young adults performed maximal and submaximal explosive isometric contractions (at 80% MVC) using the dorsiflexors of both legs (3). To assess the magnitude of bilateral deficit we used the bilateral index (BI (%)) = $100 \times [bilateral / (right\ unilateral + left\ unilateral)] - 100$ (4). Additionally, we recorded off-direction forces (abduction & adduction) and motor unit discharge characteristics of the tibialis anterior. A two-way ANOVA was conducted to compare force production between unilateral and bilateral contractions, while linear mixed-effects models analyzed motor unit (MU) discharge characteristics.

RESULTS: Bilateral index during maximal voluntary contraction was 20% lower compared to unilateral (BI: 164.8 ± 40 N, UNI: 207.8 ± 54.4 N, $p < 0.05$). A BLD was present in explosive force across all time points (F50, F100, F150, and Fmax) (4), with force being 23%, 19%, 28%, and 24% lower, respectively, in the bilateral condition.

Examining 358 motor units, we found no significant differences in maximal discharge rate (BI: 65.6 ± 27.1 pps, UNI: 63.4 ± 29.8 pps, $p = 0.71$) or recruitment speed (BI: 16.3 ± 8.8 ms, UNI: 16.8 ± 7.8 ms, $p = 0.56$). However, neuromechanical delay was significantly shorter in unilateral contractions (43 ± 10 ms) compared to bilateral contractions (49 ± 13 ms). Furthermore, off-direction forces were greater in bilateral contractions (663.5 ± 366.9 N) compared to the unilateral contractions (526.4 ± 265.4 N) ($p < 0.05$).

CONCLUSION: The reductions in maximal force and rate of force development were not associated with differences in motor unit discharge rates, suggesting that supraspinal mechanisms may contribute to the BLD. Additionally, the increased off-direction forces in bilateral contractions indicate a greater force loss strategy in bilateral contractions, suggesting less efficient movement coordination that possibly exacerbating the BLD.

PERCEPTION OF EFFORT IN MOTOR AND COGNITIVE TASKS: A COMPUTATIONAL ANALYSIS

MANGIN, T., MONTI, I., BAUDRY, S., ROY, M., RAINVILLE, P., PAGEAUX, B.

UNIVERSITÉ DE MONTRÉAL

INTRODUCTION: Pain affects performance by increasing the perceived task difficulty. According to the motivational intensity theory (1), in the presence of pain, individuals must allocate additional effort to maintain performance, leading to an increase in the perception of effort (PE).

The objective of this study is to test the effect of pain on performance. As effort is present in the motor and cognitive domains, we investigated the effect of pain on motor and cognitive performance. We hypothesized that performance could be maintained in the presence of pain at the cost of higher PE. To explore the underlying mechanisms of PE in the motor and cognitive domains, we performed computational modeling.

METHODS: Two experiments (n=20 each, exp1: motor, exp2: cognitive) were conducted. In exp1 participants had to match a line using a handgrip dynamometer. Performance was measured as force steadiness. In exp2 participants performed a modified Simon task. Performance was measured as reaction time and accuracy. In both experiments task demand (TD) was manipulated with 3 levels and each trial lasted 15s. An individualized thermal stimulation (warm – control, light or high pain) was applied during each trial. After each trial, participants reported their PE and pain. Data were analyzed using linear mixed models. Then we compared mathematical and theoretical models using maximum likelihood estimate to predict PE. In each computational model, we used the linear and logarithm of the TD as well as the objective level of thermal stimulation and subjective pain ratings as predictors.

RESULTS: In both experiments, performance was maintained ($p > .387$) in the presence of pain and PE was higher compared to the warm conditions ($p < .009$). In addition, task completion was associated with a reduced pain perception ($p < .004$).

Computational analyses revealed in the motor domain that all models favored the logarithm of the TD rather than the linear. In cognitive domain, the logarithm of the TD was a superior predictor in most models (10 models better, 3 equivalents, none were worse). Moreover, subjective pain ratings consistently provided a better prediction of perceived effort than did the objective level of stimulation. The best-fitting model differed between the motor and cognitive domain.

CONCLUSION: According to our hypothesis, the maintenance of performance in presence of pain is possible at a cost of higher effort in the task, in both motor and cognitive domains. Computational analyses highlight that the logarithm of TD predicts PE more accurately than linear models. These analyses also reveal that subjective pain perception is a better predictor of PE than the objective level of thermal stimulation. Although these analyses reveal similar components (logarithm and subjectivity), the model that best explains the data differs between the two domains, suggesting the PE underlying mechanism may be domain-specific.

CRICKET COACHES PERCEPTIONS OF A 'GOOD LENGTH' IN CRICKET BOWLING

TISSERA, K., SHORTER, K., BENSON, A.

SWINBURNE UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Bowlers play an important role in cricket, seeking to meet the dual task goals of dismissing a batter, and limiting the batting team's score. Finding a length (distance) to bowl to the batter which increases uncertainty in their responses, colloquially termed a 'good length', helps achieve these dual aims. There is conjecture around the location of this region, with a range of distances (between 3-8m) previously reported [1]. When viewed from a theoretical framework of learning, such as ecological dynamics, regions offering more than one movement solution are considered metastable regions [2]. This study explored coaches understanding of the concept of a 'good length' in relation to cricket bowling.

METHODS: An online questionnaire (Qualtrics) targeting cricket coaches internationally included fixed-response and free-text questions, with demographic and coaching experience data presented as frequencies. Thematic analysis [3] using NVivo (v15.0.0) software explored coaches understanding of key characteristics and perceptions of a 'good length' region in cricket, comparing two groups (coaches predominantly coaching either junior (<18 yrs) or senior (>18 yrs) cricketers).

RESULTS: 104 coaches (93% male, 7% female) aged 20-69 years from 11 countries responded, with 52% coaching junior and 48% coaching senior cricketers. A central theme (a region for success) emerged after thematic analysis of coaches perceptions of a 'good length', with three sub-themes. Those coaching juniors focused on the batter's role within the 'doubtful batter' sub-theme, while those coaching seniors also commented on challenging the batter. Both coaching groups shared similar sentiments for the sub-themes of 'a pause on scoring' (inhibiting performance) and 'just out of reach' (focus on the location being not too full or not too short). Three themes on characteristics that determine a 'good length' delivery emerged. The contextual nature of the region was reported by both groups (theme 1: the role of context), with those coaching seniors reporting strategic elements in addition to the individual and environmental constraints reported by those coaching juniors. Both groups included comments identifying the importance of line when defining this

region (theme 2: multidimensionality of the region), with some coaches from both groups identifying fixed distances for this region (theme 3: fixed dimensions of this length).

CONCLUSION: Insights from cricket coaches conceptualisation of the 'good length' region depict an understanding aligned to the concept of metastability [2], moving beyond common interpretations of a fixed distance. Overall, both groups of coaches shared similar sentiments around the dynamic nature of this region, with coaches of senior cricketers often demonstrating more tactical nuance to their interpretation. Findings may assist with broadening understanding of these concepts at different levels of coach education.

POSTURAL STRATEGIES ASSESSED BY JOINT TORQUES – DIFFERENCES BETWEEN CHILDREN WITH AND WITHOUT ADHD

CHRIST, T., BOHN, C., BOSTRÖM, K.J.

UNIVERSITÄT MÜNSTER

INTRODUCTION: Children with ADHD often struggle with balance and postural control unlike their unaffected peers (1). While balance ability with a focus on postural sway has been broadly investigated in the patient-group, less is known about postural strategies employed to maintain equilibrium. We complement the hip and ankle postural strategies by an upper body strategy, to additionally take movements of the head, arms and trunk into account in the effort of regaining balance (3). Our study aimed at investigating the differences in postural control strategies between children with and without ADHD.

METHODS: 41 children (17 diagnosed with ADHD, 24 unaffected controls) with a mean age of 10.0 ± 1.4 years participated in the study. For the assessment of static balance, a 25-second one-leg stand was conducted. Dynamic balance was tested by balancing over a narrow wooden beam. Kinetic data was recorded with Kistler force plates. Kinematic data was collected with the Qualisys motion capture system. Joint torque amplitudes were calculated with an inverse-dynamics approach employing the Myonardo software (4).

RESULTS: Children with ADHD generated significantly higher torques during static and dynamic balancing. While torques of the ADHD-group were only 11% higher (dynamic task) and 7.5% higher (static task) for the upper body joint group, they were 22% higher (dynamic) and 20% (static) for the ankle joint. No group differences were found for hip joint torques.

CONCLUSION: Problems with proprioception and neuromuscular control are common among children with ADHD and may demonstrate as reduced precision in muscle activation (5). Cerebellar deficits in the patient-group negatively influence balance and coordination (1). Such deficits likely interfere with the adjustment of joint torques involved in maintaining balance and stability. Children with ADHD seemingly employ the ankle- and upper body strategies more intensely than the unaffected controls. The topic is of great importance as impairments in balance and motor control may interfere with activity and participation and may increase the risk of injuries.

STATIC AND DYNAMIC POSTURAL CONTROL UNDER DIFFERENT LEVELS OF VISUAL INFORMATION IN INDIVIDUALS WITH ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION, MENISCUS SURGERY, AND HEALTHY CONTROLS

LEE, J., KIM, J., HONG, H., PARK, J.

KYUNG HEE UNIVERSITY

INTRODUCTION: Individuals with knee surgeries, such as anterior cruciate ligament reconstruction (ACL) and meniscus surgery may exhibit altered joint proprioception, resulting in an increased reliance on the visual information for balance control. This study compared postural control in individuals with ACL and meniscus surgery to healthy controls under three different visual information conditions during static and dynamic balance tasks.

METHODS: Forty-five individuals (15 ACL; 15 meniscus surgery; 15 matched healthy control) were studied. Participants performed static and dynamic balance tasks under three different conditions: (1) eyes opened (EO); (2) eyes closed (EC); and (3) strobe vision (SV; 100-ms clear & 150-ms opaque vision) [1]. For the static task, participants performed a single-leg stand for 10-sec on a force plate (1,000 Hz). For the dynamic task, participants performed the Y-balance test. Data from the single-leg standing, CoP velocity (anterior - posterior: AP and medial - lateral: ML; cm/sec) were calculated [2]. Y-balance test scores were obtained for the anterior (ANT), posteromedial (PM), and posterolateral (PL) directions, and were normalised by the limb length. Data were recorded from the involved limb (the dominant limb for controls). A 3 (group) by 3 (con-

dition) analysis of variance along with Tukey tests, was conducted to evaluate the differences in each dependent variable ($\alpha=0.05$).

RESULTS: There was no group by condition interaction in CoP velocity ($F_{2,84}=0.79$, $p>0.46$). CoP velocity differed regardless of group (AP: $F_{2,84}=30.25$, $p<0.01$; ML: $F_{2,84}=76.77$, $p<0.01$). In both AP and ML directions, the EC condition showed a higher velocity than the EO and SV conditions (both $p<0.01$). In ML direction, the SV condition showed a higher velocity than the EO condition ($p<0.01$). There was no group by condition interaction in Y-balance score ($F_{2,84}<0.20$, $p>0.82$). Y-balance score differed regardless of condition (ANT: $F_{1,84}=8.33$, $p<0.01$; PM: $F_{1,84}=6.64$, $p=0.01$; PL: $F_{1,84}=5.72$, $p=0.02$). The ACLR group showed lower ANT scores than the control group ($p<0.01$). The ACLR and meniscus surgery groups showed lower PM and PL scores than the control group (both $p<0.01$). Regardless of group, each direction of Y-balance score differed (ANT: $F_{2,84}=9.83$, $p<0.01$; PM: $F_{2,84}=11.89$, $p<0.01$; PL: $F_{2,84}=8.53$, $p<0.01$). The scores of the SV condition were lower than those of the EO condition in the ANT ($p<0.01$), PM ($p=0.01$), and PL ($p=0.02$) direction.

CONCLUSION: The influence of the level of visual information on static and dynamic postural control appears to be similar between individuals with a history of knee surgery and healthy controls. Individuals with ACLR may exhibit impaired dynamic postural control compared to those with meniscus surgery or healthy controls, highlighting the need for proprioceptive training in ACLR rehabilitation to enhance dynamic stability.

DYNAMIC ASSESSMENT OF THE TALUS-LATERAL MALLEOLUS DISTANCE DURING FORWARD SINGLE-LEG DROP LANDING IN INDIVIDUALS WITH AND WITHOUT CHRONIC ANKLE INSTABILITY

ISHIDA, A., ONOUE, S., TASHIRO, T., ARIMA, S., ISHIHARA, H., MAEDA, N.
HIROSHIMA UNIVERSITY

INTRODUCTION: Lateral ankle sprain (LAS) has a high recurrence rate, which has considered to be associated with chronic ankle instability (CAI). LAS often occurs during landing, accounting for 35% of all scenario of non-contact LAS, and ankle instability before landing has seemed as a risk factor. As an assessment of ankle instability, the talus-lateral malleolus distance has been measured using ultrasound, and it was longer in patients with CAI than that of healthy adults. Recently, we developed an assessment of the dynamics of the talus-lateral malleolus distance during gait [1]. Then, we aimed to assess the dynamics of the talus-lateral malleolus distance during forward single-leg drop landing and compare between individuals with and without CAI.

METHODS: In total, 24 young adults (38 feet, 21.8 ± 1.9 years) participated, and they were divided into the healthy group (12 adults, 24 feet) and the CAI group (12 adults, 14 feet) depending on the history of LAS and score of a Cumberland ankle instability tool [2]. The task movement was a forward single-leg drop landing from 30 cm high box to the force plate (AMTI Inc., USA). The talus-lateral malleolus distance and ankle joint angles were captured by ultrasound (Telemed Ltd., Lithuania) synchronized with three-dimensional motion capture systems (Vicon motion systems Ltd., UK). We also assessed the peak value of ground reaction force (GRF). The analysis interval was 200 ms before to after initial contact (IC) and normalized for 100%. Statistical parametric mapping was used to compare the time course of the talus-lateral malleolus distance and ankle joint angles between 2 groups. The unpaired t-test was conducted for the GRF data. The significance level was set at $p<0.05$.

RESULTS: The talus-lateral malleolus distance before IC (10%-35%) was longer in the CAI group than that of the healthy group ($p<0.01$). The CAI group showed larger ankle adduction angle before IC (0%-35%) compared to the healthy group ($p<0.05$). The vertical GRF (vGRF) was greater in the CAI group than in the healthy group ($p<0.05$).

CONCLUSION: There is deterioration of proprioception in ankle adduction position and impairment of activity in the peroneus muscles before IC in patients with CAI [3]. These dysfunctions after LAS might increase ankle adduction angle in the CAI group. In this position, the talus shifts forward and internal rotation, enlarging the talus-lateral malleolus distance. Ankle instability before IC has been considered to induce "giving way", and increased talus-lateral malleolus distance can cause LAS. Moreover, the CAI group showed greater vGRF, and repetitive high landing impact causes abnormal stress on the ankle joint structure, leading to higher ankle instability. This study suggests researcher should focus on the talus-lateral malleolus distance before IC in the CAI case.

ACUTE EFFECT OF CONTINUOUS PERTURBATIONS OF THE BASE OF SUPPORT ON REACTIVE BALANCE RESPONSE

RIZZATO, A., FAGGIAN, S., PAOLI, A., MARCOLIN, G.
UNIVERSITÀ OF PADOVA

INTRODUCTION: The understanding of the role of immediate previous experience to continuous balance perturbation in reactive postural responses and skill acquisition to an unexpected stimulus is warranted. Therefore, we aimed to investi-

gate whether exposure to two different types of continuous perturbations (CP) of the base of support (i.e., random and wave-like platform translation) affects the postural response to a sudden unexpected perturbation (UP) of the base of support, compared to a control condition (CTRL) where no CP was applied.

METHODS: Twenty-seven young adults participated in the study (N=27; F=14; 21.56±1.31yrs; 1.71±0.14m; 72.30±16.06kg). Postural balance was tested on a force plate (AMTI BP400600, USA) positioned on an electro-actuated movable plate (EnginLAB s.r.l., Italy). Subjects performed three different conditions in a random order assessed on three different days, namely: random (RND), sine wave (SIN), and control (CTRL). For each condition, in five out of ten trials, subjects did not randomly receive the UP to prevent them from always expecting a perturbation following the CP. The CP lasted 30 s, and the total displacement was the same for both SIN and RND perturbations. The UP had the following characteristics: forward direction, 50mm of displacement, and 200mm/s of ramp rate. The Area95, the mean velocity, the first peak, and the maximal oscillations (ΔCoPMax) of the center of pressure (CoP) trajectory were calculated in the 2.5s window after the UP occurred. In the CP, the Area95 and the mean velocity were calculated over the 30-second perturbations.

RESULTS: One-way ANOVA showed improvements in balance response to the UP following the RND ($p<0.001$) and SIN ($p<0.001$) compared to the CTRL condition for all the CoP-related parameters. Regarding balance control during the CPs, the two-way ANOVA showed a significant ($p<0.001$) main effect of the condition (RND vs. SIN) with lower values in the SIN compared to RND for both the Area95 and the mean velocity.

CONCLUSION: These findings suggest that young, healthy subjects could benefit from acute exposure to continuous postural perturbations in the reactive balance response to a subsequent unexpected perturbation. Therefore, it would be interesting to investigate whether continuous perturbations may be used as training, regardless of their nature, to assist or improve the response of postural control to external perturbations.

LOWER-BODY MUSCLE FORCES DURING PREFERRED AND NON-PREFERRED DEADLIFT TECHNIQUES IN POWERLIFTERS

HACKER, M., GONCALVES, B.A.M., PUERZEL, A., KAINZ, H.

UNIVERSITY OF VIENNA

INTRODUCTION: The deadlift is the last discipline of powerlifting and is crucial for competition success. The International Powerlifting Federation (IPF) allows two techniques, the sumo (SDL) and conventional (CDL) [1]. This study aims to investigate differences in muscle forces during preferred and non-preferred deadlifts. We hypothesised that those performing their preferred deadlift technique would require lower hip extensors, hip flexors, hip adductors, and knee extensors muscle forces compared to the non-preferred technique.

METHODS: Two national-level powerlifters (1 female), active members of the Austrian Powerlifting Federation, were recruited for this study. Individual one-repetition maximum was self-estimated (e1RM) according to the athlete's information in previous training sessions. The female athlete was using the sumo deadlift as the preferred technique (57.6kg; e1RM: 120kg; 20y; 4y of strength training experience). The male athlete was executing the conventional deadlift as the preferred technique (98kg; e1RM: 290kg; 27y; 8y of strength training experience). After an individual warm-up, each participant performed four sets of one repetition at 80% of preferred e1RM both in the preferred and non-preferred techniques. Lifts were performed following the rules of the IPF [1]. Joint kinematics were calculated using a Vicon motion capture system with 12 infrared cameras. Ground-reaction forces were captured with two Kistler forces plates and used to compute joint moments and muscle forces in OpenSim 4.5 [2,3]. Forces for each muscle group were calculated (hip extensors (HE), hip adductors (HAd), and knee extensors (KE)) and time-varying waveforms were used to estimate significant differences using paired t-tests via statistical parametric mapping.

RESULTS: Results indicate that during the preferred SDL, HE and KE muscle forces were lower compared to the non-preferred lift. The athlete who prefers CDL, lifts with higher KE and HE muscle forces, compared to his non-preferred technique. No significant differences in HE between the SDL and CDL were observed. In both participants KE muscle forces during the CDL were significantly higher than those during SDL, independently of the athlete's preference. The HAd muscle forces were also significantly larger during CDL compared to the SDL for both athletes.

CONCLUSION: The results of this preliminary study contradict our initial hypothesis, suggesting the preferred deadlift technique cannot be explained by lower muscle forces compared to the non-preferred technique. We suggest that athletes with lower muscle force capabilities in the HE and KE should use the SDL. However, when the goal is to train the HE and KE, the CDL is recommended.

HIP & KNEE MOMENTS IN THREE VARIATIONS OF THE COPENHAGEN ADDUCTOR EXERCISE

CHIU, L., DÆHLIN, T., DMYTRIIEVA, D., RUTHERFORD, E.
UNIVERSITY OF ALBERTA

INTRODUCTION: The Copenhagen adductor exercise (CAE) is effective for improving hip adductor muscle strength. However, CAE variations have been proposed that may increase or decrease loading of these muscles. Specifically, CAE may be performed with the support at the knee, ankle, or between these joints (MID). This study aimed to determine hip and knee loading for these CAE variations.

METHODS: Twenty-four participants (13 women) performed three repetitions of each CAE variation using their right lower limb. Reflective markers were used to model the pelvis and right lower limbs. A wooden support was placed on a force platform and the force acting on the lower limb was calculated. Sagittal, frontal, and transverse plane hip and knee net joint moments (NJM) were calculated.

RESULTS: The hip adductor NJM was 0.93 ± 0.16 Nm/kg for knee, 1.36 ± 0.21 Nm/kg for MID, and 1.54 ± 0.23 Nm/kg for ankle support placements. The sagittal hip NJM was an extensor moment (knee: -0.17 ± 0.23 Nm/kg; MID: -0.28 ± 0.32 Nm/kg; ankle: -0.38 ± 0.40 Nm/kg). Both hip adductor and extensor NJM were greatest for the ankle and smallest for the knee ($P < 0.005$) support. Hip sagittal plane NJM was significantly correlated with thigh transverse plane orientation for all variations ($R^2 = 0.94-0.96$; $P < 0.001$). There was a knee abductor (-0.12 ± 0.03 Nm/kg) and knee extensor (0.08 ± 0.04 Nm/kg) NJM for the knee support. The other variations had knee adductor (MID: 0.44 ± 0.09 Nm/kg; ankle: 0.73 ± 0.14 Nm/kg) and flexor (MID: -0.16 ± 0.01 Nm/kg; ankle: -0.43 ± 0.21 Nm/kg) NJM. Knee frontal and sagittal NJM were different between each condition ($P < 0.005$). Knee sagittal plane NJM was significantly correlated with leg transverse plane orientation for all variations ($R^2 = 0.80-0.87$; $P < 0.001$).

CONCLUSION: Hip adductor loading increased as the CAE support location was moved from the knee to the ankle. Most participants had a hip extensor NJM, however some utilized a hip flexor NJM. The correlations between thigh transverse plane rotation and hip sagittal plane NJM demonstrated that a more medially rotated thigh had hip flexor NJM while less medial thigh rotation resulted in a hip extensor NJM. Most hip adductor muscles are hip flexors while the ischiocondylar head of adductor magnus is a hip extensor. Therefore, these muscles may act synergistically to generate the hip adductor NJM while neutralizing the flexor and extensor actions. Changing thigh transverse plane rotation may alter this load sharing to favour those adductors that are flexors or extensors. CAE variations with the support distal to the knee had internal knee adductor and flexor NJM, which are equivalent to external knee abduction and extension moments. This combination of external moments may place stress on the anterior cruciate and medial collateral ligaments. As support location for the CAE moves distally, hip and knee moments increase. Consequently, potential stress on the knee ligaments should be considered when attempting to increase hip muscle loading.

EFFECTS OF MUSCLE MECHANICAL PROPERTIES ON SWEEP AND SCULL ROWERS FOLLOWING A 2000-METER ON-WATER ROWING TIME TRIAL

CHANG, C., CHEN, C.Y., LEE, S.Y., LIN, H.K., CHANG, C.Y.
NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Due to sport profile, rowing is classified into sweep rowing (single oar) and scull rowing (double oar) (1). Athletes have to repeat the rowing movement throughout the race, during the race load will accumulate continuously (2), it will affect particular muscle groups' muscle mechanical properties and promoting injury risk (3). Rowers may have bilateral muscle asymmetry due to specific technical factors. Many studies have pointed out that changes in muscle mechanical properties, such as muscle tone and stiffness, are related to sports performance and injuries (4,5). The purpose of this study was to investigate the differences in bilateral muscle mechanical properties between the dominant side and the non-dominant side of sweep and sculls rowers before and after the 2000-meter time trial test of water rowing.

METHODS: Six male sweep rowers (SW, $n=6$) and 6 male sculls rowers (SC, $n=6$) were recruited for this study. The handheld MyotonPRO device was used to collect muscle tone (frequency) and stiffness data of the posterior deltoid (PD) and vastus medialis (VM) (dominant and non-dominant sides) before and after the 2000-meter time trial test of water rowing. Two-way mixed-design analysis of variance was used to analyze differences in muscle tone (frequency) and stiffness between dominant and non-dominant at pre- and post-rowing time-trial.

RESULTS: The results of the mixed-design two-way ANOVA showed that in the sweep group, the muscle tone (frequency) of the non-dominant side PD ($F = 5.06$; $p = 0.048$) and VM ($F = 5.89$; $p = 0.036$), as well as the dominant side PD ($F = 10.45$; $p = 0.009$) and VM ($F = 6.08$; $p = 0.033$) were significantly increased after the 2000-meter time trial test. On the other hand, the muscle stiffness of the non-dominant side PD ($F = 6.12$; $p = 0.033$) and VM ($F = 5.14$; $p = 0.047$), as well as the dominant side PD ($F = 5.42$; $p = 0.042$) and VM ($F = 9.26$; $p = 0.012$) were significantly increased after the 2000-meter time trial test. In the sculls groups, the muscle tone (frequency) of the non-dominant side PD ($F = 4.40$; $p = 0.062$) and VM ($F = 3.47$; $p = 0.092$), as well as the dominant side PD ($F = 4.00$; $p = 0.074$) and VM ($F = 2.69$; $p = 0.132$) showed no significant increase after the 2000-meter time trial test. On the other hand, the muscle stiffness of the non-dominant side PD ($F = 0.67$; $p = 0.431$) and VM ($F = 2.75$; $p = 0.128$), as well as the dominant side PD ($F = 2.03$; $p = 0.185$) and VM ($F = 3.42$; $p = 0.094$) showed no significant increase after the 2000-meter time trial test.

CONCLUSION: After a high-intensity, high-load 2000-meter water rowing time trial, PD and VM in the sweep group showed an increase in muscle tone and stiffness, as well as symmetrical changes in bilateral muscle mechanical properties.

TORQUE-VELOCITY RELATIONSHIP FOR UPPER LIMBS IN POSTMENOPAUSAL WOMEN: GOODNESS OF FIT OF LINEAR AND CURVILINEAR MODELS AND DERIVED PARAMETERS.

REVUELTA-LERA, B., RIAL-VÁZQUEZ, J., CAMACHO-VILLA, A., RIVERA-MEJÍA, S.R., NINE, I., RÚA-ALONSO, M., FARIÑAS, J., ENRÍQUEZ-GONZÁLEZ, M.G., IGLESIAS-SOLER, E.

UNIVERSITY OF A CORUÑA / Q6550005J

INTRODUCTION: Women face an accelerated loss of muscle mass and strength at an earlier age than men, notably with the onset of the menopause (1). The evaluation of isokinetic metrics has been considered the gold-standard method for testing muscle strength (2) and it is not commonly used in postmenopausal women. The main aims of this study were to evaluate the goodness of fit and estimated parameters of linear and non-linear models for fitting the torque-velocity (TV) relationship, and to compare the outcomes by utilizing either target or real maximum velocities as the independent variable.

METHODS: 16 physically active postmenopausal women completed a study funded by the Spanish Ministry of Science, Innovation and University (PID2021-124277OB). Elbow flexors (EF) muscle strength was evaluated in the dominant limb using an isokinetic dynamometer. Range of motion was 20° (elbow close to full extension) to 120° (elbow flexed). Test was completed at 30, 60, 120, 180, 240, 300 and 400°/s. Peak torque was identified where >90% of the maximum target velocity was attained. Linear, polynomial and Hill regression models (3) adjusted the TV data. Since the dynamometer recorded torque even when the target velocity has not been reached, we derived the TV relationship by considering both real (i.e., the velocity achieved; TVR) and target velocity (i.e., the velocity preset on the dynamometer; TVT). The TV parameters derived from each model, the coefficient of determination (R²) and mean square error (MSE) were calculated for TVR and TVT relationships.

RESULTS: Isokinetic dynamometer did not achieve the target velocities, for values higher than 180°/s. The dynamometer report presented a peak torque reached at a lower velocity than the target velocity. The goodness of fit of linear and non-linear models for fitting TVR and TVT was excellent (R²>0.940). Nonsimilar values were observed for goodness-of-fit and parameters derived from the linear and polynomial models, indicating that TVR and TVT may not be considered equal (p<0.05). From Hills model, goodness of fit was similar for TVR and TVT but the derived parameters were significantly different (p<0.037). Considering TVR data, the best adjustment was obtained using polynomial model (R²=0.975; MSE=1.31±0.93N²m²) and the worst using Hills model. Moreover, the theoretical maximum torque (T₀) and velocity (V₀) obtained from Hills model were higher compared with the values obtained from linear and polynomial models. The polynomial model estimated the value of T₀ and V₀ lower than the other models (p<0.001).

CONCLUSION: The isokinetic evaluation can include errors due to assigning torque measurements to incorrect velocities. It is recommended that the raw data be reviewed after evaluation, as TVR and TVT cannot be used indistinctly. We recommend the polynomial model to fit the TV data for EF in postmenopausal women.

MUSCLE FIBER TYPOLOGY IS ASSOCIATED WITH PASSIVE MUSCLE STIFFNESS IN A LENGTHENED POSITION IN HUMANS

OKUDA, Y., KAWAMA, R.1, TAKAHASHI, K.1, VAN DE CASTEELE, F.2, LIEVENS, E.2, DERAIVE, W.2, WAKAHARA, T.1

1: DOSHISHA UNIVERSITY, KYOTO, JAPAN 2: GHENT UNIVERSITY, GHENT, BELGIUM

INTRODUCTION: Skeletal muscle is composed of several components with different elastic properties such as fast-twitch (FT) and slow-twitch muscle fibers and intramuscular fat. There is considerable individual variation in its composition (1). However, it remains unknown whether the individual variation in the composition affects the stiffness of the muscle as a whole. Identifying the source of variation is important for advancing the understanding of muscle stiffness from both an athletic and clinical perspective, as the muscle stiffness is relevant to physical performance (2) and injury susceptibility (3). Here, we examined whether muscle fiber typology and fat fraction are associated with passive muscle stiffness using non-invasive approaches, proton magnetic resonance spectroscopy (1H-MRS) (4) and Dixon magnetic resonance imaging, respectively.

METHODS: In 20 healthy young males, the shear modulus of the vastus lateralis (VL) was measured at rest using shear wave elastography at 50% of the right thigh length from 0° (full knee extension) to 110° of knee flexion angles (every 10°). At the same region as the shear modulus measurement, muscle carnosine concentration (an index of muscle fiber typology) and fat fraction (an index of intramuscular fat) were assessed using 1H-MRS and two-point Dixon imaging, respectively. The Pearson's correlation coefficient was used to examine the relation between VL shear modulus at slack angle (the joint angle beyond which the shear modulus firstly increased) and at 110° of knee flexion and the other measured variables.

RESULTS: The VL shear modulus at the slack and 110° of knee flexion was 3.6 ± 0.7 kPa and 9.7 ± 1.8 kPa, respectively. The carnosine concentration was 6.2 ± 1.7 mM, and the fat fraction was 7.6 ± 1.8%. The carnosine concentration was significantly and positively correlated with the shear modulus of VL at 110° of knee flexion (p = 0.026, r = 0.50), but not at the

slack angle. There were no significant correlations between fat fraction and VL shear modulus at slack angle or 110° of knee flexion.

CONCLUSION: This is the first study to show that individuals with a relatively higher carnosine concentration (higher estimated proportion of FT fibers [4]) exhibit a higher passive muscle stiffness in a lengthened position. Interestingly, these results contradict the observed characteristics of each fiber type in an animal study (5), possibly due to interactions with muscle structural factors other than intramuscular fat (e.g., the number of in-series sarcomeres and extracellular matrix mechanical properties) in humans. Our findings provide new insights into the determinants of passive muscle stiffness and would be fundamental information for understanding the adaptive plasticity of passive muscle stiffness.

THE EFFECTS OF INTER-SET STRETCHING ON BENCH-PRESS PERFORMANCE

SCARDINA, A., DI BARTOLO, L., PINTO, G., NAKAMURA, M., WARNEKE, K., GIUSTINO, V., BELLAFFIORE, M., BIANCO, A., THOMAS, E.

UNIVERSITY OF PALERMO

INTRODUCTION: Static muscle stretching is typically performed before and/or after a training session. However, especially when performed prior to exercise, such approach may impact the subsequent performance. The effects of performing stretching between sets during resistance-training has been poorly investigated. Thus, this study aims to investigate the effects of inter-set stretching, applied to the agonist (AG) and antagonist (AN) muscles, on bench-press performance.

METHODS: Twenty-one healthy male participants (23.8 ± 3.99 years, 173 ± 6.79 cm, 75.6 ± 11.8 Kg) were recruited. Before data collection, the bench press 1-RM was calculated through a standardized and validated protocol. Following the 1-RM, each participant underwent three conditions in a randomized order: pectoralis muscle stretching (AG), dorsal muscle stretching (AN) and a control condition (CC). Prior to starting the first session, anthropometric measures were taken. After a warm-up period, the main protocol consisted of performing five sets to failure of bench press at 70% of 1-RM with 90sec rest between sets. In the AG and AN sessions, participants performed 30 seconds of static stretching during the rest periods between sets. In the CC session, no stretching intervention was performed during the rest periods. Data were collected using the T-Force® device. The primary outcome was the total lifted volume across each AG, AN and CC session. The secondary outcomes were force (N), velocity (V) and power (W).

RESULTS: Our results showed no difference in the total lifted volume ($p=0.395$) between the three conditions. Similarly, no differences were found in N production ($p=0.642$), V ($p=0.940$) and W ($p=0.921$) between groups.

CONCLUSION: Based on our results, inter-set static stretching has no effects on bench-press performance. Acutely incorporating static stretching during inter-set rest periods may optimize training time efficiency without hampering performance.

HEALTHY YOUNG ADULTS EXECUTE COMMONLY PRESCRIBED LEG STRENGTH-TRAINING EXERCISES WITH AN ASYMMETRICAL KNEE FLEXION-EXTENSION KINEMATICS PROFILE

HORTOBAGYI, T., MALÁRIK, E., KOVÁCS, B.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

INTRODUCTION: Resistance training is a key exercise modality for increasing muscle strength and size. While health policy governing agencies clearly define the dose parameters of resistance training, there is limited information on how individuals execute the recommended resistance training exercises. The purpose of the present study was to characterize knee joint kinematics of often-prescribed resistance training exercises and determine the day-to-day kinematic consistency of execution.

METHODS: Healthy young adults ($n=8$; 4 females; age: 27.1 ± 5.8 yrs; height: 172.6 ± 7.6 cm; mass: 73.8 ± 13.1 kg) participated in the study. Technogym leg press (LP) and knee extension (KE) machines were programmed to 40% eccentric (ECC) and 40% concentric (CON) overload of 60% 1RM baseload. The extension-flexion phases of LP and KE were paced at 60 bpm by a metronome. Volunteers performed the two exercises twice one week apart. We video-recorded knee joint angular displacement in the sagittal plane and computed knee joint range of motion (ROM) and average and maximum knee angular velocity during LP and KE.

RESULTS: In LP, average knee ROM did not differ between CON ($64.8 \pm 8.4^\circ$) and ECC overload ($64.5 \pm 6.6^\circ$, $p>0.05$). In KE, knee ROM also did not differ between CON ($72.1 \pm 7.2^\circ$) vs. ECC overload ($71.4 \pm 9.5^\circ$, $p>0.05$). In LP, mean angular flexion and extension velocity during CON overload was $37.2 \pm 6.4^\circ/\text{s}$ vs. $28.4 \pm 5.0^\circ/\text{s}$. In LP, mean angular flexion and extension velocity during ECC overload was $34.1 \pm 4.7^\circ/\text{s}$ vs. $30.8 \pm 3.7^\circ/\text{s}$. In KE, mean angular flexion and extension velocity during CON overload was $37.5 \pm 6.3^\circ/\text{s}$ vs. $34.2 \pm 5.6^\circ/\text{s}$. In KE, mean angular flexion and extension velocity during ECC overload was $42.0 \pm 5.9^\circ/\text{s}$ vs. $31.3 \pm 3.7^\circ/\text{s}$. In both exercises, the flexion vs. extension velocity was always faster (all $p<0.05$). Intra-

class correlation coefficients revealed low day-to-day consistency of knee ROM for LP (CON: 0.54; ECC: 0.60) and for KE (CON:0.46; ECC:0.39).

CONCLUSION: Even healthy young adults seemed to have difficulty in following metronome-paced LP and KE with an ECC and CON overload and performed these exercises with an asymmetric flexion-extension velocity profile inconsistently across two days of testing.

USING MACHINE LEARNING MODEL FOR THE ELECTROMYOGRAPHY DATA CLASSIFICATION OF THE DOMINANT AND NON-DOMINANT LIMB

ABOOZARI, N., BEHM, D., SHAHIDI, R.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Skeletal muscle plays a pivotal role in body movement. Surface electromyography (EMG) is a non-invasive technique for measuring muscle activity, but its interpretation remains complex. Recent developments in machine learning offer the potential to improve EMG classification with acceptable accuracy. The aim of this study was to develop and evaluate a machine learning-based model to classify the activity of dominant and non-dominant limb based on their EMG signals.

METHODS: A data series from 8 healthy participants (aged 28.5 ± 7.6 years) was used for the machine learning development process. Participants performed a knee extension maximum voluntary isometric contraction (MVIC) to measure the EMG activity of the vastus lateralis. Data were collected for the dominant and non-dominant vastus lateralis muscles. EMG signals were recorded at a sampling rate of 2000 Hz, amplified, filtered, and stored for analysis.

The machine learning pipeline involved signal preprocessing, feature extraction, clustering, and evaluation. Preprocessing included signal standardization, normalization, and segmentation to isolate meaningful EMG data. Frequency-domain features were extracted using the Fast Fourier Transform to capture spectral characteristics of muscle activity. Unsupervised Fuzzy C-Means clustering was applied to classify data into dominant and non-dominant limb groups based on EMG signal properties.

RESULTS: The classification model successfully grouped the data into two clusters using fuzzy c-means clustering. The results indicated a clear separation between the activity of the dominant and non-dominant limb based on muscle activation patterns. The fuzzy membership values indicated a strong separation between clusters, with an overall classification accuracy of 88%.

CONCLUSION: This study used an advanced machine learning framework to classify muscle activation patterns. The results showed acceptable accuracy, demonstrating the models potential to distinguish the activity of dominant and non-dominant limb. These results support the use of ML in evaluating muscle activity status and its applications in rehabilitation, musculoskeletal research, prosthetics, and muscle disorder diagnosis.

ASSOCIATIONS BETWEEN PHYSICAL FITNESS AND WEIGHT STATUS IN PORTUGUESE CHILDREN: A MULTIVARIATE ANALYSIS

SANTOS, C., MAIA, J., KATZMARZYK, P.T., GARBELOTO, F., GARGANTA, R., FARIAS, C., BARREIRA, T., CHAPUT, J.P., TANI, G., HEDEKER, D., PEREIRA, S.

FACULTY OF SPORT, UNIVERSITY OF PORTO

INTRODUCTION: Physical fitness (PF) is a significant factor in children's health and well-being [1]. Excess body weight is often linked to lower PF levels [2]. The extent to which this relationship persists after accounting for other relevant factors remains unclear. Hence, this cross-sectional study aimed to examine whether PF differs between normal-weight and overweight/obesity children in boys and girls after adjusting for age, fundamental movement skills (FMS), and moderate-to-vigorous physical activity (MVPA).

METHODS: A total of 1,031 children (52.9% girls) aged 6–10 years were randomly selected from schools in northern Portugal [3]. PF was assessed with five standardized tests: standing long jump, handgrip strength, shuttle run, 50-yard dash, and PACER. Body mass index was calculated, and children were classified as normal weight or with overweight/obesity using WHO cut-off points [4]. FMS was evaluated using five object control tasks [5]. MVPA was objectively assessed with accelerometry (Actigraph wGT3X-BT) over seven consecutive days. Multivariate analysis of covariance (MANCOVA) was used separately for girls and boys, with age, FMS, and MVPA as covariates.

RESULTS: After adjusting for age, FMS, and MVPA, weight status differentiates PF multivariate profiles within each sex (girls: Wilks' Lambda=0.749, $p<0.001$; boys: Wilks' Lambda=0.751, $p<0.001$). More specifically, girls with overweight/obesity performed worse than their normal-weight peers in all PF tests (standing long jump: $F=26.29$, $p<0.001$; shuttle run: $F=32.72$, $p<0.001$; agility: $F=27.16$, $p<0.001$; PACER: $F=43.18$, $p<0.001$), except for handgrip strength ($F=63.58$, $p<0.001$), where they had higher values. A similar profile was observed in boys, with those with overweight/obesity being less fit in

standing long jump ($F=20.98$, $p<0.001$), shuttle run ($F=45.13$, $p<0.001$), agility ($F=19.17$, $p<0.001$), and PACER ($F=49.20$, $p<0.001$), but stronger in handgrip strength compared to normal-weight peers ($F=51.18$, $p<0.001$).

CONCLUSION: This study reinforces that even after adjusting for age, MVPA, and FMS, boys and girls with overweight and obesity are less physically fit than their normal-weight peers, except in handgrip strength. Excess weight is critical in determining PF levels, independent of other contributing factors. Therefore, we recommend implementing interventions combining weight management strategies with targeted efforts to enhance PF as early as possible, ensuring a holistic approach to improving children's health and well-being.

PHYSICAL ACTIVITY AND SELF-CARE AS PREDICTORS OF RESILIENCE IN HEALTHCARE PROFESSIONALS: A CROSS-SECTIONAL STUDY IN NORTHERN GREECE

PANAYIOTOU, G., BELLALI, T., LIAMOPOULOU, P., MANOMENIDIS, G.
EUROPEAN UNIVERSITY OF CYPRUS

INTRODUCTION: Healthcare professionals (HPs) experience significant occupational stress, increasing their risk of burnout and mental health issues. Resilience—the ability to adapt to adversity—is critical for well-being. Self-care and physical activity (PA) are linked to lower stress and improved emotional regulation, yet HPs often struggle to engage in PA due to workload demands (1-3). While research highlights the role of self-care and PA in reducing burnout, their direct influence on resilience remains underexplored. This study explores their impact on HPs resilience in Northern Greece.

METHODS: A cross-sectional study was conducted (Sept-Dec 2023) with 438 HPs (mean age: 44.6 ± 9.5 years, work experience: 16.4 ± 9.7 years) from three public hospitals in Northern Greece (response rate: 79.6%). The sample included 200 physicians and 238 nurses. Participants were recruited via hospital website invitations and completed anonymous self-administered questionnaires: (a) demographic and professional characteristics, (b) the Self-Care Scale (Cronbach's $\alpha > 0.90$), (c) the IPAQ-SF for PA (MET-min/week), and (d) the CD-RISC-10 for resilience (Cronbach's $\alpha = 0.895$). Data analysis used SPSS v.29.0, including descriptive statistics, the Kolmogorov-Smirnov test for normality, Spearman's correlation, and multivariate linear regression (significance level: $p < 0.05$).

RESULTS: Resilience was moderate (CD-RISC-10: 26.8 ± 6.46), while self-care levels were high (134.51 ± 21.83). PA was classified as moderate (1364.8 ± 1408.6 MET-min/week), with 36.8% reporting low PA, 46.2% moderate, and 16.9% high PA. Male HPs exhibited higher resilience than females ($p=0.01$). Resilience correlated positively with self-care ($r=0.555$, $p<0.001$) and PA ($r=0.282$, $p=0.002$). Multivariate regression identified gender, self-care, and PA as resilience predictors ($F=25.177$, $p<0.001$, $R^2=39.4\%$), with higher self-care and PA levels linked to greater resilience.

CONCLUSION: This study highlights the importance of self-care and PA in enhancing resilience among HPs. Higher self-care and PA levels were associated with greater resilience, reinforcing their protective effects against stress and burnout. The findings emphasise the need for structured PA programs and self-care initiatives to support HPs well-being. Future research should explore long-term interventions and policies promoting resilience in healthcare settings.

INFLUENCE OF 24-HOUR MOVEMENT BEHAVIOR ON ARTERIAL STRUCTURE, FUNCTION, AND HEMODYNAMICS IN ADULTS: THE ROLE OF PHYSICAL ACTIVITY, SEDENTARY BEHAVIOR, AND SLEEP

GOMEZ GARCIA, A., RIVOIR, S., ACUÑA, A., CASTRO, A., BUA, V., GARCIA-BAYCE, A., MAGALLANES, C., ZÓCALO, Y., BIA, D.
UNIVERSIDAD DE LA REPÚBLICA

INTRODUCTION: Cardiovascular (CV) health is impacted by a range of lifestyle behaviors, including sedentary behavior (SB), sleep (SL), and physical activity (PA). Arterial structure, function, and hemodynamics are key indicators of CV risk. Parameters such as arterial stiffness, central and brachial blood pressure, and arterial diameters are associated with long-term CV outcomes. However, the extent to which PA, SB, and SL influence these vascular parameters remains unclear.

METHODS: In 233 healthy subjects (without physical limitations, known disease, or the use of medications with lipid-lowering, antihypertensive, or hypoglycemic effects), the following data were recorded: (1) weight, height, and body composition; (2) PA, SB, and SL assessed by accelerometry (recordings: 7 consecutive days, on wrist and waist; GT3X, Acti-Graph, U.S.A.); and (3) at rest: (i) hemodynamic characteristics (aortic and brachial blood pressure [techniques: applanation tonometry and oscillometry]), (ii) structural characteristics (diameters and wall thickness of carotid, femoral, and brachial arteries [technique: ultrasound]), and (iii) functional characteristics (aortic, carotid, femoral, and brachial stiffness [techniques: pulse wave velocity; applanation tonometry and ultrasound]) of the CV system.

A stepwise analysis was conducted: (1) The association between PA, SB, and SL variables with levels of exposure to cardiovascular risk factors (CRF) was quantified, as well as the association between CV characteristics and levels of exposure to CRF. (2) CV variables were standardized to z-scores using the mean and standard deviation obtained from a reference subgroup that had no exposure to traditional CRF. (3) After quantifying the degree of association between z-scores of CV variables and CRF, multiple linear regression models were constructed using CV z-scores as the dependent variable and PA, SB, SL, and CRF as independent variables.

RESULTS: Arterial structural variables showed a stronger association with physical activity, particularly with vigorous physical activity and step count. Specifically, femoral diameter was positively related to average step count and energy expenditure. Additionally, significant relationships were observed with parameters related to sedentary break interruptions and sleep duration. Local arterial stiffness was more closely associated with sedentary behavior and sleep, showing that greater sleep efficiency and less sedentary time were linked to lower arterial stiffness. At the regional arterial stiffness level, carotid-femoral pulse wave velocity was associated with both PA and sleep efficiency. Specifically, more time spent in moderate-to-vigorous PA and higher activity counts were associated with lower arterial stiffness, whereas greater sleep fragmentation showed an inverse relationship. Hemodynamic variables, including brachial and central blood pressure, were primarily associated with moderate-to-vigorous physical activity.

CONCLUSION: Physical activity, especially higher-intensity activity, was associated with better arterial structural and functional characteristics. Sedentary behavior and sleep showed relationships with local and regional arterial stiffness. Blood pressure was mainly linked to moderate-to-vigorous physical activity and sleep parameters.

HIGH-INTENSITY CIRCUIT TRAINING (HICT) FOR IMPROVING GENERAL AND JOB-SPECIFIC FITNESS IN STRUCTURAL FIRE-FIGHTERS.

GUTIÉRREZ ARROYO, J., GARCÍA-HERAS, F., CARBALLO-LEYENDA, B., RODRÍGUEZ-MEDINA, J., VILLA-VICENTE, J.G., RODRÍGUEZ-MARROYO, J.A.
UNIVERSITY OF LEÓN

INTRODUCTION: Structural firefighters (FF) perform strenuous work under hazardous and unpredictable conditions, where physical demands expose them to risks affecting their safety and health (Plat et al., 2011). Maintaining high physical fitness is essential to perform occupational tasks safely and efficiently (Smith et al., 2011). High-intensity circuit training (HICT) has been used to incorporate job-specific tasks such as lifting, pushing, pulling, and carrying, closely resembling FF duties (Gutiérrez-Arroyo et al., 2023). This study aimed to evaluate the effects of an HICT program on physical fitness and thermophysiological performance in a job-specific fitness test that includes key firefighting tasks.

METHODS: Seventeen professional Spanish FF participated in a 9-week HICT program (2 sessions per week). Sessions lasted 45–60 minutes and involved job-specific muscle actions at high intensity (>80% HRmax). Pre- and post-intervention assessments included body composition, physical fitness tests, and a simulated fire suppression test (FST) with five tasks (tool handling, tower ascent, mannequin drag, hose deployment and drag, and hose advancement), performed twice with a 25-minute rest interval. Performance, heart rate (HR), gastrointestinal temperature (T_{gi}), physiological strain index (PSI), rating of perceived exertion (RPE), and thermal sensation (TS) were measured.

RESULTS: After 9 weeks of HICT, significant improvements ($p < 0.05$) were observed in multiple physical fitness parameters (range: 3.4–33.4%), as well as in total performance (11.2%) and heat tolerance (rate of increase in T_{gi} and PSI: -29.2% and -10.2%, respectively) during the FST. Additionally, the maximum T_{gi} decreased from 39.0 ± 0.4 °C pre-intervention to 38.4 ± 0.4 °C post-intervention.

CONCLUSION: HICT appears to be an effective training method to enhance both general and job-specific fitness in FF, improving thermophysiological response and potentially increasing safety during firefighting tasks. These findings highlight the importance of tailored physical conditioning programs for FF; however, further research is needed to confirm these results.

FIREFIGHTER FITNESS: LOOKING BEYOND OCCUPATIONAL STANDARDS

FERGUSON, A., BISSAS, A.
UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Fitness assessments for firefighters in the UK are designed to ensure they meet the physical demands of their role. Gym-based tests for cardiorespiratory fitness and muscular strength are commonly used as they offer a practical and accessible way to assess fitness. This study evaluates the performance of a group of firefighters with varying

biological profiles on approved fitness tests, to examine whether these tests differentiate fitness levels beyond the necessary occupational requirement of passing the test.

METHODS: Firefighters (106 men and 30 women) from one of the UK's Fire and Rescue Services were assessed as part of their annual fitness testing. Cardiorespiratory fitness was assessed by the Chester Treadmill Test (1), muscular strength by an overhead barbell press (25 kg) and flexibility by the sit-and-reach test. All 136 firefighters included in the analysis successfully passed their Chester Treadmill and strength tests. Resting Blood Pressure (BP) and Heart Rate (HR) were followed by further measurements of HR and the rate of perceived exertion (RPE) during the Chester test. Several Independent-Samples T-tests were conducted to test for differences.

RESULTS: The sample's age was (38.81 ± 9.50) years, height (1.76 ± 0.08) m, mass (83.48 ± 15.13) kg, BPrest $(143/88 \pm 17/10)$ mmHg and HRrest (73.71 ± 7.34) bpm. The group's HR and RPE at the end (12 min) of the Chester Test was 172.52 ± 16.47 bps and 14.18 ± 2.37 respectively. When the group was divided into sub-groups based on the median age, the younger sub-group (<38) showed lower BPrest ($p<0.001$) and RPE ($p<0.01$) at 2 and 4 min of the Chester test but higher HR at 2, 6, 8, 10, 12 min ($p<0.01$) than the older sub-group (≥ 38). When the split was based on BMI (cut-off: 25) the healthy-weight sub-group exhibited better flexibility ($p<0.05$), lower Systolic BPrest ($p<0.001$) and RPE at 12 min ($p<0.05$). Comparing 30 women and 30 men matched for age and BMI, revealed that the only difference beyond the lower Systolic BP ($p<0.001$) for women, was for RPE 12 min with men responding with 12.77 ± 2.06 compared to 14.30 ± 2.17 for women ($p<0.01$). When looking within the men ($n = 106$) and women groups separately, no differences were observed for women, whilst men with BMI less than 25 showed lower RPE 12 min ($p<0.01$), and those of younger age (<39) lower HR during the latter stages of the Chester test ($p<0.001$).

CONCLUSION: Despite variations in sex, age, BMI, blood pressure, heart rate, and RPE, all firefighters successfully met the required standards. Thus, regardless of individual physiological differences, the tests are generally achievable across the workforce. The uniform pass rate suggests that the tests may be suitable for ensuring a baseline level of fitness across this firefighter population, although it may not fully capture the range of fitness levels present within this diverse group.

LONGITUDINAL CHANGES IN PHYSICAL ACTIVITY AMONG PARENTS OF YOUNG CHILDREN

IKEZAKI, M., SOMEYA, Y., MATSUNAGA, M., SUZUKI, K., TAKAZAWA, Y.

JUNTENDO UNIVERSITY

INTRODUCTION: Physical activity is important for health, but it is low among parents in Japan, particularly those in their 20s to 50s. While cross-sectional studies have examined the relationship between children's age and parents' physical activity, longitudinal studies on this topic remain scarce. Therefore, the aim of this study is to investigate longitudinal changes in physical activity among parents of young children.

METHODS: This study was conducted in 2022 and 2023 among 1999 parents (age: 39.23 ± 5.4 years; male: 546 [27.3%], female: 1451 [72.6%], other: 2 [0.1%]) with children aged 3-10 years in 2022, and analyzed changes in their physical activity over a one-year period. Physical activity was defined as engaging in at least 30 minutes of activities such as brisk walking or various sports on at least one day in the past seven days. The rate of initiation of new physical activity was assessed during the observation period. Statistical analyses were performed using McNemars test.

RESULTS: The age distribution was as follows: 20s: 51 (2.6%), 30s: 1014 (50.7%), 40s: 882 (44.1%), 50s/60s: 52 (2.6%). The implementation rate of parents who engaged in physical activity was 38.4% in 2022 and 44.7% in 2023. Significantly more participants started physical activity (287, 14.4%) than stopped (160, 8.0%) during the observation period ($p<0.001$, respectively). According to the age group, significantly more participants in their 30s and 40s started physical activity than stopped (30s: 146 [14.4%] started, 83 [8.2%] stopped; 40s: 125 [14.2%] started, 67 [7.6%] stopped; $p<0.001$). On the other hand, those in their 20s and 50s showed no significant change in their physical activity levels (20s: 8 [15.7%] started, 8 [15.7%] stopped, $p=1.000$; 50s: 8 [15.4%] started, 2 [3.8%] stopped, $p=0.109$).

CONCLUSION: Changes in physical activity varied by the age of parents with young children. Further research is required to identify other factors influencing parents' physical activity.

CAN AEROBIC OR RESISTANCE-BASED EXERCISE SNACK IMPROVE PHYSICAL FITNESS IN YOUNG ADULTS?

RYOSUKE, M., YANAOKA, T., KUROSAKA, S.

HIROSHIMA UNIVERSITY

INTRODUCTION: The previous study showed that a few adults met the physical activity guidelines due to lack of time (Garcia-Hermoso et al., 2023). Some time-efficacy exercises improved physical fitness and reduced the risk of cardiovascular disease (Islam et al., 2022). For instance, high-intensity interval training improved cardiorespiratory fitness (CRF) and muscle strength in young adults (Callahan et al., 2021). Short bouts of high-intensity exercise spread across the day, termed exercise snack (ES), has been shown to improve CRF and resting serum glucose concentration (Allison et al., 2017), but it is not clear the effects of ES on skeletal muscle mass and strength. Moreover, no study examines whether aerobic- (AES) or resistance-based ES (RES) is more effective in physical fitness. This study aimed to examine the effects of AES and RES on physical fitness.

METHODS: Eleven untrained young males were participated in this study and randomly assigned AES ($n = 5$, 22.2 ± 1.2 years old, Body mass index (BMI); 24.7 ± 2.6 kg/m²) and RES ($n = 6$, 22.3 ± 1.8 years old, BMI; 21.9 ± 1.2 kg/m²). Participants performed to the training session (AES: step exercise with 20 cm stair, RES: squat) 2 times per day, 3 day a week, for a total of 54 sessions over 8 weeks. The exercise session consisted of vigorous-intensity exercise for a minute and rest on

chair, repeated three times. At the baseline, middle (4–5 weeks) and post intervention, body composition (i.e., body mass and skeletal muscle mass), peak oxygen uptake (VO_{2peak}) and donated leg extension isometric maximum voluntary contraction (MVC) were measured.

RESULTS: Body composition did not significantly change in both interventions ($p>0.05$). Both interventions significantly increased VO_{2peak} (AES: $+6.0\pm0.9$ ml/kg/min, $p<0.001$, RES: $+4.8\pm2.8$ ml/kg/min, $p=0.002$). Magnitudes of increases in MVC were higher in RES than in AES at the middle (AES: $+10.7\pm7.4\%$, RES: $+24.4\pm7.5\%$, $p=0.014$) and post intervention (AES: $+12.3\pm6.5\%$, $p=0.010$, RES: $+34.3\pm7.3\%$, $p<0.001$).

CONCLUSION: The present study demonstrated that AES and RES significantly improved VO_{2peak} through the eight weeks intervention (11% and 10%, respectively), which is consistent with the previous study reported that a six-week ES with stair climbing improved CRF (12%) (Allison et al., 2017). Moreover, the present study revealed that RES was more efficiency to improve muscle strength than AES although AES and RES significantly improved muscle strength. The previous study suggested that high-intensity interval resistance training improved muscle strength (26%) (Moro et al., 2020), which is similar to the present results in RES. Therefore, RES in young adults may provide more health benefits than AES due to an increase in muscle strength. In conclusion, ES used in the present study, regardless of aerobic or resistance exercise, improved CRF and muscle strength in young adults. Additionally, RES improved muscle strength compared to AES.

PHYSICAL ACTIVITY AND SEDENTARY LIFESTYLE AMONG FEMALE UNIVERSITY STUDENTS STUDYING SPORT SCIENCE AND PHYSICAL ACTIVITY AT TAIBAH UNIVERSITY, SAUDI ARABIA

BUKHARI, R., ALAHMADI, M.

TAIBAH UNIVERSITY

INTRODUCTION: In 2018, Saudi Arabia introduced the Sport Science and Physical Activity (SSPA) major for female students at several universities, including Taibah University in Madinah, western Saudi Arabia. A recent self-report study indicated that 52% of Saudi female university students spend more than 7 hours per day sitting (Alahmadi et al., 2024). However, physical activity and sedentary behaviors have not been objectively assessed among the SSPA female students using device-based tools such as pedometers. Therefore, this study aimed to objectively assess physical activity levels and sedentary behavior using pedometers among female SSPA students at Taibah University.

METHODS: A sample of 40 female university students from the College of Education at Taibah University participated in the study. Body weight (kg) was measured using a digital scale (Seca 813), and height (cm) was measured using a portable stadiometer (Seca 213). Participants wore pedometers for seven consecutive days, with their daily step counts recorded. The average daily steps taken by each participant were calculated for weekdays and weekends. The daily step average was calculated as follows: [(steps on weekdays $\times$ 5) + (steps on weekends $\times$ 2)] $\div$ 7. A step count target of $<5,000$ steps/day indicated a sedentary lifestyle, 5,000–7,499 steps/day indicated less activity, and $\geq 7,500$ steps/day indicated an active lifestyle (Tudor-Locke et al., 2012). Statistical analyses were conducted using SPSS (Version 22). Data are presented as mean $\pm$ standard deviation or frequency (percentage), and a paired t-test was used to compare daily step counts between weekdays and weekends.

RESULTS: The mean age, height, weight, and BMI of participants were 21.35 ± 1.63 years, 159.0 ± 4.26 cm, 51.25 ± 8.14 kg, and 20.36 ± 3.07 kg/m², respectively. The average daily steps were $8,737 \pm 4,085$ on weekdays and $7,688 \pm 4,042$ on weekends. There was no significant difference in step counts between weekdays and weekends ($P = 0.16$). The overall average daily step count was $8,437 \pm 3,485$ steps. Among the participants, 7.5% were sedentary, 32.5% were less active, and 60.0% were physically active. Additionally, only 22.5% of participants achieved $\geq 10,000$ steps/day, meeting the physical activity guidelines.

CONCLUSION: The findings indicate that while a small proportion (7.5%) of SSPA female students exhibited a sedentary lifestyle, the majority (77.5%) did not meet the recommended physical activity guidelines of $\geq 10,000$ steps per day.

PRELIMINARY STUDY ON THE EFFECTS OF SHORT-TERM CARDIAC REHABILITATION AND PHYSICAL ACTIVITY ON POSTURE AND RISK OF FALLING IN ELDERLY PATIENTS AFTER AN ACUTE CARDIOVASCULAR EVENT.

CAMPOLI, F., VITARELLI, M., CAMINITI, G., GROSSI, A., FRANCHINI, A., VOLTERRANI, M., CAPRIOLI, L., EDRISS, S., BONAIUTO, V., ROMAGNOLI, C., ANNINO, G., PADUA, E., MESSINA, G.

SAN RAFFAELE ROME UNIVERSITY

INTRODUCTION: Cardiac rehabilitation is recommended for patients with chronic heart disease and those recovering from acute cardiovascular events to restore functional capacity or maintain autonomy in daily activities, especially in elderly and frail individuals. Prolonged immobility from hospitalization increases risks of hypokinetic syndrome, orthostatic hypotension, mood swings, and vascular complications [1, 2]. This study evaluates the impact of cardiac rehabilitation and adapted physical activity on fall risk, balance, cervical mobility, and sleep quality in elderly patients post-acute cardiovascular event.

METHODS: 20 participants over 65 (6 women, 14 men; 72.7 ± 5.4 years) were recruited from the cardiology department at IRCCS Pisana in Rome following a recent acute cardiac event. Initial assessments measured fall risk (Conley scale), the postural control (stabilometric test), cervical mobility (Moover® inertial sensor), and sleep quality (Pittsburgh Sleep Quality Index - PSQI) [3]. Participants underwent a 20-day intensive training protocol: day I: walking, days II-VII: calisthenics/balance exercises (30 min) and aerobics with pedals (30 min); day VIII-discharge: gym activity with aerobic exercise (50-60% maximum HR, 30 min) and group exercises. The final assessments were conducted before discharge.

RESULTS: Post-intervention, participants showed a low fall risk (0.5 ± 0.9 Conley Scale). the training protocol carried out in the gym allowed a maintenance of the stabilogram length with open eyes (pre 229 ± 63.1 mm, post 228.5 ± 72.2 mm) and a reduction with closed eyes, demonstrating an improvement in postural control. Cervical mobility improved by an average of 2 degrees in all directions, with statistically significant improvement ($p < 0.01$) in anterior flexion-extension. Sleep quality (PSQI) increased by 12% ($p = 0.3$).

CONCLUSION: Intensive cardiac rehabilitation improved postural control and cervical mobility within 20 days in elderly patients post-acute cardiovascular event. Although sleep quality showed a 12% increase, it was not statistically significant, possibly due to the short duration of the study. The protocol supported functional capacity and autonomy, highlighting the value of a structured, personalized approach in post-cardiac event rehabilitation. Future research should examine the benefits of continuing the training protocol at home to determine if regular physical activity can sustain or enhance observed improvements.

CP-MH20 Military Performance and Rehabilitation

AVAILABILITY OF WATER AD LIBITUM DURING A 1 HOUR SIMULATED MILITARY MARCH IN THE HEAT DOES NOT ALTER THERMOREGULATION OR POSTURAL SWAY

MARINO, F., COOKE, B., CHANG, M.

CHARLES STURT UNIVERSITY

INTRODUCTION: Adequate hydration and water availability are regarded as essential for maintaining both physical and cognitive performance, particularly in the heat. More recent studies suggest that ad libitum drinking is sufficient to maintain performance so that additional drinking may not be required to improve performance for a range of situations. Maintaining posture is a critical and complex ability with few studies showing that prolonged exercise without fluid ingestion negatively affects postural stability. However, it is not known whether fluid replacement overlaid by heat stress has a similar affect. This study investigated whether the availability of water ad libitum during exercise heat stress alters postural sway.

METHODS: Nine healthy volunteers (6 men, 3 women) completed a 60 min simulated military march in warm conditions (30°C , 50% rh) dressed in military fatigues, helmet and carrying a pack (10% body mass). Participants completed two trials in randomised reverse order with either ad libitum fluid availability (HYD) or fluid restricted (NHYP). The march consisted of 3 x 20 min stages escalating each 10 min in speed and gradient (range 4 – 7 km/h; 1% -5.5% gradient) with each stage separated by ~ 5 min when measures of postural sway, lactate, and other measures of fatigue were completed. During the march, heart rate (HR), core and skin temperatures (T_c , T_s , respectively) were recorded continuously with perceptual measures of rating of perceived exertion (RPE) and thermal sensation (ThS) recorded each 5 min. Nude body mass pre and post march were recorded adjusted for consumed water to calculate sweat rate.

RESULTS: During the march T_c increased ($P < 0.05$) from 15 min in both conditions and was similar by the end (38.3 ± 0.6 NHYP vs $38.5 \pm 0.5^\circ\text{C}$ HYD). T_s increased ($P < 0.05$) over time in both conditions and was $32.7 \pm 1.0^\circ\text{C}$ for NHYP and $32. \pm 1.1^\circ\text{C}$ for HYD ($P > 0.05$). HR increased during the march but was not different between conditions reaching 166 ± 9.9 bpm (HYD) and 156 ± 26.8 bpm (NHYP) by the end. The amount of water consumed during HYD was 495.1 ± 190.3 ml. The sweat rate was 1.65 ± 0.36 l/hr for HYD and higher than 1.23 ± 0.23 l/hr ($P < 0.05$) for NHYP. Postural sway measured as the centre of pressure (COP) path at pre, 20, 40 min and post-exercise was not different between conditions ranging from 0.21 – 0.22m (NHYP) and 0.21 – 0.24m (HYD).

CONCLUSION: Heat strain during the simulated march with the addition of water availability did not result in thermoregulatory or cardiovascular differences between conditions. These findings are not dissimilar to studies showing that drinking to dictates of thirst is enough to maintain performance. However, postural sway as measured by COP was not different with and without the availability of water which suggests that this critical human motor control ability remains intact following a long march. The reasons for this are not clear but might include a different exercise modality.

THE IMPACT OF PHYSICAL FITNESS AND READINESS ON ACUTE AND OVERUSE INJURIES IN SWISS CONSCRIPTS

OESCHGER, R., GILGEN-AMMANN, R.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM

INTRODUCTION: It is well known that basic military training (BMT) is physically and mentally demanding for the conscripts [1]. The current study aims to examine how conscripts in the Swiss Armed Forces physically prepare to BMT, what resources they utilize or what training methods are being used, if they feel "military ready" at the beginning of BMT and if a physical preparation for BMT results in less injuries during BMT.

METHODS: At the beginning of the BMT 532 male conscripts (20 ± 1 years, 178 ± 7 cm, 73.8 ± 11.1 kg) of communications intelligence, armored infantry, rescue technicians and fusilier infantry performed objective physical fitness tests (PFT) [1] and answered questionnaires to assess physical activity behavior and the use of supported training methods prior to the start of BMT. Additionally, musculoskeletal injuries suffered during the BMT was provided by medical records. Binomial logistic regressions were performed to predict the presence of an overuse or an acute injury based on points reached in the PFT, subjective readiness, MET-minutes of moderate physical activity before BMT ('MET moderate'), and MET-minutes of vigorous physical activity before BMT ('MET vigorous').

RESULTS: A 19% of the Swiss conscripts changed their physical activity training behavior due to the upcoming BMT and 10% of conscripts utilized a smartphone application as a training aid. A total of 194 (36.5%) conscripts were injured, 70 acute and 143 overuse injuries during BMT were reported. The Spearman's rank correlation between PFT and subjective readiness was $r = 0.37$, between subjective readiness and 'MET moderate' $r = 0.19$, and between subjective readiness and 'MET vigorous' $r = 0.41$. The binomial logistic model revealed the PFT as a significant predictor for overuse injury ($\beta = -0.023$, $SE = 0.011$, $z = -2.213$, $p = 0.027$, $OR = 0.977$). However, subjective readiness ($p = 0.89$), 'MET moderate' ($p = 0.37$), and 'MET vigorous' ($p = 0.91$) were not significant predictors. None of the investigated variables were significantly associated with acute injuries (all $p > 0.05$).

CONCLUSION: The PFT was found to be a significant predictor for overuse injuries in Swiss conscripts during BMT. This highlights the importance of adequate physical preparation in reducing the risk of overuse injury during BMT. The moderate correlation between the volume of vigorous physical activity and subjective readiness suggests that Swiss conscripts who engaged more in vigorous physical activity before BMT felt more ready for the military service. However, this feeling of readiness did not translate into a reduced injury risk. Only 10% of conscripts used a training application. This may indicate an unused potential of technology in supporting physical activity for BMT preparation. Military organizations could benefit from offering digital tools or training platforms to enhance conscripts' physical readiness even before the start of BMT.

TACTICAL ATHLETE – HOW UNIFORM INFLUENCE THERMOREGULATION

MELLO, D., GODLESKY, L.1, FARIAS, F.1, CASTRO, D.J.1, PEDRETTI, G.L.1, SENA, R.1, BALDUÍNO, A.L.1, ROSA, S.3, SILLERO, M.4

1 ESCOLA DE EDUCAÇÃO FÍSICA DO EXÉRCITO ; 2 UNIVERSITY OF THE AIR FORCE ; 3 CENTRO DE CAPACITAÇÃO FÍSICA DO EXÉRCITO ; UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Tactical athletes, including military personnel, firefighters, and police officers, face extreme conditions that impact their performance and thermoregulation. Uniform design and materials play a crucial role in heat management, influencing comfort, safety, and efficiency. Therefore, the aim of this study was to analyze the effect of uniform on skin temperature using infrared thermography.

METHODS: The research was conducted with a non-probabilistic sample of 10 male soldiers, age of 27.70 ± 2.71 yrs. in a controlled environment, with air temperature and relative humidity monitored using an Instrutherm® HT-270 thermohygrometer. Infrared thermography with a Flir® E76 thermal camera was used to compare skin temperatures in two conditions: with and without the Brazilian Army's new camouflage uniform. Soldiers underwent acclimatization and body temperature monitoring before measurements. Data were described using descriptive and inferential statistics. A significance level of $p \leq 0.05$ was considered.

RESULTS: Soldiers with Army's new camouflage uniform presented statistically significant increases in skin temperature in the right trapezius (0.87%, $p=0.028$) and left trapezius (1.27%, $p=0.007$), right chest (2.16%, $p<0.001$) and left chest (2.83%, $p<0.001$), right biceps (2.35%, $p=0.002$) and left biceps (3.21%, $p<0.001$), right costal region (2.00%, $p<0.001$) and left costal region (1.51%, $p<0.001$), as well as the left knee (6.58%, $p<0.001$). On the other hand, regions such as the right neck (0.03%, $p=0.906$) and left neck (0.24%, $p=0.466$) showed no significant differences.

CONCLUSION: This study highlights the impact of military uniforms on skin temperature, particularly in high-metabolic muscle and joint regions. Increased heat retention was observed, emphasizing the need for uniform designs that enhance ventilation and thermal regulation. Optimizing these factors can improve comfort, performance, and operational efficiency for tactical athletes.

Keywords: thermoregulation, tactical athletes, uniform.

PREDICTING ENERGY REQUIREMENTS FOR SOLDIERS IN EXTREME COLD: A SIMPLE AND PRACTICAL APPROACH TO PREVENT BODY MASS LOSS

COCA, M., CHARLOT, K., BOURRILHON, C., HEDOUIN, L., SANLIAS, C.

LBEPS

INTRODUCTION: Soldiers during military expeditions and athletes during competitions usually fail to compensate for the increase in energy expenditure, with potential deleterious consequences (body mass loss (BML), decrease in cognitive and physical performance...). Moreover, environmental constraints, particularly extreme cold, exacerbate this phenomenon. To better understand mechanisms involved, various studies were carried out during military expeditions in the extreme cold of Greenland between 2019 and 2024 on French soldiers (n = 46). The aim of these studies was to understand the effects of this environment on the components of energy intake (EI) and to identify an effective strategy for combating the effects of a negative energy balance.

Using the data gathered during these previous studies (Resting metabolic rate (RMR), EI, BML), the objective was to develop and verify the accuracy of an equation predicting individual energy requirement during this kind of expedition in order to conceive customized rations for each participant and theoretically avoid major BML.

METHODS: Total EE is dependent on two factors which are the RMR and the physical activity related EE (PAEE). The RMR was calculated using the FAO/WHO/UNU equation. The overall EE was determined observing the BML (of previous studies) in regards on EI during the expeditions, using the equation: $EE = EI + (BML \times 6,18)$. To convert BML (g) into Kcal we used the coefficient 6,18 (Charlot, 2021) where the BML is explain by 40% of lean body mass (LBM) (1g represent 1,19Kcal) and 60% fat mass (1g represent 9,5 Kcal). Therefore, in mean, 1g of BML represent 6,18 Kcal.

RESULTS: In the previous studies and this one, the EI was meticulously measured, energy density and weight of each meal were assumed. To individualize the amount of EE of each participants we use an equation linking the RMR with the EE : $Coef = EE / RMR$. Using the previous study, the coefficient mean was $2,36 (\pm 14\%)$. With this coefficient, we would anticipate the EI required to keep a neutral energy balance during an extreme cold expedition using the following equation $EI = RMR \times Coef$. Following this method, the only measurement needed to anticipate the EI is the RMR.

CONCLUSION: In the context of an extreme cold expedition, this realistic and simple method would help nutritionists to quantify the energy requirements needed to avoid BML. Future expedition will serve to test and confirm the accuracy of this approach.

PRE-COMPETITION RMSSD PREDICTS ARCHERY SHOOTING PERFORMANCE

CHEN, Y., KING, J., CHEN, S., KUO, W.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Research demonstrates that heart rate (HR) and heart rate variability (HRV) can reflect an athlete's adaptation to competitive stress (1,2). Archery is a unique sport that requires fine perceptual and motor control, which can be impaired by excessive sympathetic activation. While most studies analyzed single-session electrocardiography (ECG) data in resting states before competition, little is known about the relationship between performance and HR as well as HRV during competition. Therefore, this study aimed to examine these relationships.

METHODS: We recruited 8 skilled collegiate recurve archers (4 females; 18.6-21.2 years; 5.5-11.2 years of experience; weekly training 15-25 hours; personal best: 625-662) to participate in a simulated competition consisting of 10 sessions in 10 separate days. Each session included 2 runs, with each run involving the shooting of 6 ends of 6 arrows at a 122-cm target face from 70m, resulting in 720 arrows per archer. ECG recordings were obtained in a sitting posture with eyes open for 3 min before each session as resting-state data, as well as during each run (13-15 min) to capture in-competition physiological responses. This resulted in 10 resting-state and 20 in-competition ECG datasets per archer. The ECG signals were converted into R-R intervals time series to calculate heart rate (HR) and different HRV measures reflecting cardio vagal activity. The analyzed HRV indices included root mean square roots of successive differences (RMSSD), absolute power of high frequency (HF, 0.15-0.4 Hz) components, and standard-deviation of the Poincare plot Crosswise (SD1) as time-, frequency-, and non-linear measures, respectively. To examine which index at which measurement condition could best predict the shooting scores, we employed 8 (2 measurement conditions x 4 indices) separate generalized estimation equation (GEE) models to analyze the data. Alpha was set at .0125 for multiple-comparison correction.

RESULTS: All GEE models had good model fit, with QIC values ranging from 27.644 to 57.934. Among all models, only RMSSD at the resting state could significantly negatively predict the score ($\beta = -.002$, $p < .001$). In contrast, none of the other indices, whether measured at resting state or during competition, show a significant relationship with performance.

CONCLUSION: These findings demonstrated that even a single 3-min pre-competition ECG recording could effectively predict performance outcomes, while in-competition recording may be less reliable, possibly due to movement artifacts. Interestingly, lower HRV, linked to lower vagal regulation due to higher stress, appeared to enhance shooting performance, highlighting a potential adaptive role of stress in precision sports such as archery.

INDIVIDUALISED AND MOTIVATIONAL PRESCRIPTION OF VIRTUAL EXERCISE (IMPROVE) FOR PATIENTS AWAITING JOINT ARTHROPLASTY: AN EVIDENCE-BASED PREHABILITATION SERVICE

KALIARNTAS, K.1,2, HAMILTON, D.3, CAMPBELL, A.2, PITKETHLY, A.2, BRUN LACEY, E.4, CLEMENT, N.5,6

1. UNIVERSITY OF PATRAS, 2. EDINBURGH NAPIER UNIVERSITY, 3. GLASGOW CALEDONIAN UNIVERSITY, 4. EDINBURGH WESTERN GENERAL HOSPITAL, 5. UNIVERSITY OF EDINBURGH, 6. EDINBURGH ROYAL INFIRMARY HOSPITAL

INTRODUCTION: The annual cost for surgical procedures in the UK is approximately £10.9 billion and a significant amount concerns orthopaedic procedures such as hip and knee arthroplasties [1]. Prehabilitation is the systematic process of improving patients physical, emotional, and nutritional status between diagnosis and surgery [2]. Home based prehabilitation seem to improve pain symptoms and function before hip and knee arthroplasty [3]. The aim of this project was to develop and remotely deliver a multimodal intervention to patients waiting for a hip or knee arthroplasty and assess key outcomes such as functional, health status, sedentary behaviour as well as safety and feasibility.

METHODS: In this opt-in service, eligible patients were identified through hospital waiting lists and were sent a leaflet. The intervention was delivered online by two Clinical Exercise Physiologists (CEPs) through MS Teams. The intervention consisted of one-to-one instructed exercise sessions, physical activity prescription, dietary advice, behavioral and emotional support for a period of 24 weeks. Each patient could receive up to 20 sessions. Outcome measures included: Western Ontario and McMaster Universities (WOMAC) index, 30 seconds sit-to-stand (StS) repetitions, time during a single leg stance, International Physical activity Questionnaire (IPAQ), Self-Efficacy for managing chronic disease scale (SEMCD), Self-Reported health status and Quality of Life (EQ5D5L). In addition, patient satisfaction was measured through a customized survey. Paired samples t-tests were used with significance level $p < 0.05$ on SPSSv26 for the analysis.

RESULTS: In total, 750 leaflets were posted and there were 154 responses which results to a 20% response rate. Due to exclusions and drop-outs, 96 patients were finally recruited. The overall WOMAC score reduced significantly after the intervention (-8%, $p < 0.05$). The StS performance improved by 43% ($p < 0.05$), time on single leg stance improved by 70% ($p < 0.05$), and the overall sedentary time decreased significantly (-21%, $p < 0.05$). Similarly, there was a statistically significant improvement in the patients' self-efficacy (+9%, $p < 0.05$) and a significant improvement of the self-reported health status (EQ5D5L, +7.5%, $p < 0.05$). The overall patient satisfaction and feedback was overwhelmingly positive and no accidents or adverse events were recorded.

CONCLUSION: The results show that it is safe and feasible to remotely deliver individualized exercise interventions to orthopaedic patients. The intervention was delivered as intended according to current evidence and international guidelines. Functional outcomes, self-reported health status as well as self-efficacy were significantly improved, and sedentary behavior significantly reduced after the intervention. These results can inform the design and implementation of future services and implementation research.

EFFECTS OF BREAKING UP SITTING TIME WITH ISOMETRIC WALL SQUAT EXERCISE ON VASCULAR FUNCTION, BLOOD PRESSURE, AND CARDIAC AUTONOMIC MODULATION IN SEDENTARY ADULTS: A RANDOMIZED CONTROLLED TRIAL

FARAH, B., CAVALCANTE, A., REGO, T., SILVA, J., BARRETO, D., SANTOS, J., SILVA, G., CORREIA, M., RITTI-DIAS, R.
UNIVERSIDADE FEDERAL RURAL DE PERNAMBUCO

INTRODUCTION: Prolonged uninterrupted sitting has been associated with impaired vascular function, increased blood pressure, and cardiac autonomic dysfunction, highlighting the need to break up sitting time throughout the day, especially during work. Isometric wall squat exercise (IWSE) has proven effective in improving cardiovascular parameters in both normotensive and hypertensive individuals. However, whether this exercise is effective as a strategy to break up sitting time remains unknown. Thus, the aim of this study was to analyze the effects of breaking up sitting time with IWSE on vascular function, blood pressure, and cardiac autonomic modulation in sedentary adults.

METHODS: This randomized controlled trial (#RBR-10k2wxrg) included 40 participants without known cardiovascular diseases (35 ± 11 y.o. and 61% women) with high sedentary behavior (≥ 6 hours/day). Participants were randomly assigned to the IWSE group (2-minute breaks during occupational activities, incorporating IWSE while maintaining their knees at the angle determined by the incremental test every 60 minutes of sitting) or to the SHAM group (standing for 2 minutes every

60 minutes of sitting during occupational activities). Popliteal artery vascular function, ambulatory and clinic blood pressure, and cardiac autonomic modulation (assessed by heart rate variability) were evaluated at baseline and after 12 weeks. To compare the effects of the interventions (IWSE or SHAM) on cardiovascular parameters, Generalized Estimating Equations were used, followed by a post hoc pairwise comparison. An intention-to-treat analysis was conducted to estimate overall effects, including all randomized patients regardless of dropouts. The predicted mean matching method was used for this purpose. The significance level was set at $P < 0.05$ for all analysis.

RESULTS: Per-protocol analysis showed that breaking up sitting time with IWSE increased the maximum diameter of the popliteal artery (IWSE: 5.2 ± 0.2 vs. 5.7 ± 0.3 mm; SHAM: 5.6 ± 0.2 vs. 5.3 ± 0.2 mm, $P=0.011$), while the intention-to-treat analysis indicated that the SHAM group reduced the baseline diameter of the popliteal artery (IWSE: 4.9 ± 0.2 vs. 5.3 ± 0.23 mm; SHAM: 5.3 ± 0.2 vs. 5.1 ± 0.2 , $P=0.008$). No effects of the interventions were observed on other vascular indicators, ambulatory and clinical blood pressure, or cardiac autonomic modulation ($P>0.05$ for all).

CONCLUSION: Breaking up sitting time with IWSE during occupational activities did not improve blood pressure, cardiac autonomic modulation, or vascular function but altered vascular structure by increasing the arterial diameter of the popliteal artery in sedentary adults.

DOES PROSTHETIC WALKING PRACTICE COMBINED WITH VIRTUAL REALITY ACUTELY IMPROVE BALANCE ABILITY? A PRELIMINARY STUDY USING A SIMULATED PROSTHESIS

NAGAO, T., ARIMA, S., TASHIRO, T., TAMURA, Y., TAKAUE, R., HARA, T., MAEDA, N.

HIROSHIMA UNIVERSITY

INTRODUCTION: Lower-limb amputees need prosthesis walking to maintain their physical activity level and improve quality of life [1]. However, acquiring a prosthetic walking is difficult, potentially leading to reduced physical activity. Recently, the combination of virtual reality (VR) with prosthetic walking practice has been attracting attention as a tool to enhance its efficiency [2]. Despite this interest, few studies have investigated the effects of VR on static and dynamic balance abilities, which are important for prosthetic walking. This study aimed to confirm the acute effects of prosthetic walking practice combined with VR on balance ability in healthy adults wearing a simulated prosthesis as a preliminary study.

METHODS: The participants were 14 healthy adults with no experience wearing a simulated prosthesis. The simulated prosthesis was a trans-femoral prosthesis with a 3R60 knee joint (OttoBock, Ltd, Japan). Participants were randomly divided into two groups: VR group, which practiced prosthetic walking with VR video showed a first-person perspective walking motion, and control group, which practiced without VR video. The prosthetic walking practice consisted of a 5-minute in-situ foot stamping in the parallel bars [3]. Dynamic balance ability was assessed using the Timed up and Go test (TUG test). Static standing balance was measured using the Zebris PDM-S system (Zebris Medical GmbH, Germany) for 30 seconds in the closed-eye, closed-leg standing posture. The measured parameters were center of pressure (COP) sway area, COP path length, and average COP sway speed. The improvement rate in balance ability before and after practice was calculated. Statistical analysis was performed using a t-test between groups for each improvement rate. The significance level was set at 5%.

RESULTS: The improvement rates of the VR group (TUG test: $17.8 \pm 4.8\%$, COP sway area: $32.2 \pm 15.9\%$, COP path length: $23.8 \pm 8.8\%$, COP sway speed: $23.6 \pm 9.0\%$) were significantly higher than those in the control group ($12.1 \pm 2.6\%$, $1.9 \pm 27.4\%$, $6.2 \pm 15.4\%$, $6.2 \pm 15.3\%$) ($p<0.05$, respectively).

CONCLUSION: Performing in-situ foot stamping movements with VR video of walking motion gives the sensation as if the person is walking forward. This characteristic of VR effectively increased the load on the prosthetic side, and balance ability was significantly improved compared to the control group. The results of this study suggest that VR can be used in the rehabilitation of lower limb amputees, with the advantage of being safer and more flexible in terms of location. Further studies with lower-limb amputees and biomechanical studies focusing on walking should be conducted in the future to clarify the effects of VR in combination with prosthetic walking practice.

THE EFFECTS OF EXERCISE AT DIFFERENT TIMES OF DAY ON PHYSICAL ACTIVITY BEHAVIOUR IN INACTIVE ADULTS

CHENG, C., LIU, C.Y., CHEN, Y.C.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Prescribed moderate-intensity aerobic exercise on health issues has been extensively investigated but additional exercise interventions may lead to behavioural compensation (e.g., reducing physical activity at other times). However, it is still unclear whether the timing of exercise can affect physical activity behaviours. This study was to examine the effect of exercise at different times of day on physical activity behaviours over a 72-hour period across exercise and non-exercise days.

METHODS: 22 (20 females) young healthy physically inactive adults (age: 24 ± 5 yr; BMI: 21.8 ± 2.2 kg/m²) were recruited in a randomized crossover study with either 45-min brisk walking in the morning (8:00 ~ 11:00, Mwalk) or in the evening

(18:00 ~ 21:00, Ewalk). Heart rate (HR) and rating of perceived exertion (RPE) were measured during exercise. Physical activity levels (i.e., step counts), physical activity intensity, and sedentary behaviours were recorded via a pedometer and an accelerometer over a 72 hours period (the exercise day for 24 hours, EX day; non-exercise day, 24 hours before and after EX day). The habitual physical activity levels were recorded over a period of 7 consecutive days.

RESULTS: There were no differences in HR (120 ± 25 vs. 119 ± 23 bpm, $p = 0.603$) and RPE (11 ± 2 vs. 11 ± 2 , $p = 0.538$) during exercise between Mwalk and Ewalk. Compared to habitual physical activity (5406 ± 1306 steps), both Mwalk (12797 ± 3226 steps) and Ewalk (13580 ± 3903 steps) increased physical activity levels on the EX day ($p < 0.0001$) and there was no difference between 2 trials ($p = 0.437$). Nonetheless, we did not observe any of behavioural compensation in physical activity levels, physical activity intensity, and sedentary behaviours, as no significant differences were found between Mwalk and Ewalk, regardless of whether it was an exercise day or a non-exercise day (all, $p > 0.05$).

CONCLUSION: A 45-min of brisk walk prescribed either in the morning or evening can enhance physical activity levels in physically inactive adults. The timing of brisk walking does not appear to induce behavioural compensation (i.e., reduction of physical activity and/or changes in the pattern of physical activity intensity) across exercise and non-exercise days.

ASSOCIATION BETWEEN PARENTS AND PRESCHOOLERS ACCELEROMETER-MEASURED PHYSICAL ACTIVITY

TOTTORI, N., SHIMIZU, M., MIZUOCHI, H., SUWA, T., MORITA, H.

HYOGO UNIVERSITY OF TEACHER EDUCATION

INTRODUCTION: The World Health Organization guidelines on physical activity for children under five recommend at least 180 minutes of daily total physical activity for children aged 3-4 years. Parents play a crucial role in promoting children's physical activity. Higher levels of parental moderate-to-vigorous physical activity (MVPA) are associated with greater child MVPA. However, few studies have directly measured physical activity, and even fewer have focused on preschoolers. The aim of this study is to investigate the association between parents' and preschoolers' accelerometer-measured physical activity in Japan.

METHODS: The sample comprised data from 32 preschoolers and their parents (28 mothers and 27 fathers) from Japan. Preschoolers wore the thigh-worn activPAL accelerometer and parents wore the waist-worn ActiGraph GT3X accelerometer for 6 consecutive days including two-day weekend. They must meet a minimum wear time criterion of at least 480 minutes per day for a minimum of three days ensuring that at least one of these days on a weekend. In preschoolers, the mean daily step count was calculated and categorized as meeting the total physical activity guideline according to achievement of $\geq 11,500$ steps per day. In parents, the MVPA was estimated by acceleration counts $\geq 2,020$ counts/min and categorized as meeting the physical activity guideline of 150 min of MVPA per week.

RESULTS: The mean daily step counts for preschoolers was $11,909 \pm 2,183$ steps. Approximately half of the sample met the TPA guideline (48.5%, 95%CI, 30.3-66.7). The weekly spent time in MVPA for mothers was 110.4 ± 54.4 min and for fathers was 228.1 ± 175.8 min. The daily step counts for preschoolers was significantly correlated with the weekly spent time in MVPA for fathers ($r = 0.414$, $p = 0.032$), but not with that of mothers ($r = 0.318$, $p = 0.099$). Paternal adherence of physical activity guideline was positively associated with children meeting the total physical activity recommendation (OR = 7.222, 95%CI, 1.440-36.224).

CONCLUSION: The higher level of paternal MVPA was correlated with greater total PA in children. In addition, meeting the physical activity guidelines in fathers was associated with meeting the total physical activity guideline in preschoolers. The findings suggest that paternal physical activity plays an important role in supporting preschoolers in meeting the total physical activity guideline.

THE NEW WAY TO TRAIN: SOCIAL ANXIETY RELATED TO EXERCISE, ONLINE FITNESS PROGRAMS, AND THE MOTIVATORS AND BARRIERS TO EXERCISE IN COLLEGE STUDENTS

BOGART, S., MILLER, A., KOTERBA, E., ELLIOT, A.

UNIVERSITY OF TAMPA

INTRODUCTION: Exercise's positive impacts on anxiety are well established (e.g., DeWolfe et al., 2023). However, in an interesting contrast, those with higher anxiety exercise less than the general population (Lantz et al., 1997), suggesting that anxiety may act as a barrier to exercising. This barrier might be particularly relevant in the context of gym-based exercise, where social and environmental factors could exacerbate anxiety. The purpose of this study was, therefore to evaluate whether college students who do not exercise at a gym have higher anxiety and exercise-specific anxiety than those who do.

METHODS: The present study included 333 students from a private liberal arts institution (263 females; 66 males; 1 nonbinary/third gender). On average, participants were 19.5 years old (SD=1.55; Range=18-34). Participants completed a survey that measured their exercise habits and exercise-based and general anxiety. Exercise anxiety was measured using the Social Exercise and Anxiety Measure (SEAM; Barbara, 2006), which yields three subscales: Self-Efficacy (SES), one's belief in their ability to complete exercises, Gym Avoidance (GA), hesitancy to attend a gym, and Exercise Importance (EI), personal significance of physical activity. They also completed the Generalized Anxiety Disorder 7 (GAD; Spitzer et al., 2006) to measure overall anxiety.

RESULTS: Participants were categorized into two groups: "exercisers" consisted of those who reported exercising at the gym within the past week ($n=212$) and "non-exercisers" those who had not exercised at the gym in the past week ($n=121$).

Non-exercisers exhibited less confidence in their ability to perform exercise-related tasks ($M=64.15$, $SD=19.20$) than exercisers ($M=78.92$, $SD=19.76$; $t(325)=4.78$, $p<.001$). In addition, non-exercisers considered exercise less important to their day-to-day lives ($M=4.64$, $SD=1.98$) compared to exercisers ($M=5.84$, $SD=1.84$; $t(330)=3.37$, $p<.001$). Finally, non-exercisers were more likely to avoid attending the gym ($M=4.01$, $SD=1.06$) relative to exercisers ($M=2.55$, $SD=1.07$; $t(329)=8.64$, $p<.001$). Further, those with higher rates of general anxiety were more likely to report reduced confidence in exercising and a reluctance to attend a gym ($ps<.001$). Interestingly, anxiety did not predict exercise importance.

CONCLUSION: Overall, the results indicate an underlying difference between those who exercise at a gym and those who do not. Namely, individuals who were reluctant to attend a gym had higher rates of anxiety overall. Furthermore, lower social efficacy scores of the non-exercisers may reflect a reluctance to go to the gym. Additionally, the lower exercise importance scores of non-exercisers may suggest a lack of perceived value in exercise. Not surprisingly, non-exercisers were more likely to express gym avoidance, which would be expected in individuals who do not see the value in going to the gym and lack confidence in their ability to exercise in a public venue. Overall, the role of anxiety in exercise is nuanced.

ACCELEROMETER-DETERMINED ADHERENCE TO THE 2020 WHO GUIDELINES ON PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOUR BY FIRST-YEAR STUDENTS AT A SMALL RESIDENTIAL COLLEGE.

BULL, A., TANEL, M., SALHUS, E., THURSTON, M., GISLER, P.
COLORADO COLLEGE

INTRODUCTION: Studies examining physical activity (PA) in college and university students often report mixed results when compared to various national and international guidelines. In some cases, less than half of the participants meet recommendations for PA (1-3), while others have found that nearly all students meet PA guidelines (4,5). Some of these mixed results may be due to studies utilizing self-report instruments when examining PA (1) or comparing results to guidelines requiring PA to be completed in at least 10-min bouts (2,3). The 2020 WHO Guidelines On Physical Activity And Sedentary Behaviour (6) suggest that adults accumulate at least 150 min/week of moderate-intensity PA (MPA) or 75 min/week of vigorous-intensity PA (VPA), or an equivalent combination of moderate and vigorous-intensity PA (MVPA), with no requirement that PA be in at least 10-min bouts. Our aims were to use hip-worn accelerometers to assess min/week of MVPA of first-year students at a small residential college, determine the percentage of students meeting the WHO recommendation for MVPA, and to determine differences, if any, in PA between female and male students.

METHODS: A total of 2,477 first-year college students were invited to participate in the study in 2018, 2019, 2021, 2023, and 2024. Nearly 400 students were excluded due to participation on a National Collegiate Athletic Association (NCAA) sponsored team. PA was assessed in 131 student volunteers by waist-worn accelerometry for all waking hours over seven consecutive days. Validated wear time of at least 600 min/day for four weekdays and one weekend day of the 7-day wear period was required for inclusion in data analysis. Intensity and duration of PA was determined, and minutes of MVPA calculated for those who met the wear time criteria.

RESULTS: Data for 109 students (71 females, 38 males) who met the wear time criteria resulted in a mean + standard deviation of 522 ± 181 min of MVPA over the 7-days. All participants accumulated at least 150 min of MVPA for the week, with a range of 179 to 1,135 min/week. Independent t-tests showed no significant difference between females and males for minutes/week of MVPA ($p = 0.112$; 502 ± 163 and 560 ± 205 min/week, respectively) or MPA ($p = 0.292$; 465 ± 138 and 497 ± 173 min/week, respectively). However, there was a significant difference in min/week of VPA between females and males ($p = 0.009$; 37 ± 40 and 63 ± 59 min/week, respectively).

CONCLUSION: The first-year college students examined here demonstrated 100% compliance with the 2020 WHO Guidelines On Physical Activity And Sedentary Behaviour. There was no significant difference in MVPA or MPA between females and males, however, males participated in significantly more min/week of VPA than females.

CLINICAL EXERCISE PHYSIOLOGISTS: AN UPDATE ON THE CURRENT SITUATION IN AUSTRIA

BIRKLBAUER, A., HOFMANN, P.2, BIRKLBAUER, J.
UNIVERSITY OF SALZBURG, 2 UNIVERSITY OF GRAZ

INTRODUCTION: It is becoming increasingly aware that regular exercise is vital for preventing and managing long-term health conditions (1). For this reason, exercise therapy—recognized as a highly cost-efficient intervention—has been progressively implemented in guidelines (e.g. 2) and may be as effective as established pharmacological therapies for a wide range of non-communicable diseases (3, 4).

A growing body of research calls for a personalized approach (5) and the necessity of individualized exercise prescriptions, while also highlighting the inadequacy of a one-size-fits-all approach (6). Therefore, an increasing number of countries have been incorporating clinical exercise physiologists (CEPs), who are university graduates specialized in sports and exercise science as well as health and therapy issues, into their healthcare systems (7).

METHODS: CEPs are experts in the tailored exercise prescriptions for both healthy and diseased individuals. They work with individuals experiencing chronic and complex medical conditions, injuries, and disabilities, assisting in restoring optimal physical function or health. CEPs work across a range of health settings including health and rehabilitation centres or public and private hospitals.

Recently, Carrard et al. (8) and Zhou et al. (7) compared the Australian with Swiss and Chinese healthcare systems, which has shed light on the varying international roles of CEPs. However, more countries (e.g. the UK, New Zealand, Canada, and Hong Kong) are integrating CEPs into their healthcare systems.

RESULTS: In Austria, exercise scientists were legalized as CEPs by the Austrian government in 2012, when they were formally accredited as health professionals under the designation of Training Therapists (TTs), which is recognized as an allied healthcare profession. However, TTs were initially only allowed to work as salaried employees. By January 1st, 2025, the restriction to work only in a salaried but not in a self-employed position has now been amended by legislation. Currently, TTs may offer Training Therapy in an outpatient setting; only medical referral from a qualified physician is mandatory. They must comply with the same requirements as other healthcare professions (e.g., mandatory documentation, first aid measures).

CONCLUSION: Although self-employed work is now permitted, health insurance companies have yet to introduce—unlike other healthcare professions—reimbursement for these services. Consequently, this means that this necessary type of therapy remains inaccessible to some segments of the Austrian population who cannot afford it.

CHANGES IN CARDIOMETABOLIC RISK FACTORS IN MIDDLE AGED ADULTS FOLLOWING A 12-WEEK COMMUNITY-BASED LIFESTYLE INTERVENTION.

BONE, B., BRACKEN, R., CHURM, R.

SWANSEA UNIVERSITY

INTRODUCTION: Increased prevalence of obesity and physical inactivity within individuals has been linked to increased risk of developing cardiometabolic diseases (CMD), such as cardiovascular disease (CVD) and type 2 diabetes (T2DM) [1]. Alternative modified sports, such as walking rugby, have been suggested to engage at risk individuals in regular physical activity [2]. Community-based lifestyle programmes have been successfully used to reduce CMD through education and behaviour change [3]. Therefore, the aim of this study was to determine whether a 12-week community-based programme, using walking rugby, could impact CMD risk in middle-aged adults

METHODS: N=16 individuals (14M, 2F) (age = 54.1±9.0yrs, BMI = 31.5 (5.8) kg/m²) were recruited to one walking rugby club in South Wales and completed a 12-week community-based lifestyle intervention. The intervention comprised weekly sessions (attendance = 60.4%) which included 45-minute health education and 45-minute walking rugby training, and a pedometer-based programme (increasing average daily step count by 10%). Anthropometry, blood pressure, bioelectrical impedance analysis, fasted lipid and glucose profiles, incremental shuttle walk test (ISWT) and International Physical Activity Questionnaire (IPAQ) were assessed at baseline and 12-week follow-up. 10-year CVD and T2DM risk was assessed using QRISK3 and QDiabetes algorithms. Data was analysed using repeated measures MANOVA for metabolic syndrome variables (glucose, waist circumference, blood pressure, triglycerides, HDL cholesterol) with post-hoc pairwise comparison. Paired t-tests (parametric) and Wilcoxon signed rank tests (non-parametric) with Bonferroni-Holm correction were performed for other variables.

RESULTS: At baseline, 69% participants presented with elevated BMI (>30kg/m²), 75% elevated waist circumference (WC) and 43% elevated QRISK3 score (>10%). At 12 weeks, significant improvements were seen in HDL cholesterol (21.1%, p=0.01) and, WC (-2.43%, p=0.007). However, HbA1c also increased (6.67%, p=0.004). ISWT walk distance and time to completion improved by 8.1% (p=0.035) and 9.8% (p=0.04) respectively. Weekly step count and IPAQ score improved from baseline; however, these changes were not significant (p>0.05).

CONCLUSION: Walking rugby-based lifestyle programme has potential to improve CMD risk factors and cardiorespiratory fitness in at risk adults. Future research with a larger population sample would benefit the efficacy of similar programmes to impact CMD risk.

PELVIC FLOOR MUSCULATURE VS UPPER AND LOWER LIMBS STRENGTH: PRELIMINARY RESULTS OF CHANGES AND ASSOCIATIONS FOLLOWING A MULTIDISCIPLINARY APPROACH TO FEMALE URINARY INCONTINENCE

CORDELLAT-MARZAL, A., VELASCO, M.C., ROLDÁN, A., MONFERRER-MARÍN, J., SALES, A., PINAZO-CLAPÉS, C., PINAZO-HERNANDIS, S., BLASCO-LAFARGA, C.

UNIVERSITY OF VALENCIA, SPAIN

INTRODUCTION: Urinary incontinence (UI) is a common condition in women that worsens with age. Although its pathogenesis is multifactorial, reduced pelvic floor muscle (PFM) strength is a primary contributing factor [2]. The 5-sit-to-stand (5STS) test has emerged as a key indicator of health in older adults. Given the biomechanical connection between 5STS performance and PFM activation, the present study analyses the neuromuscular impact of a PFM short multidisciplinary intervention (MI; 8 weeks of specific physical exercise & 6 educational sessions) in a group of healthy older women.

METHODS: 12 healthy elderly women [65,83 (5,64) years; 67,17 (8,94) Kg] were assessed of their PFM according to the PERFECT's guidelines (Power, Endurance, Repetitions and Fast) before and after MI. Upper (handgrip) [3] and lower limb strength [5-sit-to-stand -time & relative power, RP- [4] were also assessed. After normality test, Wilcoxon and Spearman was applied to elucidate improvements and associations.

RESULTS: Only the four types of strength from PFM improved ($p < 0.05$). At baseline, PowerPFM showed a moderate negative association with Time5STS ($r = -0.639$; $p = 0.025$) which increased after specific training ($r = -0.889$; $p = 0.001$). Additionally, new associations emerged between PowerPFM and RP5STS ($r = 0.645$; $p = 0.024$) and RepetitionsPFM and RP5STS (PRE: $r = -0.615$; $p = 0.033$; POST: $r = 0.628$; $p = 0.029$). Moreover, after MI, RepetitionsPFM also became associated with Time5STS ($r = -0.831$; $p = 0.001$). FastPFM showed a moderate positive association with RP after MI ($r = 0.670$; $p = 0.01$).

CONCLUSION: Eight weeks of MI were enough to improve PFM [5], but the specificity of training did not ensure improvements on upper and lower limbs strength. The few associations prior to the study suggest that each neuromuscular system follows a different aging process and should be specifically trained [6], though associations post changes point to some synergic improvements in lower limb strength. Noteworthy, new studies should thus confirm that introducing the 5STS may be valuable to avoid the use of a perineometer or facilitate the inclusion criteria in multidisciplinary pelvic floor programs, as suggested by our post-training associations.

BREAKING BARRIERS: THE ROLE OF SPORTS IN ENHANCING HEALTH AND INCLUSION FOR CHILDREN WITH CHRONIC DISEASES

SANCHEZ-OLIVER, A., FERNÁNDEZ-GAVIRA, J., SAÑUDO, B., GASER, D., STÖCKER, N., PERALTA, M., MARQUES, A., PAPA-KONSTANTINO, S., NICOLINI, C., SITZBERGER, C.

UNIVERSIDAD DE SEVILLA

INTRODUCTION: Children and adolescents (CaA) with chronic diseases face significant barriers to physical activity, limiting their physical, psychological, and social well-being. Despite the well-documented benefits of sports participation, accessibility, adherence, and inclusion remain major challenges. This systematic review evaluates the impact of sports-based interventions on CaA with chronic conditions, identifying key outcomes and intervention characteristics that promote holistic health improvements.

METHODS: A systematic review of sport-based interventions for CaA with chronic diseases was conducted following PRISMA guidelines. Eight databases were searched, including randomized controlled trials and observational studies assessing physical and psychosocial outcomes. The review included interventions targeting conditions such as autism spectrum disorders (ASD), cerebral palsy, obesity, ADHD, and cancer, among others.

RESULTS: From an initial pool of 10,123 records, 52 studies were included, involving 2,352 participants aged 3-18 years. Findings revealed that sport-based interventions significantly improved motor performance, physical fitness, and social competencies. Notably, children with ASD showed enhanced social interactions through structured team sports, while those with obesity benefited from increased physical activity levels and improved self-perception. Additionally, ADHD participants exhibited better attention control and emotional regulation. Importantly, adherence rates were high, demonstrating the feasibility of such interventions.

CONCLUSION: This review highlights the transformative potential of sports participation for CaA with chronic diseases. Beyond physical benefits, engagement in structured sports fosters social integration, psychological resilience, and im-

proved quality of life. The findings advocate for the inclusion of tailored, accessible sports programs within healthcare and educational settings to optimize well-being in this vulnerable population. Future research should focus on long-term adherence strategies and policy-level implementation to maximize impact.

THE ACUTE EFFECT OF AEROBIC, RESISTANCE, AND CONCURRENT EXERCISE ON DYNAMIC CEREBRAL AUTOREGULATION IN HEALTHY YOUNG ADULTS

CURTIN, E., BUYS, P., WESTON, M., EGAÑA, M., GILDEA, N.

TRINITY COLLEGE DUBLIN

INTRODUCTION: The acute effects of resistance (RES), moderate-intensity continuous (MICE), and concurrent (CONE) exercise on dynamic cerebral autoregulation (dCA), as well as potential sex differences in dCA post exercise remains unexplored. This forms an important area of investigation given exercise poses a challenge to dCA and evidence suggests that females have impaired resting dCA compared to males (Labrecque et al., 2019). However, whether this impairment extends post exercise remains unknown. This study aimed to investigate the acute effects of these exercise modalities on dCA in healthy young adults, and to explore potential sex differences therein.

METHODS: 12 males (mean $\pm$ SD, 24 $\pm$ 3.6 years) and 14 females (23 $\pm$ 2.1 years) volunteered to take part in this study. Participants completed two preliminary and four experimental visits. On visits one and two, participants completed a ramp incremental cycling test to exhaustion and 1 repetition maximum (1RM) test, respectively. Participants then completed four separate experimental trials that were matched for time (30 minutes): sedentary control day (CONT), RES exercise at 70% 1RM, MICE at 90% gas exchange threshold (GET), CONE consisting of RES and MICE. dCA was assessed pre, and 10 minutes post experimental trials using a single sit-to-stand manoeuvre. Middle cerebral artery blood flow velocity (MCAv) was measured via transcranial Doppler ultrasonography and mean arterial pressure (MAP) was measured via finger plethysmography. Baseline MCAv was taken as the last 60 seconds of seated rest. dCA was quantified as the percentage fall in MCAv relative to the percentage fall in MAP upon standing ($\Delta\%$ MCAv/ $\Delta\%$ MAP). dCA responses were analysed using a mixed model ANOVA.

RESULTS: Baseline MCAv remained unaffected by condition or time ($P>0.05$). Females exhibited higher baseline MCAv compared to males ($P=0.01$). However, there were no significant interactions between condition, time, and sex ($P>0.05$). The fall in MCAv upon standing was not significantly different 10 minutes post any experimental condition in comparison to pre, except for the RES trial, where the fall in MCAv in both absolute (10.37 ± 4.20 vs 12.89 ± 3.27 cm/s, $P=0.01$) and relative (16.16 ± 6.11 vs $20.38\pm 5.20\%$, $P=0.01$) terms was greater 10 minutes post. For the fall in MAP, there was no main effect of condition or time ($P>0.05$). No sex differences were reported for the fall in MCAv or MAP ($P>0.05$). dCA remained unchanged following all experimental conditions ($P=0.61$). No sex differences in dCA were found pre or 10 minutes post any experimental trial ($P=0.17$).

CONCLUSION: These findings suggest that: (1) dCA remains intact 10 minutes post-RES, MICE, and CONE, suggesting that acute exercise does not alter dCA responses in healthy young adults; and (2) provides evidence of no sex differences in dCA, highlighting that both males and females exhibit similar dCA both before, and 10 minutes post these exercise conditions.

VASCULAR AND CARDIOMETABOLIC HEALTH IN POSTMENOPAUSAL WOMEN FOLLOWING RESISTANCE TRAINING PROGRAMMES DIFFERING IN SET CONFIGURATIONS: PRELIMINARY RESULTS FROM CARE PROJECT

ENRIQUEZ-GONZALEZ, M., RIAL-VÁZQUEZ, J., RÚA-ALONSO, M., NINE, I., RIVERA-MEJIA, S.L., FARIÑAS, J., REVUELTA-LERA, B., IGLESIAS-SOLER, E.

UNIVERSITY OF A CORUÑA

INTRODUCTION: Hormonal changes of menopause impact on women's health (1). Resistance training is recommended on reducing the risk of cardiovascular disease (2) and improving cardiometabolic health in postmenopausal women (3). Set configuration has been demonstrated to influence various physiological responses and adaptations (4,5). The aim of this study was to explore the blood pressure, arterial stiffness, and lipid profile changes in postmenopausal women following resistance training protocols differing in set configuration.

METHODS: 16 physically active postmenopausal women participated in a study funded by the Spanish Ministry of Science, Innovation and University (PID2021-124277OB). After medical evaluation and familiarization, participants were assigned to control (CON) and experimental groups: 9 sets of 4 repetitions with 45s rest (4S), or 4 sets of 9 repetitions with 120s rest (9S). Target variables were assessed before, after 12-weeks of training and after 8-weeks of follow-up. Systolic (sBP), diastolic (dBP), and mean arterial pressure (MAP) were evaluated at rest for 10min using Task Force System. Arterial stiffness was evaluated via Popmetre, measuring finger-to-toe pulse wave velocity (ft-PWV) and ankle-brachial index (ABI). Lipid profile analysis included total cholesterol (CHOL), HDL, LDL, triglycerides (TGL), and CHOL ratio.

RESULTS: ANOVA did not detect a main effect of group, time, and group×time interaction ($p>0.05$) for sBP, dBP and MAP. Compared to pretest lower descriptive values of sBP were found in follow-up for 4S (109.96 to 99.08mmHg). Moreover, compared to pretest, lower descriptive values of dBP (70.27 to 63.72mmHg) and MAP (87.32 to 79.09mmHg) were found in follow-up for 4S. Main group effect was detected for ft-PWV, being overall values higher in 9S (17.51 ± 0.88 m/s) compared to CON (13.61 ± 1.08 m/s). Main time effect showed lower ABI in follow-up compared to pre and posttest for 4S (2.09 ± 0.04 to 1.10 ± 0.10) and 9S (2.02 ± 0.04 to 0.90 ± 0.30). ANOVA did not detect a main effect of group, time, and group×time interaction ($p>0.05$) for LDL, TGL and CHOL ratio. Lower overall CHOL and HDL were observed in follow-up compared to pre and posttest ($p<0.01$) for 9S and 4S. Descriptive data found lower TGL in follow-up for 9S (87.30 ± 15.10 mg/dL) compared to pre (105.50 ± 22.40 mg/dL) and posttest (109.80 ± 43.30 mg/dL).

CONCLUSION: Preliminary results showed that none of the variables analyzed were modulated by set configuration after middle-term programmes. However, descriptive data raises a tendency to lower sBP, dBP and MAP after intervention and follow-up for 4S. Experimental groups improve vascular health in follow-up presenting ABI values lower than 1.1. Finally, a tendency towards a better lipid profile was observed for experimental groups.

ACUTE EFFECTS OF HIGH-INTENSITY AEROBIC EXERCISE ON COGNITIVE FUNCTION IN REGULARLY ACTIVE YOUNG ADULTS: A CROSSOVER STUDY

SHAMEL, F., EMIR, Z.
GAZI UNIVERSITY

INTRODUCTION: Aerobic exercise is recognized for its positive impact on cognitive functions, primarily through increased brain-derived neurotrophic factor (BDNF) and improved cerebral blood flow(1). Short-term cognitive improvements are particularly valuable in real-life scenarios that demand focus and quick decision-making, such as exams or competitions(2). Despite these benefits, the acute effects of high-intensity aerobic exercise on cognitive functions in regularly active individuals remain underexplored. Investigating these short-term effects can provide insight into the role of exercise in enhancing immediate cognitive performance.

METHODS: Twenty regularly active young adults participated in a randomized crossover study. Each participant completed two sessions (exercise and control) separated by a one-week washout period. A 20-minute high-intensity aerobic exercise session was performed. Cognitive performance, including reaction time, aim accuracy, and visual memory, was assessed at three time points: before exercise (T0), 30 minutes after (T1), and 60 minutes after (T2).

RESULTS: The exercise group showed significant improvement in reaction time at T1 ($p = 0.031$, $\eta^2p = 0.138$) and T2 ($p = 0.036$, $\eta^2p = 0.194$), with large effect sizes (Cohen's $d = 1.265$, $d = 0.979$). Visual memory improved at T1 ($p = 0.070$, $\eta^2p = 0.148$), but the effect diminished by T2 ($p = 0.501$, $\eta^2p = 0.028$). Although aim accuracy showed improvement, the group-by-time interaction was not significant ($p = 0.245$, $\eta^2p = 0.089$). No sequence effect was observed ($p > 0.1$).

CONCLUSION: This study shows that high-intensity aerobic exercise can significantly improve reaction time and visual memory in regularly active young adults, especially within the first 30 minutes after exercise. However, these improvements decrease by 60 minutes, highlighting the short-term nature of the effects. Although aim accuracy showed some improvement, it was not statistically significant. These findings suggest that short bursts of aerobic exercise may be useful for boosting cognitive functions in time-sensitive tasks such as exams or decision-making under pressure.

SIX-WEEK PASSIVE STATIC STRETCHING OF THE LOWER LIMBS REDUCES SYSTOLIC BLOOD PRESSURE IN INDIVIDUALS WITH ESSENTIAL HYPERTENSION

TONINELLI, N., CÈ, E., GIANNATTASIO, C., MALOBERTI, A., ESPOSITO, F.
UNIVERSITÀ DEGLI STUDI DI MILANO; UNIVERSITÀ DI MILANO-BICOCCA

INTRODUCTION: Passive static stretching (PS) improves endothelial function and reduces arterial stiffness in healthy and pathological subjects [1]. Recent evidence suggests that stretching a limited number of muscles elicits systemic cardiovascular adaptations in young participants [2]. Thus, local PS could improve cardiovascular health in hypertensive subjects (HS), characterized by elevated blood pressure and possible low exercise tolerance [3]. We hypothesize that systemic

endothelial function, central arterial stiffness, and blood pressure will improve after a six-week PS intervention for the lower limbs in HS.

METHODS: 24 HS participated in this longitudinal non-randomized crossover study. Blood pressure was recorded with a sphygmomanometer. Carotid-to-femoral Pulse Wave Velocity (PWVcf) was measured with the Complior system as an index of central arterial stiffness. Flow-mediated dilation (FMD) and nitrate-mediated dilation (NMD) were assessed in the brachial artery via ultrasound to evaluate systemic vasomotor control. Assessments were conducted at baseline (T0) and after a 6-week control period (T1), followed by a 6-week PS intervention (20 min/day, 5 days/week) (T2), and a final session after a 6-week follow-up (T3).

RESULTS: No changes were observed in T1 for all variables (all $P \geq 0.06$). In T2, systolic blood pressure (SBP) decreased from 126 ± 11 to 122 ± 11 mmHg ($P < 0.013$). No changes were found in diastolic blood pressure ($P = 0.126$), pulse pressure ($P = 0.172$), mean arterial pressure ($P = 0.071$), PWVcf ($P = 0.515$), brachial artery diameter ($P = 0.615$), FMD% ($P = 0.167$), and NMD% ($P = 0.800$). In T3, SBP returned to pre-intervention values ($P = 0.042$ vs. T2; $P = 0.534$ vs. T1).

CONCLUSION: A six-week PS protocol for the lower limbs reduced SBP in HS, but effects were reversed after the follow-up, highlighting the need for continuous stimulus to sustain the training benefits. The absence of central and systemic adaptations suggests SBP reduction resulted from decreased stiffness in involved and non-tested vessels or other unevaluated mechanisms (e.g., reduced sympathetic overdrive, renin-angiotensin system activation).

TELEHEALTH EXERCISE TRAINING IN PERIPHERAL ARTERIAL DISEASE (TEXTPAD) STUDY: A PILOT RANDOMIZED CONTROLLED TRIAL IN SOCIOECONOMICALLY DISADVANTAGED POPULATIONS

CUCATO, G., RADHAKRISHNAN, A., KANER, E., FONG, M., PRENTIS, J.

NORTHUMBRIA UNIVERSITY; NEWCASTLE-UPON-TYNE HOSPITALS NHS FOUNDATION TRUST; NEWCASTLE UNIVERSITY

INTRODUCTION: Peripheral arterial disease (PAD) is a common condition among older adults, particularly those in socioeconomically disadvantaged populations. Supervised exercise is a key treatment for PAD-related claudication, but access to such programs is limited, especially following the COVID-19 pandemic. Telehealth interventions offer a promising alternative, but their feasibility and effectiveness in these populations remain unclear. This study aimed to assess the feasibility and preliminary effectiveness of a home-based telehealth intervention combining exercise and behaviour change counselling for patients with PAD from socioeconomically deprived areas of the UK.

METHODS: A pilot randomised controlled trial was conducted with PAD patients recruited from the Vascular Unit of Freeman Hospital in Newcastle and resided in the lowest 30% of socioeconomically deprived areas. Participants were randomised into a telehealth intervention or usual care group. The intervention involved weekly behaviour change sessions targeting main PAD risk factors, plus supervised exercise sessions via videoconference. Usual care included general advice on physical activity (e.g., unsupervised walking). Feasibility was assessed through recruitment, adherence, and retention. Secondary outcomes included the 6-minute walk test (6MWT), Walking Impairment Questionnaire (WIQ), Vascular Quality of Life Questionnaire (VascQoL-6), and risk factors (smoking and alcohol), measured at baseline and 12 weeks. We compared delta values (post-pre values) using an independent t-test, with $P > 0.05$ as significant.

RESULTS: Of 99 patients screened, 36 were enrolled and randomised (19 intervention, 17 control). By 12 weeks, 25 participants completed the study (13 intervention, 12 control). In the intervention group, the median attendance was 20 of 24 possible exercise sessions and 11 of 12 behavioural counselling sessions. Changes in the 6MWT were not significantly different between groups ($p > 0.05$). However, WIQ speed improved in the intervention group (mean change $+22.2 \pm 4.6$) than the control group ($+5.5 \pm 4.9$; $p = 0.002$), as WIQ stair-climbing ($+20.0 \pm 7.0$ vs. -5.6 ± 5.3 ; $p = 0.001$). The intervention group also experienced a greater increase in disease-specific quality of life (VascQoL-6: $+3.7 \pm 0.81$ vs. $+0.41 \pm 0.95$; $p = 0.01$). Notably, 3 of 6 baseline smokers (50%) in the intervention group quit smoking compared to 0 in the control group, whereas minimal changes in alcohol intake were observed in both groups.

CONCLUSION: Despite the recruitment challenges, this home-based telehealth intervention proved feasible and showed preliminary effectiveness in enhancing subjective functional capacity, quality of life, and smoking cessation among PAD patients from socioeconomically disadvantaged backgrounds. These findings indicate that telehealth could represent a valuable alternative to traditional supervised exercise programmes for managing PAD, with further research required to refine the intervention and evaluate its long-term clinical impact.

ACUTE CARDIOVASCULAR RESPONSES TO A SHORT SPRINT INTERVAL TRAINING SESSION IN NORMOTENSIVE VS. HYPERTENSIVE INDIVIDUALS

BOULLOSA, D., SAMPAIO-COSTA, M., WALTER-DA-SILVA-BARBOSA, G., OLIVEIRA-JUNIOR, S.A., MÜLLER, P.T.
FEDERAL UNIVERSITY OF MATO GROSSO DO SUL

INTRODUCTION: The current evidence suggests a significant but limited efficacy of high-intensity interval training (HIIT) for the chronic reduction of blood pressure (BP) in hypertensive individuals. Interestingly, despite its time efficiency, there is very limited data on the safety of HIIT protocols with hypertensive individuals. Given the cardiovascular risk associated with elevated BP and HR responses during HIIT protocols, more information is warranted for the safe use of these protocols for the treatment of hypertension. In this regard, short Sprint Interval Training (sSIT), a HIIT modality which consists of repeated short (≤ 10 s) sprinting bouts, has shown its effectiveness to improve both aerobic and anaerobic fitness indices with a reduced cardiovascular strain and better affective responses than other HIIT protocols. However, there is no data on the acute responses of sSIT protocols with hypertensive individuals.

METHODS: Ten normotensive (42.3 ± 13.1 years, 25.9 ± 2.1 kg/m²) and 10 hypertensive individuals (47.3 ± 7.15 years, 28.4 ± 3 kg/m²) volunteered for participation in this study. After the clinical examination and completing an incremental cycling test after exhaustion, participants underwent two sSIT sessions with, at least, 48h in-between. The protocols consisted of 10 sprints of 5s with 80% of the aerobic power recorded in the incremental test, with 50s of active recovery at 25W. Heart rate (HR), systolic (SBP) and rate pressure product (RPP) were recorded before, during (5th and 10th sprints), and after the protocols with the auscultatory method.

RESULTS: Hypertensive individuals exhibited a lower HR after the 10th sprint during the second sSIT session when compared to the first sSIT session ($p < 0.001$), with no significant differences observed between groups. Moreover, hypertensive individuals exhibited higher SBP values than normotensive controls in most moments ($p = 0.006$), with similar SBP values observed between groups after the 10th sprint in the second session ($p = 0.323$). In addition, hypertensive individuals showed safe mean RPP values during both sessions ($< 25,000$ mmHg*bmp) with only significant differences observed between groups after the 5th sprint during the second session ($p = 0.014$).

CONCLUSION: The sSIT protocol used in the current study demonstrated to be safe for hypertensive individuals when considering RPP values. Further, hypertensive individuals exhibited higher cardiovascular responses when compared to the normotensive control group who showed a progressive increase in cardiovascular strain during the protocol. A first bout of a sSIT session may reduce the cardiovascular strain in a second sSIT session in hypertensive individuals, which was not observed in the normotensive control group. Further studies should elaborate on the comparison of this and other sSIT protocols with other HIIT formats.

CP-MH23 Training in Older Adults

EFFECTS OF A COMMUNITY-BASED MULTIMODAL EXERCISE PROGRAM ON PHYSICAL AND COGNITIVE FUNCTION OF OLDER ADULTS: A PILOT PRE-POST STUDY

SEBASTIAO, E., SIQUEIRA, V., MINGYI, Y., SILVA, J.
UNIVERSITY OF ILLINOIS URBANA-CHAMPAIGN

INTRODUCTION: Aging is associated with an increased risk of chronic disease and loss of function, profoundly affecting independence and quality of life. Physical activity, particularly exercise training, has been highly recommended for older adults. Community-based exercise programs for older adults play an important role in encouraging, enabling, and engaging older adults to participate in regular, appropriate, and health-promoting exercise; therefore, helping to mitigate the decline in both physical and cognitive outcomes that commonly occurs with advancing age [1]. This study examined the effects of a 16-week community-based multimodal exercise program (CBMEP) on physical and cognitive function of older adults.

METHODS: This pilot pre-post study included and enrolled eight older adults (Age: 76.87 ± 3.22 years; 50% women). The 16-week program consisted of Monday through Friday, 60-minute fitness classes at a recreational center, with participants attending at least three days per week. The exercise program incorporated stretch, balance, resistance, aerobics, yoga, and tai-chi, and it was delivered by trained students majoring in Kinesiology and supervised by an experienced graduate student. Participants were assessed pre- and post-16 weeks of intervention on measures of lower extremity function (Short Physical Performance Battery; SPPB), functional mobility (Timed Up and Go; TUG), functional muscle power (Stair Climbing Power Test; SCPT), walking endurance (2-Minute Walking Test; 2MWT) and global cognition (Montreal Cognitive Assessment; MOCA). Data were analyzed using paired t test with a significance set at $P < 0.05$, and percentage improvement (PEI), which was calculated using the following: $PEI = (Pre - Post)/Pre \times 100$.

RESULTS: After 16 weeks of a multimodal exercise program, a trend toward improved functional muscle power from pre- to post-intervention was observed (SCPT; Pre: 4.32 ± 0.59 s vs. Post: 3.89 ± 0.89 s; $P=0.05$; PEI = 9.95%). No significant improvements were found for lower extremity function (SPPB; Pre: 11.38 ± 0.74 vs. Post: 11.75 ± 0.46 ; $P=0.29$; PEI = 3.25%), functional mobility (TUG; Pre: 6.05 ± 0.61 s vs. Post: 5.73 ± 0.79 s; $P=0.19$; PEI = 5.29%), walking endurance (2MWT; Pre: 640.63 ± 65.79 ft vs. Post: 669.93 ± 81.32 ft; $P=0.21$; PEI = 4.57%), or global cognition (MOCA; Pre: 27.67 ± 2.58 vs. Post: 28.00 ± 2.00 ; $P=0.47$; PEI = 1.19%).

CONCLUSION: Our findings suggest that 16 weeks of CBMEP did not significantly improve the selected outcomes. However, the results indicated a trend toward improved functional muscle power. Although the selected physical and cognitive function outcomes did not show significant effects, the observed maintenance of these functions over time could be viewed as positive, given the normal declines associated with aging.

EFFECTS OF INTEGRATED LOWER LIMB POWER TRAINING WITH VISUAL FEEDBACK ON HEALTH AND PERFORMANCE IN COMMUNITY-DWELLING ELDERLY

KAO, Y., HSU, M., GUO, L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Lower extremity muscle power critically impacts mobility and quality of life in older adults. Aging leads to declines in Type II muscle fibers and strength, linked to reduced mobility, higher disability risk, and cognitive impairment, affecting daily living activities[1]. Muscle power training uses progressive, high-intensity exercises with rapid movements to quickly enhance force generation, unlike endurance training, which focuses on sustained effort[2]. The study examined lower extremity power training with visual feedback to improve health performance in community-dwelling elderly individuals.

METHODS: Twenty-five elders from two centers were recruited: one was assigned to the intervention group ($n=11$) and the other to the control group ($n=14$). The intervention group participated in a 12-week progressive resistance training program with two sessions per week, while the control group continued their usual activities. Outcome variables included body composition, muscle strength, physical performance, Heart Rate Variability (HRV), and the Montreal Cognitive Assessment (MoCA), measured at baseline, mid-intervention, and post-intervention, except HRV and MoCA, which were assessed only at baseline and post-intervention. Repeated-measures ANOVA and generalized estimating equations were used for statistical analyses, with $p<0.05$ deemed significant.

RESULTS: Our results revealed muscle strength improved in both groups. The control group showed significantly increased strength in the left quadriceps and bilateral hamstrings from baseline to mid-phase. The intervention group improved in quadriceps, hamstrings, and right-hand grip strength from mid to post-phase, while no further changes occurred in the control group. Diastolic blood pressure ($\eta^2=3.936$, $p=0.047$) and HRV, measured by the root mean square of successive differences ($\eta^2=5.10$, $p=0.024$), showed significant interaction effects, increasing in the intervention group. Gait speed improved significantly in the intervention group ($p=0.004$), along with overall Short Physical Performance Battery (SPPB) scores. Regarding cognitive function, orientation ability and total score showed significant differences between groups ($p=0.003$; $p=0.04$), with the control group experiencing a significant decline in orientation ability. Systolic blood pressure and oxygen levels increased in both groups without between-group differences, while the body mass remained unchanged.

CONCLUSION: The control group showed early strength gains, likely due to higher activity levels, while the intervention group, following progressive overload, achieved greater long-term improvements. Power training improved parasympathetic activity and cardiac regulation, enhancing physical performance and cognitive function.

EFFECTS OF A PRAGMATIC, COMMUNITY-BASED, 6-WEEK MINI-TRAMPOLINE EXERCISE PROGRAMME ON FUNCTIONAL ABILITY, POSTURAL CONTROL AND BALANCE CONFIDENCE OF OLDER ADULTS

BAMPOURAS, T., SMITH, S., JONKER, L., JAMIESON, J., BENHAM, A.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Physical activity (PA) increases functional ability and balance in older individuals, but engagement is low [1]. Improving engagement with PA in the community, requires a range of programmes on offer [2]. Trampoline-based exercise increased power in older individuals in the laboratory [3]. The present study explored the effect of a pragmatic, community-based 6-week trampoline exercise programme on functional ability and postural control in older adults.

METHODS: Forty-six older adults (>60 years) were randomly allocated to a mini-trampoline (EXP, $n=25$) or a usual (CON, $n=21$) exercise group. EXP exercised on individual mini-trampolines while CON with standard exercise class activities. Both groups exercised at a community centre for 6 weeks, for 30 minutes, twice a week; participants completing $<70\%$ (i.e. <9) sessions were excluded from the analysis [4]. Functional ability (timed-up and go (TUG) time), leg power (sit to stand time (STS) and power (STS-P)), postural control (single leg stance path (SL-P) and velocity (SL-V)) and performing ambulatory activities confidence (Activities-specific Balance Confidence (ABC) scale) were measured before (PRE) and after (POST) the

6-weeks. Age, height, body mass and sex between groups was compared was baseline. A generalised linear mixed-effects model was used to examine for differences in all variables between EXP and CON.

RESULTS: A total of 29 participants attended ≥ 9 sessions (EXP: $n=16$, 64.5 ± 3.8 years; CON: $n=13$, 64.1 ± 2.7 years). There were no differences in age, height, body mass or sex between groups. No adverse effects were reported by any participant. No significant interaction or group main effect existed for TUG, STS and ABC but there was a significant PRE-POST main effect, with performance improvement at POST (TUG: PRE = 9.35 ± 1.23 s, POST = 8.68 ± 1.22 s, $P = 0.001$, $g = 0.547$; STS: PRE = 17.5 ± 3.33 s, POST = 15.3 ± 4.52 s, $P = 0.182$, $g = 0.554$; ABC: PRE = $93.8 \pm 8.12\%$, POST = $96.2 \pm 4.60\%$, $P = 0.001$, $g = 0.34$). SL-P and SL-V showed no significant interaction or main effects.

CONCLUSION: Whilst there was no difference between interventions for any outcome, both EXP and CON groups improved functional ability, leg power and balance confidence but not postural control. A notable outcome of the study is the comparable adherence rate above the specified 70% attendance and the lack of adverse events in both groups. These results support that a pragmatic, community-based mini-trampoline exercise programme may be an effective exercise option for older adults to support promotion of PA in this population and merits further investigation.

ACCEPTANCE AND FEASIBILITY OF A NOVEL TRAINING ALGORITHM IN A NURSING HOME ENVIRONMENT

BÖCKER, J., SACHS, L., DREY, M., KAISER-STOLZ, C., BLOCH, W., DEKANT, A., RITTWEGER, J.

GERMAN AEROSPACE CENTER

INTRODUCTION: Sarcopenia is a rising problem worldwide, mainly due to the steady increase in life expectancy. It is scientifically well-established that strength training is the most important measure to counteract sarcopenia. However, the implementation of strength training in nursing homes with a particularly large number of people affected is often prevented by a number of barriers. Such barriers often have an influence on the acceptance and feasibility of an intervention. However, these two aspects are as important as the effectiveness of a training. Thus, the aim of this study was to investigate acceptance and feasibility of a recently proposed training algorithm in nursing homes.

METHODS: The staff of 5 nursing homes were trained in the KNIMS algorithm stage B (Weber et al., 2024) and exercised over 4 weeks (5 times a week, Monday till Friday) with 28 residents. Each training session was documented, the performance of the individual exercises was recorded, the subjective assessment of the exercise intensity of the residents was surveyed and the motivation of the residents was assessed by the nursing staff. For the analysis, we divided acceptance and feasibility as follows: combined acceptance and feasibility (cAF) quantifying the adherence of the residents to the training, operational feasibility (opF) describing the integration of the training in the daily activities of a nursing home, and exercise performance feasibility (EPF) as applicability of the exercises to the residents.

RESULTS: The cAF was at least 54%, the opF was 91% and the EPF ranged from 88% to 94.2% depending on the kind of exercise. The opF was higher than 100% in two facilities, as training sessions were also offered at weekends in addition to the planned training sessions from Monday to Friday. In contrast, the number of weekly training sessions at one facility was reduced due to a lack of staff as a result of a COVID-19 outbreak. Finally, it turned out that the training motivation was higher for training in a group ($P = 0.007$), but the training intensity was higher during individual training ($P < 0.001$).

CONCLUSION: The study demonstrates that the training algorithm is both accepted (by the instructing staff and the residents) and feasible/implementable in a nursing home environment. It has been shown that, contrary to our previous assumption, training is also possible at weekends. It was also shown that the exercises of the algorithm consisting of squat, lunge and one-leg stand can be performed by the majority of residents. The biggest barrier to carrying out the training, thus influencing acceptance as well as feasibility, is the availability of staff as obtained in the facility with the COVID-19 outbreak. The efficacy of the algorithm needs to be proven in the future.

THE APPETITE PROJECT: EFFECTS OF NUTRITIONAL AND EXERCISE INTERVENTIONS ON PHYSICAL FUNCTION, BLOOD BIOMARKERS, AND BODY COMPOSITION IN A GROUP OF OLDER ADULTS

BOZZATO, M., GONNELLI, F., MOTANOVA, E., PRATT, J., DALLA COSTA, V., SAMPIERI, A., SPINELLO, G., VALLI, G., MARTINO, G., DE VITO, G.

UNIVERSITY OF PADUA

INTRODUCTION: Age-related muscle function decline can significantly impair health and quality of life. Loss of appetite and inadequate macronutrient intake, especially protein, can contribute to this decline. This study was part of a multi-country randomised controlled trial (APPETITE project) aimed at evaluating the effects of plant protein and fibre (PPF) supplements

incorporated within a personalised diet (PD), a physical activity (PA) program, or their combination (Horner et al., 2024). Our aim was to assess the effects of such interventions on functional, anthropometric and blood-based markers.

METHODS: Fifty-two older adults ($M=9$, age 72.1 ± 5.0 y, height 1.6 ± 0.1 m, body mass 65.6 ± 11.1 kg) were randomly distributed into 4 groups: PD, PA, personalised diet and physical activity (PD+PA), and control (CTRL). Participants were tested before and after a 12-week intervention, regardless of group assignment. The PD intervention consisted of dietary counselling and daily consumption of PPF (25g twice a day); the PA group received supervised exercise classes in a group setting (one hour, twice a week); the PD+PA group incorporated both PD and PA interventions whereas participants allocated in CTRL group were only required to perform testing sessions while maintaining their habitual diet and physical activity level. We assessed body composition through dual-energy x-ray absorptiometry (DXA); physical function through chair stand test, gait speed test, 400 meters walking test, handgrip dynamometry, and maximal isometric voluntary torque (MVT); blood biomarkers of neuromuscular system function such as the C-terminal agrin fragment (CAF) and the brain-derived neurotrophic factor (BDNF). A two-way repeated measures ANOVA was performed to detect differences across groups and time points.

RESULTS: Of all the measurements, we found significant time effects on DXA lean mass ($p<0.05$), chair stand test ($p<0.05$), gait speed ($p<0.05$), and MVT ($p<0.001$). However, no between-group differences or time-group interactions were detected.

CONCLUSION: Despite some changes in functional and body composition outcomes, the analysis did not highlight differences in either the physical activity or the personalised diet interventions. However, this analysis was carried out in a subgroup of a broader project, therefore with a reduced sample size. It will be essential to reconsider the results when the complete data set from the other study centres will be available. The study was funded under the European Joint Programming Initiative 'A Healthy Diet for a Healthy Life'.

EFFECT OF SET CONFIGURATION OF RESISTANCE TRAINING ON CARDIOVASCULAR AUTONOMIC MODULATION AND BAROREFLEX SENSITIVITY ADAPTATIONS IN POSTMENOPAUSAL WOMEN: PRELIMINARY FINDINGS OF THE CARE STUDY

RÚA ALONSO, M., RIAL-VÁZQUEZ, J., RIVERA-MEJÍA, S.L., ENRÍQUEZ-GONZÁLEZ, M.G., NINE, I., FARIÑAS, J., REVUELTA-LERA, B., IGLESIAS-SOLER, E.

UNIVERSITY OF A CORUÑA

INTRODUCTION: Menopause has been identified as a cardiovascular sex-specific risk factor for women (1), due to the hormonal changes that increase the risk of dysfunction in cardiovascular autonomic modulation, leading to a higher prevalence of cardiovascular diseases (2). Resistance training (RT) is recommended to counteract, or even reverse, some adverse effects of menopause (3). Set configuration has been demonstrated to modulate cardiovascular responses to RT (4). However, no evidence exists regarding cardiovascular adaptations in postmenopausal women. Therefore, the aim of this study was to explore adaptations in cardiac autonomic modulation and baroreflex sensitivity following two resistance training interventions that differed in set configuration in postmenopausal women.

METHODS: Preliminary results from CARE study, funded by the Spanish Ministry of Science Innovation and University (PID2021-124277OB), involved 16 physically active, normotensive postmenopausal women. Following a medical examination and familiarisation and testing sessions, participants were randomly assigned to one of three groups: long set configuration (9S), short set configuration (4S), or a control group. Both RT groups exercised at a moderate intensity (12RM load), 2 days per week for 12 weeks, but differed in set configuration. The 9S group performed 4 sets of 9 repetitions with 120s rest, while the 4S executed 9 sets of 4 repetitions with 45s rest. Before, after intervention and in a follow-up assessment, cardiac autonomic modulation [root mean square of differences between adjacent pulse interval (RMSSD), heart rate (HR), high frequency power (HF)], baroreflex sensitivity (BRS) and its effectiveness (BEI) were evaluated at rest.

RESULTS: No significant main effects of time, group, or interaction were detected for any parameter ($p\geq0.112$), except for HR, where 9S group showed globally lower values compared to the 4S group ($p=0.048$). Furthermore, a main effect of time was observed for BRS ($p=0.047$), with overall improvements being evident following the post-test evaluation.

CONCLUSION: After 12 weeks of RT intervention, no cardiovascular adaptations were observed in postmenopausal women, regardless of the set configuration. These preliminary results suggest that physically active postmenopausal women may experience lesser benefits from incorporating RT routines compared to sedentary women with cardiometabolic risk (5), with an active lifestyle being the key factor for improving cardiovascular health in postmenopausal women (2).

METABOLIC REHABILITATION IN CARDIOVASCULAR PATIENTS ASSESSED BY CPET-BASED ANALYSIS OF FAT OXIDATION

GARBSCH, R., SCHÄFER, H., KOTEWITSCH, M., TESCHLER, M., MOOREN, F.C., SCHMITZ, B.

UNIVERSITY WITTEN/HERDECKE; FACULTY OF HEALTH

INTRODUCTION: Cardiac rehabilitation (CR) is a comprehensive intervention addressing the physical and psychological challenges of coronary artery disease (CAD). While the overall effects of exercise-based CR on cardiopulmonary fitness are well documented, the metabolic CR effects are underreported. This study investigated fat oxidation (FatOx) during exercise as a function of mitochondrial capacity and evaluated the effects of CR on FatOx improvement in patients with CAD.

METHODS: 256 CAD patients (21% female, 56.6±6.7 years; 79% male, 55.2±7.5 years) after myocardial infarction (MI) and/or reperfusion via percutaneous transluminal coronary angioplasty referred to 3–4 weeks of exercise-based CR underwent full-clinical assessment including cardiopulmonary exercise testing (CPET) at admission (pre) and before discharge (post). Breath-by-breath spirometric data was used to calculate substrate oxidation rates including FatOx using a stoichiometric approach. Data was then plotted as percentage of peak VO₂. Responder analysis was performed for submaximal and peak exercise capacity based on VO₂ at ventilatory threshold 1 (VT1) and VO₂peak as well as for maximal fat oxidation (MFO) using the typical error method. MFO was compared to published data from healthy controls. Mean area under the curve (AUC) for relative FatOx values was calculated with 95% confidence interval.

RESULTS: At the start of CR, patients exhibited significant limitation in physical exercise capacity at submaximal (12.4±3.3 ml/min/kg; 50.2±12.6% predicted reference) and peak exercise (18.5±4.6 ml/min/kg; 73.8±15.5% predicted reference). FatOx capacity was significantly impaired in CAD patients (MFO: 0.31±0.14 g/min; AUCpre: 11.1[10.6–11.7]) compared to healthy controls (MFO: 0.46±0.17 g/min; p<0.001). Stratification by age and sex revealed that limited FatOx was more pronounced in female and older patients (AUC: 8.1[7.7–8.5] and 9.2[8.8–9.7]). No evidence of reduced FatOx linked to number of affected coronary vessels or previous MI was observed. During rehabilitation, overall FatOx improved significantly (+20.7%, AUCpost: 13.4[12.8–13.9]; p<0.001), while females showed only minimal improvement (+2.5%) compared to males (+24.4%). The responder analyses revealed that 35% of patients showed a response in VO₂@VT1, while 43% improved in VO₂peak. The responder analysis also identified a subgroup of patients (11%) who showed no improvement in VO₂ at submaximal or peak exercise but exhibited a significant improvement in MFO (AUCpre: 10.2 [9.7–10.7], AUCpost: 17.5 [16.9–18.2]; +72.3%).

CONCLUSION: CAD patients demonstrated improved FatOx capacity in response to CR which appears limited in females with CAD. MFO may identify responders to CR in terms of beneficial metabolic adaptations, potentially linked to restored mitochondrial function, in addition to traditional outcome assessments based on VO₂ uptake.

SPPB IN OLDER ADULTS: NOT ALWAYS A GOOD CHOICE

BLASCO-LAFARGA, C., CARRILLO-SALA, M., MONFERRER-MARÍN, J., ROLDÁN, A., CORDELLAT, A., MONTEAGUDO, P., BLASCO-LAFARGA, N.M., NAVARRO PEREZ, J.

UNIVERSITY OF VALENCIA, SPAIN

INTRODUCTION: Despite its wide use in Primary Care (1), the Short Physical Performance Battery (SPPB) presents limitations. A score below 10 pts is associated with increased all-cause mortality (2), but it's been suggested a ceiling effect in non-frail individuals as well as limited applicability to track performance changes over time (3). This study analyses this applicability compared to the gait speed in the 200-meter walking test (GS200), in a sample of old patients referred from Primary Care who were assigned to two different short physical interventions of 8-weeks, according to their fitness level.

METHODS: One hundred and two adults >60 years were assigned to Gesmed-Marcha (GM; N=53, 37 women; Nordic walking plus inspiratory muscle training) or Gesmed-ViuActiu (GVA; N=49, 37 women; multicomponent exercise). Changes in body mass index (BMI), SPPB (Total: SPPBT, balance: SPPBB, 5STS test, and 4-meter gait speed), and GS200, were analysed by means of a General Linear Model (repeated measures in pre-post training; sex and PEI as factors), and the Mann Whitney or Wilcoxon test as non-parametric alternative.

RESULTS: At baseline, BMI and % fat mass were significantly worse (p< 0.05) in GVA compared to GM in men [31.36 (1.67) vs 27.59 (0.70) kg/m²; 32.03 (1.39) vs. 27.01 (0.92) % fat mass] and women [29.26 (0.78) vs. 27.34 (0.66) kg/m²; 40.35 (0.95) vs. 35.28 (0.90) % fat mass]. SPPBT and GS200 also reflected a significantly lower functional capacity in GVA individuals (p< 0.05). Following training, GVA showed significant improvements in SPPBT [Men, pre: 10.60 (0.37) vs. post 11.88 (0.31) pts., p= 0.004; Women: pre 10.39 (0.22) vs. post 11.50 (0.19) pts., p < 0.001] and its subscales except for balance; as well as in GS200 [Men pre 1.36 (0.07) vs post 1.66 (0.08) m/s, p < 0.001; Women pre 1.38 (0.04) vs post 1.51 (0.05), p < 0.001] m/s. Conversely, no significant improvements were found in SPPBT or its subscales in GM except for 4Vel in women, whilst there were always significant improvements in GS200 [Men: pre 1.86 (0.07) vs post 1.95 (0.07) m/s, p= 0.011; Women: pre 1.64 (0.04) vs. post 1.69 (0.04) m/s, p= 0.019]. Noteworthy, whatever the PEI, all subgroups had baseline balance median scores of 4 points, a maximum score with no option for improvements.

CONCLUSION: Despite its short duration, both Gesmed PEI showed to be effective in improving functionality and live expectancy through improvements in Gait Speed. However, SPPB confirmed its ceiling effect, mostly in balance, and lack of capacity to track performance changes in fitter older adults. This limits its applicability to analyse PEI effects in Primary Care. Alternatively, GS200 confirms to be sensitive and a powerful alternative in these interventions.

TWELVE WEEKS OF STEP-BOX GROUP AEROBIC EXERCISE DOES NOT IMPROVE PULMONARY AND AUTONOMIC NERVE FUNCTION IN POSTMENOPAUSAL WOMEN

KIM, D., PARK, J., KANG, Y., TAN, Y., RYU, B., LEE, S., PARK, Y., HWANG, M.
INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Menopause causes a rapid decline in the female hormone estrogen, which leads to decreased pulmonary function and autonomic nerve imbalance. Regular aerobic exercise is a well-known behavioral intervention to improve pulmonary and autonomic nerve function. Step-box group exercise training is a practical and effective moderate-to-high intensity aerobic exercise that improve cardiorespiratory fitness and lower body muscle strength by performing rhythmic repetitive movements accompanied by music. However, research studies investigating the effects of step-box exercise on pulmonary function or autonomic nerve balance in postmenopausal women are rare. This study aimed to evaluate the effect of a long-term step-box group training on pulmonary and autonomic nerve function in postmenopausal women.

METHODS: Twenty-four postmenopausal women participated in the study and were randomly assigned to step-box group training (SBT) or control group (CON). The SBT group performed 50 minutes of step-box aerobic exercises, three times per week for 12 weeks at 60–80% of age-predicted maximal heart rate. To assess pulmonary function, forced vital capacity (FVC), forced expiratory volume in one second (FEV1) were measured and FEV1/FVC ratio was calculated using a COSMED PFT system. Heart rate variability indices including the standard deviation of NN intervals (SDNN) and the root mean square of successive differences (RMSSD) were analyzed to evaluate autonomic nerve function.

RESULTS: There was no significant group by time interaction in pulmonary function parameters (FVC, FEV1, and FEV1/FVC, $p \geq 0.28$) between SBT and CON group. Heart rate variability parameters also did not change in either group (SDNN and RMSSD, $p \geq 0.40$).

CONCLUSION: This study results suggest that 12 weeks of step-box group training were not sufficient to induce measurable changes in pulmonary and autonomic nerve function in postmenopausal women. Further research studies are needed to determine the proper frequency, intensity, session time, and minimum training duration of step-box group training that can positive affect pulmonary and autonomic nerve function in postmenopausal women.

INTRODUCTION: Artistic, acrobatic, and rhythmic gymnastics are physically demanding sports characterized by high-volume and high-intensity training, which during pubertal growth, co-occurs with rapid skeletal growth and hormonal changes that may affect soft tissue properties. This training regime, combined with the pressure to maintain a lean physique, can lead to low energy availability, hormonal disruptions, late menarche, and low bone density increases the risk of musculoskeletal injuries, particularly in lower leg injuries like Medial Tibial Stress Syndrome (MTSS). The aim of the present study was to evaluate the prevalence of MTSS and to assess demographic, pubertal stage, bone properties, and anatomical features associated with the diagnosis of MTSS in young gymnasts.

METHODS: A total of 274 young female competitive gymnasts from three disciplines of gymnastics (rhythmic, acrobatic, and artistic) were included in this study. They all trained at the same professional level from different specialized clubs and were clinically evaluated for the presence of MTSS. Data collected included demographic information, training characteristics, pubertal status, anthropometric features, muscle strength, joint range of motion, and bone strength.

RESULTS: MTSS was found in 70 (25.6%) out of 274 young female gymnasts assessed, who had an average age of 11.8 ± 1.9 years. There was a higher prevalence among artistic gymnasts 23/60 (38.3%) compared to rhythmic gymnasts with 33/154 (21.4%), and acrobatic gymnasts with 15/60 (25.0%) ($p=0.040$). Logistic regression showed that rhythmic gymnasts with MTSS versus those without MTSS had lower ankle plantar-flexor strength ($p>0.001$) and lower tibial bone strength ($p=0.004$); acrobatic gymnasts with MTSS versus those without MTSS had lower tibial bone strength ($p=0.022$) lower fat percent ($p=0.017$) and trained more hours per week ($p=0.032$); and artistic gymnasts with MTSS versus those without MTSS had lower ankle plantar-flexors and dorsi-flexors strength ($p=0.003$; $p=0.006$, respectively), higher hip flexor strength ($p=0.012$) and lower tibial bone strength ($p=0.014$).

CONCLUSION: The main findings of the current study indicate that one out of every four female gymnasts experienced MTSS during the training period. Artistic gymnasts showed the highest prevalence of MTSS compared with acrobatic and rhythmic gymnasts. Reduced tibial bone strength, reduced plantar flexor muscle strength, and increased hours of training were associated with MTSS in young competitive gymnasts. These findings will enable better screening and monitoring throughout training seasons, as well as designing injury-prevention programs and providing valuable data that can guide clinicians, trainers, and medical teams treating young female gymnasts in preventing bone stress injuries such as MTSS.

ARE PREVIOUS ANKLE SPRAINS IN ADOLESCENT FEMALE SOCCER PLAYERS RELATED TO STATIC AND DYNAMIC BALANCE AND ONE-LEGGED JUMPS?

INOUE, Y., MISU, S., TAMURA, A.
KONAN WOMENS UNIVERSITY

INTRODUCTION: The incidence of ankle sprains is high in adolescent female soccer players. The highest risk factor for ankle sprains is having a preexisting ankle injury, as athletes with prior sprains have a higher risk of recurrence. This study investigated the results of the static and dynamic balance tests and one-leg jump tests in adolescent female soccer players with and without a history of ankle sprains to develop measures for the prevention of ankle sprain injuries.

METHODS: The study included a total of 217 female soccer players aged 13.2 ± 0.9 years with 6.8 ± 2.3 years of soccer experience. A survey was conducted to determine whether the players had a history of ankle sprains, whether the injury occurred within 1 year, the injured side, etc. The Y-balance test (YBT), closed-eye single-leg balance test (SLBT), and single-leg hop test (SHT) were executed. In all participants, the results of each test were compared between the left and right lower extremities with and without a history of an ankle sprain and with and without injury within 1 year. Statistical analysis was performed using the t-test for independent samples, t-test for corresponding samples, and χ^2 goodness-of-fit test, with a 5% significance level. This study was conducted after obtaining approval from the Konan Women's University Research Ethics Review Committee (Approval No. 2024005).

RESULTS: In this study, 82 (31%) and 63 (24%) participants had a history of ankle sprain in the right and left lower extremities, and 52 (20%) and 37 (14%) had it in the right and left lower extremities within 1 year, respectively. Overall, the YBT result was significantly lower only in the posterior lateral reach of the left lower extremity ($p < 0.05$). Participants with a history of left ankle sprain had significantly more positive results in the closed-eye SLBT ($p < 0.05$). The YBT result was significantly lower in participants with a history of left ankle sprain within 1 year ($p < 0.05$) as was the right anterolateral lower extremity reach on the YBT ($p < 0.05$). The SHT results were not significantly different between the right and left extremities for all participants or those with or without a history of an ankle sprain.

CONCLUSION: Participants with a history of left ankle sprains showed asymmetry between the left and right lower extremities in the closed-eye SLBT and YBT. Soccer requires asymmetrical performance between the left and right lower extremities. Therefore, asymmetry in single-leg postural control has been reported to increase the risk of sports injuries. The results of this study indicate the need for interventions, which consider the results of this study, to prevent recurrent ankle sprains. Therefore, interventions to prevent ankle sprain recurrence must consider the injured side and timing of the injury.

THE RELATIONSHIP BETWEEN INTRINSIC FOOT MUSCLES AND TOE GRIP STRENGTH DURING JUMP LANDING IN ADOLESCENT ATHLETES, AND THE SEX DIFFERENCES

SATOSHI, A., SAKURA, O., HONOKA, I., TSUBASA, T., NORIAKI, M.
HIROSHIMA UNIVERSITY

INTRODUCTION: We previously investigated the relationship between jump landing ability, intrinsic foot muscles, and toe grip strength in adolescent athletes, and no correlations were found between these variables [1]. However, it was reported that sex differences in foot arch and function exist during adolescence [2], suggesting that the foot-related factors contributing to balance ability may differ between males and females. This study aimed to examine the relationship between intrinsic foot muscle morphology, toe grip strength, and jump landing ability in adolescent athletes, separately for males and females.

METHODS: The study focused on the left foot of 104 males and 67 females. The cross-sectional areas of the abductor hallucis (AbH), flexor hallucis brevis (FHB), and flexor digitorum brevis (FDB) were measured using an ultrasonography. Toe grip strength was assessed with a toe grip dynamometer. The arch height ratio was calculated to represent foot morphology. The stability of the single-leg forward jump landing was evaluated using the Dynamic Postural Stability Index (DPSI), which is derived from composite ground reaction forces in the anterior-posterior (APSI), medial-lateral (MLSI), and vertical (VSI) directions. Sex differences in each measurement item were examined using an unpaired t-test. Correlation coefficients between the muscle cross-sectional areas of each intrinsic foot muscle, toe grip strength, and jump landing ability were calculated separately for males and females to explore the relationships.

RESULTS: All the cross-sectional areas of the intrinsic foot muscles, toe grip strength, and arch height ratio were significantly higher in males than females ($p < 0.05$), but there was no difference in DPSI. In males, the cross-sectional area of the FHB showed a significant negative correlation with DPSI, MLSI, APSI, and VSI, and toe grip strength showed a significant positive correlation with DPSI and VSI ($p < 0.05$). In females, the FHB showed a significant negative correlation with DPSI, MLSI, and VSI, while the FDB showed a significant positive correlation with APSI ($p < 0.05$).

CONCLUSION: There were sex differences in the foot factors related to jump landing ability between adolescent athletes. In males, improving only toe grip strength may reduce jump landing ability. In females, it is important to consider both

conditions, as the development of FDB alone or a decrease in the foot arch height ratio may hinder the improvement of jump landing ability. It was also suggested that the development of FHB is important for improving jump landing ability in both sexes. The muscle morphology of FHB is involved in good jump landing ability in healthy adults [3], and active improvement of muscle function would be important in adolescent athletes.

COMPARING FUNCTIONAL PERFORMANCE ACROSS MALE AND FEMALE YOUTH BASKETBALL ATHLETES: INSIGHTS FROM PRESEASON SCREENING

WILKE, C., OFFERHAUS, C., SCINICARELLI, G.
GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Understanding gender-specific functional characteristics in youth basketball is essential for developing targeted training and injury prevention strategies. Variations in balance, agility and jumping ability may be attributed to differences in biomechanical demands, neuromuscular adaptations and training responses between male and female athletes (Márquez et al. 2017). Basketball performance relies on agility, strength, balance and power, making these attributes critical for skill execution and injury prevention (Sattler et al. 2015).

This study aims to examine functional performance during preseason screening of male and female youth basketball players to conclude on gender specific injury prevention approaches.

METHODS: 55 male and female youth Basketball players (F: n 21, age 15.8 ± 1.7 ; BMI 20.9 ± 2.6 ; M: n 34, age 16.3 ± 1.7 ; BMI 21.6 ± 2.5) underwent a test battery with standardized functional performance tests assessing balance (Y-Balance Test), agility (T-Test) and jumping (Countermovement Jump, Hop for Distance, Side Hop Tests) (Scinicarelli et al. 2021). A one-way ANOVA ($p < .05$) was performed to compare the means of single-leg results (dominant, non-dominant and limb symmetry index) across two independent groups (male and female).

RESULTS: Preliminary analysis revealed gender differences. As to be expected, male athletes outperformed females in jumping-related tests (CMJ-Dom: $p < .001$; df, 1; F, 45.307; CMJ-NDom: $p < .001$; df, 1; F, 25.146; JFD-NDom: $p < .001$; df, 1; F, 15.337; SH-NDom: $p .01$; df, 1; F, 7.057), while female athletes demonstrated better balance performance (YBT-Dom: $p .03$; df, 1; F, 4.489). Agility measures showed results favouring male athletes (T: $p < .001$; df, 1; F, 32.912).

CONCLUSION: The observed gender differences highlight the need for gender specific training as well as injury prevention programs. To address performance gaps female athletes should focus on plyometric and strength training to enhance jumping and agility, while male athletes would benefit from balance, core stability, and proprioceptive exercises to improve postural control. These strategies may optimize performance, contribute to more effective training adaptations and reduced injury risk.

ANTERIOR TIBIOFIBULAR GAP WITH AND WITHOUT WEIGHT-BEARING IN ADOLESCENT ATHLETES: AN ULTRASOUND-BASED STUDY

ODA, S., SHOGO, T., TSUBASA, T., SATOSHI, A., HONOKA, I., TAKERU, A., RYOSUKE, K., NORIAKI, M.
HIROSHIMA UNIVERSITY

INTRODUCTION: Anterior inferior tibiofibular ligament (AITFL) injuries commonly occur under weight-bearing conditions with forced ankle dorsiflexion and external rotation. Pediatric AITFL injuries may lead to future ankle instability if not properly treated [1]. We have investigated the ultrasonography (US) assessment of the anterior tibiofibular gap (ATFG) in healthy adults about AITFL injuries, considering weight-bearing and ankle angles [2]. However, the study has not been conducted in adolescents. The purpose of this study was to explore the feasibility of US assessment of ATFG in adolescent athletes considering weight bearing and ankle angles.

METHODS: Forty-nine adolescent athletes (32 men and 17 women, 98 feet) participated in this study. ATFG was assessed using US (GE Healthcare Inc., Japan) in the sitting and standing position. Three ankle angle conditions were set on the tilt table: neutral position (N); dorsiflexion, 20° (D20); and dorsiflexion, 20° with external rotation, 30° (D20ER30). The AITFL was imaged approximately 1 cm proximally from the thickest part of the ligament at the ankle using an anterior US approach [3]. The ATFG was eventually calculated in Image J software (National Institute of Health, Bethesda, USA). Two-way repeated-measures analysis of variance (ANOVA) was used to examine differences between the ATFG as the dependent variable and postures (sitting and standing position) and ankle angles (N, D20, and D20ER30) as the independent variables. The Bonferroni test was used as a post hoc test for the ankle angles. The significance level was set at $p < 0.05$.

RESULTS: The results of the two-way ANOVA indicated that there was no interaction effect between postures and ankle angles ($F = 0.06$, $p = 0.94$). Main effects were observed for measurement postures ($F = 11.09$, $p < 0.01$) and ankle angles ($F = 32.07$, $p < 0.01$). The post hoc test revealed significant differences between D20 and D20ER30 in the sitting position, N and D20ER30 in both the sitting and standing positions ($p < 0.05$ respectively).

CONCLUSION: Our finding was that the ATFG in adolescent athletes varies depending on weight-bearing and ankle angles. The fibular lateralization and decreased fibular external rotation that occur during growth result in changes to the anatomical characteristics of the syndesmosis anatomy, differing from the features in the adulthood [4]. Moreover, prevention of pediatric AITFL injuries is crucial in children, as the tibia and distal fibula are more prone to fractures due to the physis. This study, which demonstrates changes in the ATFG under weight-bearing conditions and ankle angles in the growing population, is expected to provide fundamental data for understanding pediatric AITFL injuries.

THE ASSOCIATION BETWEEN PERCEIVED ACUTE SPORTS INJURY AT THE TIME OF OCCURRENCE AND THE SEVERITY OF SPORTS INJURIES IN YOUNG JAPANESE NATIONAL CHAMPIONSHIP-LEVEL ATHLETES.

KIMOTSUKI, Y., OGASAWARA, I., IWASAKI, S., NAGAI, K., NISHIDA, K., KANZAKI, N., HOSHINO, Y., MATSUSHITA, T., KURODA, R., UCHIDA, R., TAKE, Y., NAKATA, K.

OSAKA UNIVERSITY GRADUATE SCHOOL OF MEDICINE, FORT LEWIS COLLEGE, CO, USA, KOBE UNIVERSITY GRADUATE SCHOOL OF MEDICINE, KANSAI ROSAI HOSPITAL, DAINI OSAKA POLICE HOSPITAL

INTRODUCTION: Psychological studies have suggested that the strong stress responses likely reduce athletes decision-making capacities, leaving them vulnerable to errors, collisions, and compromised motor control, thereby increasing injury risk. [1]

Exploring athletes perceptions during acute sports injuries is essential to more thoroughly comprehend the mechanisms behind sports injury development, which may be linked to athletes' stress responses. This study aimed to understand how the perceptions of young athletes at the national championship level at the time of acute sports injury are related to the severity of the injury.

METHODS: 202 Japanese (Male=97 & Female=105) aged 18 to 24, who competed at the national championship level, completed an online survey. The survey inquired about their perceptions during injuries and their experiences with acute sports injuries. Participants responded to 20 questions about self-evaluated psychological and situational characteristics at the time of injury on 5-point Likert scale (e.g., being angry and feeling pressure). The severity of the sports injury was assessed in 7 categories of the time taken to return to play sports. It was hypothesized that "concerning the coach," "competing against rivals," "feeling impatient," and "feeling pressure" will link to the "severity" of the sports injury. Path analysis was employed to examine the effects of the variables on the severity of acute injuries. Multiple hypothesized models were tested exploratively and judged by goodness of fit indices.

RESULTS: A final model emerged after model changes and showed the highest goodness of fit indices ($\chi^2 = 0.475$, significance probability = 0.789, GFI = 0.998, AGFI = 0.988, CFI = 1, and RMSEA = 0.00). The final model revealed that "severity" was predicted by "feeling pressure" (path coefficient = 0.27, $p < 0.001$), which was nuanced by "concerning the coach" (path coefficient 0.28, $p < 0.001$) and "feeling impatient" (path coefficient 0.55, $p < 0.001$) as well as that "concerning the coach" was linked to "feeling pressure" (path coefficient 0.55, $p < 0.001$).

CONCLUSION: It has been suggested that the impatience and pressure perceived by athletes when they got injured may stem from their concerns about their coaches' evaluations. This anxiety could trigger stress responses, potentially leading to acute sports injuries.

THE ASSOCIATION BETWEEN TENDINOPATHY, TENDON STRUCTURE, AND MUSCLE STRENGTH IN YOUNG ELITE FEMALE GYMNASTS: A 12-MONTH FOLLOW-UP STUDY

STEINBERG, N.1, ELBAZ, L.1,2, DAR, G.2

1. THE ACADEMIC COLLEGE LEVINSKY-WINGATE; WINGATE CAMPUS, ISRAEL. 2. DEPARTMENT OF PHYSICAL THERAPY, FACULTY OF SOCIAL WELFARE AND HEALTH STUDIES, UNIVERSITY OF HAIFA, ISRAEL.

INTRODUCTION: Engaging in gymnastics involves rigorous physical activities, including the repeated execution of extreme movements that exert high forces on the musculoskeletal system. These extensive and complex movements expose gymnasts to high physical stresses and loads, increasing the risk of lower-extremity injuries. Achilles and patellar tendinopathy are one of the most frequently diagnosed injuries in gymnasts, with a limited chance of recovery. The aim of the present study was to examine the relationships between clinical diagnoses of tendinopathy, tendon structure, and muscle strength in young elite female gymnasts over a 12-month training period.

METHODS: A total of 274 competitive female gymnasts (aged $M=12.1\pm1.9$ yrs at baseline) at the same professional training level were assessed at baseline. Two-hundred and seven gymnasts (out of the 274) were assessed at both baseline and followed-up 12-months later for patellar-tendon and Achilles-tendon structure by Ultrasound Tissue Characterization (UTC), as well as for anthropometric measures and muscle strength (hip abductors, hip adductors, knee extensors, knee flexors, ankle plantar-flexors and ankle dorsiflexors). Additionally, all gymnasts were clinically diagnosed at the two time points by the same professional physical therapist for patellar and Achilles tendinopathy.

RESULTS: At baseline, patellar tendinopathy and Achilles tendinopathy were found in 26.6% and 31.4% of the 207 gymnasts, respectively. At the 12-month follow-up, 37.2% and 38.6% remained healthy; 9.7% and 15.5% had recovered; 36.2% and 30.0% had developed tendinopathy; and 16.9% and 15.9% remained with-tendinopathy, respectively. Using the Kruskal-Wallis test, the healthy and recovered from tendinopathy groups exhibited decreased prevalence of disorganized patellar tendon and Achilles tendon fibers from baseline to follow-up, whereas increased prevalence was seen in those who sustained or had developed tendinopathy ($p<.05$). A two-way repeated-measures ANOVA showed patellar-tendinopathy X time interactions for knee-extension, hip-abduction and hip-extension strength; and Achilles-tendinopathy X time interactions for ankle-plantarflexion and ankle-dorsiflexion strength ($p<.005$), indicated higher muscle strength at follow-up for the recovered and healthy groups compared to the developed and remained groups.

CONCLUSION: Between one-third and one-half of the young elite female gymnasts had tendinopathy, with limited chance of recovery. At baseline, gymnasts without tendinopathy exhibited higher muscle strength and lower prevalence of disorganized patellar-tendon and Achilles-tendon fibers than gymnasts diagnosed with tendinopathy. Twelve months later, the recovered gymnasts exhibited higher muscle strength and lower prevalence of disorganized tendon fibers than those who had sustained or developed tendinopathy. These findings should be addressed in training programs for young elite female gymnasts, to prevent and manage tendinopathy.

Conventional Print Poster Presentations

CP-MH25 Warm-up and Recovery

ANALYSIS OF SPORT RECOVERY METHODS - EVIDENCE-BASED RECOMMENDATIONS

VUINOV, O., BALANEAN, D.

WEST UNIVERSITY OF TIMISOARA

INTRODUCTION: Recovery from intense physical exertion is essential for athletes to maintain performance and prevent overtraining or injuries. Various active and passive recovery methods, such as hydrotherapy, massage, compression garments, and stretching, aim to reduce fatigue and muscle soreness. However, the optimal application of these strategies remains unclear, and practical guidelines for athletes and coaches are still debated.

METHODS: The review analyzes 120 studies from peer-reviewed journals indexed in PubMed, Clarivate Analytics, Scopus, ScienceDirect, and the Cochrane Library, published over the last five years, with a focus on high-performance sports research. Studies include randomized controlled trials (RCTs), crossover trials, case-control, cohort, and longitudinal studies to ensure methodological rigor. Active recovery methods such as stretching and low-intensity exercise are compared with passive strategies like cold-water immersion (CWI), sleep, relaxation techniques, and nutrition. All included studies provide practical recovery guidelines.

RESULTS: Active recovery timing and type significantly influence performance and injury prevention. Prolonged static stretching (>60s per muscle) can impair strength, while dynamic stretching (20–30s) may offer benefits. Passive recovery methods, such as CWI, affect muscle recovery and nerve function by altering ion exchange, slowing action potential generation, and reducing contraction speed. Cryotherapy, including CWI and ice packs, provides small but consistent benefits 48–96 hours post-exercise.

CONCLUSION: Evidence-based recommendations highlight active recovery techniques, like low-intensity exercises, for improving blood flow, lactate clearance, and endurance. Passive methods, including massage, compression garments, and water immersion, effectively reduce fatigue and muscle soreness. Recovery strategies should be tailored to individual needs, sport-specific demands, and exercise intensity. Further research is needed to refine long-term guidelines for athletic recovery.

THE EFFECT OF THE FIFA+ WARM UP PROGRAM ON KNEE INSTABILITY AND MOTOR PERFORMANCE IN YOUTH SOCCER PLAYERS.

SOUSSI, B., HORVATH, T., LACZA, Z., AMBRUS, M.

UNIVERSITY OF PHYSICAL EDUCATION OF BUDAPEST

INTRODUCTION: This study aimed to investigate the effect of the FIFA+ warm up program on knee instability and motor performance in youth soccer players

METHODS: Thirty youth soccer players were divided into two groups: the experimental group (FIFA+) performed the FIFA+ program for 10 weeks, while the control group followed their usual warm-up routine. Dynamic knee valgus (DKV) and squat depth were assessed using a Microsoft Azure Kinect camera and dynaknee software. Maximal isometric muscle

force was measured with a dynamometer. The Y Balance test was used to evaluate dynamic balance, while a counter-movement jump test assessed lower limb power. The knee range of motion was measured with a goniometer, and the T-test was used to evaluate agility

RESULTS: After the intervention, the FIFA+ group showed a significant decrease in DKV and squat depth ($p < 0.01$), while the control group showed no significant changes ($p > 0.01$). Both groups improved in motor performance, with slight progress noted in the FIFA+ group. However, neither group demonstrated significant improvement in dynamic balance ($p > 0.01$)

CONCLUSION: While the FIFA+ program may not substantially enhance overall motor performance or match the effectiveness of other training regimens, it shows potential for addressing biomechanical deficiencies and reducing the risk of injuries, particularly those related to dynamic knee valgus.

ACUTE EFFECTS OF MASSAGE ON STIFFNESS OF THE MEDIAL GASTROCNEMIUS AND ITS FASCIA: RELATIONSHIP TO THE THICKNESS OF MUSCLE AND SUBCUTANEOUS FAT

ITO, R., TAKAHASHI, K., KAWAMA, R., WAKAHARA, T.

1:DOSHISHA UNIVERSITY 2:KYOTO TANABE MEMORIAL HOSPITAL

INTRODUCTION: Massage is widely used in clinical and sports settings. However, it remains controversial whether massage decreases tissue stiffness (muscle and fascia). Some studies reported that massage decreased the stiffness of muscle (1) or deep fascia (2), but others reported no effect on the stiffness of muscle (3) or aponeurosis (2). In massage therapy, the fingers of the therapist apply mechanical stress to the muscle and fascia through the superficial tissues. This suggests that massage effects were affected by the thicknesses of superficial tissue covering the muscle and the muscle itself. Therefore, this study aimed to examine the acute effects of massage on muscle and fascia stiffness of the medial gastrocnemius (MG) and its fascia and their relationships with muscle thickness (MT) and subcutaneous fat thickness (SFT).

METHODS: The participants were 14 healthy adults (8 males and 6 females). Massage was applied by a physical therapist with its intensity was subjectively standardized across participants as much as possible. No intervention was applied on another day as a control condition. The intervention period was 11 min [massage for 2 min $\times$ 4 sets with a 1 min interval]. The shear modulus of MG, shear wave velocity of MG fascia, ankle joint dorsiflexion ROM, and passive torque were measured before (Pre), immediately after (Post1), and 30 min after (Post2) the intervention. The MT and SFT were measured using an ultrasound imaging device at Pre. Data were analyzed using the Friedman test, post hoc Wilcoxon signed-rank test with Bonferroni corrections, and Spearman's rank correlation coefficient.

RESULTS: The shear modulus of MG was significantly increased from Pre to Post1 (+1.3 kPa [median difference], $p = 0.011$) in the massage condition, but not in the control condition. The main effect of the time was not significant for the ankle joint dorsiflexion ROM, passive torque, or the shear wave velocity of MG fascia in the massage or control conditions. Additionally, there were no significant correlations between the changes in the shear modulus of MG and MT ($\rho = -0.238$, $p = 0.413$), SFT ($\rho = -0.253$, $p = 0.382$) or MT+SFT ($\rho = -0.306$, $p = 0.288$) in the massage condition.

CONCLUSION: Our results indicate that massage can increase muscle stiffness irrespective of MT and SFT, which is contrary to the prevailing belief. A possible explanation for the increase in shear modulus is inflammation (4) induced by massage. The present findings suggest that athletes and therapists should understand the possibility of an increase in muscle stiffness immediately after massage.

A STRUCTURED 7 MINUTES WARM-UP PROGRAM FOR PADEL PLAYERS

ARRIAZA, R., HERNANDEZ-VAZQUEZ, C., ARRIAZA, C., FERNANDEZ-ROMERO, J.J.

UNIVERSITY OF A CORUÑA

INTRODUCTION: Padel is considered as the fastest-growing sport in the world. Female players make up 37.5% of recreational players and 54% of padel players are 26 years old and above. It is fun, and easy to play, which makes it very attractive for people who either has never practiced sport or who quit sport long time ago and consider it as a sport without risk of injury or physical requirements. According to our studies, less than 50% of padel players perform some kind of warm-up before playing, and one of the reasons argued is that the court is usually occupied by the players of the previous match, and that renting the court is too expensive to waste time warming-up instead of playing.

METHODS: A web search was done in order to find if there is scientifically sound information for amateur player on the subject "Warm-up for padel". Almost no sites included the different phases of a structured program, and were not specific for padel: most of them referred to stroke practise in the court. To solve this problem, we have designed a 7 minute warm-up program (the INCIDE padel warm-up) that can be completed in the aisles surrounding the courts. In this way, the players could enter the court ready to practise the different racket strokes for specific technical warm-up and start playing.

RESULTS: Phase 1: General Mobility (2 minutes) 1. Mobility for Spine and Shoulders (2 minutes) - Arm Circles: 30 seconds (15 seconds forward and 15 seconds backward). Forward lung with shoulder sweep (15 repetitions on each side). - Lateral Cross over lunge (10 repetitions on each side). - Shoulder Rotations: Raise your shoulders towards your ears and then roll them backward, 10 repetitions

Phase 2: General Activation (2 minutes) 2. Activation Tasks (2 minutes) – Walking heel rise with overhead reach (10 repetitions on each side). Jumping Jacks: 30 seconds. - Front Plank: 30 seconds. (Ensure you maintain good body alignment). - Side Plank: 15 seconds on each side (30 seconds total).

Phase 3: Change of Direction (3 minutes) 3. Change of Direction Tasks (3 minutes) - Light Jogging Forward and Backward: 1 minute. (Run from one end of the hallway to the other, touching the ground at each end). - Lateral Shuffles: 1 minute. (Side movements from one side to the other along the hallway). - In-Place Running with Direction Changes: 1 minute. (Run in place and make a turn every 10 seconds, simulating direction changes during the game).

CONCLUSION: The INCIDE padel warm-up program was tested during the 24/25 padel season, and most of the players found it easy to perform and adequate for their sport level.

The INCIDE padel warm-up program has been uploaded to the Internet to offer a free tool for players who want to use it

PRE-EXERCISE HIGH-INTENSITY LASER THERAPY ALTERS DYNAMIC MUSCLE DISPLACEMENT USING ULTRASOUND SPECKLE TRACKING AFTER FATIGUE: PRELIMINARY RESULTS

HUNG, W., WANG, H.K.

NATIONAL TAIWAN UNIVERSITY COLLEGE OF MEDICINE

INTRODUCTION: Muscle fatigue, defined as a decrease in force or power during intense exercise, raises injury risk [1], highlighting the need for preventive strategies in sports. High-intensity laser therapy (HILT) has been shown to mitigate strength loss from fatigue [2], yet its effects on muscle contractile behaviors—specifically muscle shortening and displacement—remain unclear. Research using ultrasound speckle tracking (UST) has linked muscle displacement to isometric contractions [3], showing reduced displacement during fatigue [4]. However, the potential of pre-exercise HILT to counteract these changes has not been thoroughly explored. This study hypothesizes that pre-exercise HILT can attenuate declines in muscle displacement and force loss from fatigue, as assessed through UST.

METHODS: Eight healthy males (23.44 ± 1.59 years) received HILT with a Class 4 laser (900 J) and a sham treatment on two separate days, in randomized order. After each treatment, participants performed concentric knee extensions at $60^\circ/\text{s}$ to induce fatigue. Before and after fatigue, maximal voluntary isometric contraction (MVIC) knee extensions were performed on an isokinetic dynamometer, measuring muscle displacement and peak torque. Ultrasound imaging quantified vastus lateralis displacement (mm) and MVIC decline (%). Two-way repeated measures ANOVA and paired t-tests analyzed muscle displacement and strength loss.

RESULTS: A significant time-treatment interaction was found for muscle displacement ($p = 0.03$). Displacement differed between HILT and sham both pre- and post-fatigue ($p = 0.033$ and $p = 0.001$, respectively). The post-fatigue displacement change was lower with HILT (2.12 ± 1.6 mm) than sham (3.43 ± 1.15 mm, $p = 0.03$). MVIC declined less with HILT ($17.75 \pm 12.86\%$) than sham ($30.61 \pm 17.29\%$, $p = 0.007$).

CONCLUSION: Preliminary findings suggest HILT reduces fatigue-induced declines in muscle displacement and strength. Muscle contractile decline post-fatigue may stem from inadequate blood flow. Laser-induced vasodilation could enhance contractility, minimizing strength loss. Future research should explore whether muscle displacement serves as a marker for force loss post-fatigue.

NEUROMUSCULAR PRIMING WITH SPINAL CORD TRANSCUTANEOUS STIMULATION: EFFECTS ON LOWER LIMB MOTOR PERFORMANCE

ZACCARON, S., MARI, L., DALLEVA, M., STAFUZZA, J., PARPINEL, M., LAZZER, S., REJC, E.

UNIVERSITÀ DEGLI STUDI DI UDINE & UNIVERSITÀ DEGLI STUDI DI VERONA

INTRODUCTION: Neuromuscular priming strategies can be implemented to enhance muscle strength and power generation [1], which are critical determinants for daily life activities and athletic performance. However, the effects of non-invasive spinal cord transcutaneous stimulation (scTS) on motor control and neuromuscular performance in healthy subjects are not known. Therefore, the aim of this study was to investigate the effects of an exercise-based priming protocol combined with scTS on the neuromuscular performance of lower limbs in young active males. We also evaluated how scTS alone influenced lower limb motor performance.

METHODS: Twelve volunteers (age: 22.7 ± 2.1 years) participated in this randomized crossover, sham-controlled study. Maximal voluntary contraction of the knee extensors (MVC) and maximal explosive power of the lower limbs were assessed at baseline, with scTS or sham stimulation, and after the priming protocol with scTS or sham across four experi-

mental sessions. Further, characteristics of evoked potentials to scTS related to spinal circuitry excitability were assessed in supine position before and after the scTS priming protocol. The exercise component of the ~25-minute priming protocol was characterized by low-volume, low- and high-intensity lower limb motor tasks.

RESULTS: We found trends toward enhanced mechanical outputs following the scTS priming protocol, whereas the sham priming protocol was associated with reduced neuromuscular performance. This resulted in a 9% difference between the scTS and sham priming protocols during MVC of knee extensors ($p=0.002$). Similarly, for maximal explosive power, the mean differences in peak force and rate of force development (RFD) were 3.1% and 21.1%, respectively ($p = 0.019$ and 0.002 , respectively). Conversely, no significant differences were observed between baseline and maximal efforts performed with scTS or sham for any of the investigated variables (p values between 0.850 and 0.465). Furthermore, assessment of evoked potentials to scTS in supine showed a trend of increased excitability after scTS priming protocol.

CONCLUSION: scTS priming protocol enhanced the performance of lower limb maximal efforts when compared to the sham priming protocol. This is associated with trends of increased spinal excitability after the scTS priming protocol. Positive effects of scTS priming protocol on maximal neuromuscular performance might be related with spinal excitability modulation that brings neural networks closer to the activation threshold and amplifies descending neural drive during exercise. No effects of scTS alone might be related to the interference of stimulation with neural processes (2).

ACUTE EFFECTS OF NERVE GLIDING VERSUS STATIC STRETCHING ON STIFFNESS AND STRENGTH AT HIGH AND MODERATE STRETCH AMPLITUDES.

HITIER, M., VIEIRA, D., DURIGAN, J.L.Q., BABAU, N.
UNIVERSITÉ DE BOURGOGNE EUROPE

INTRODUCTION: Acute stretching effects have widely been studied in the literature. However, the mechanisms and structures involved in stretch tolerance remain poorly understood (1). While muscle structures play a key role, other factors are also implicated such as fascia and nervous tissue (2). This study investigated stretching modalities targeting specific anatomical structures (nerves or muscles) at different intensities (at pain threshold and 10% below). The objective is to determine whether nerve-targeted stretching can contribute to reducing muscular and/or neural stiffness and to increasing the range of motion without affecting force production.

METHODS: 21 physically active volunteers (12 women and 9 men) participated in this randomized crossover study. Experimental sessions involved stretching exercises in five conditions: static stretching, nerve gliding flossing performed both at pain threshold and 10% below, and a control condition where participants rested passively.

The static stretching protocol included five 60-seconds sets, while nerve gliding flossing was comprised of five 30-repetitions sets at 0.5 Hz combining dorsiflexion/plantar flexion and cervical spine flexion/extension. Testing included maximal voluntary isometric contractions of the right hamstrings, EMG measurements of biceps femoris (BF) and semitendinosus (ST), passive knee extension (PKE), Stand and Reach test (SR), and ultrasound elastography to measure shear wave velocity of the right sciatic nerve and BF. A two-factor ANOVA was used to compare effects before and after the interventions.

RESULTS: No significant interaction between condition and time was observed for maximal torque ($p= 0.971$) or EMG activity of the BF ($p = 0.381$) and ST ($p = 0.553$). The control condition had no significant effect on amplitude, whereas all stretching modalities demonstrated a time-dependent improvement. For both PKE and SR, the amplitude increased immediately after the experimental session ($p < 0.001$). Shear wave velocity of the BF muscle significantly decreased after stretching ($p= 0.003$), with no significant differences between conditions ($p= 0.433$). However, the sciatic nerve shear wave velocity decreased over time only in the nerve gliding flossing at pain threshold condition ($p < 0.001$).

CONCLUSION: All stretching modalities increased the amplitude without significantly affecting strength. However, nerve gliding flossing induced an additional performance gain by reducing shear wave velocity on the nerve, suggesting that stretch tolerance may be partly modulated by nerve properties. Therefore, nerve gliding flossing could be as critical as muscle stretching in optimizing both amplitude and strength, making it an important part of sports training protocols.

DEVELOPMENT OF A NEW INDEX OF RECOVERY AFTER SPORTS INJURY: EXCITABILITY OF CENTRAL NERVOUS SYSTEM FUNCTION DURING MUSCLE STRENGTH ADJUSTMENT.

OKAYAMA, Y., DAIKUYA, S.
HOKURIKU UNIVERSITY

INTRODUCTION: Tissue healing, muscle strength, range of motion, and performance tests are often used to assess return to play after sports injuries. However, muscle strength itself can sometimes cause injury, and a smaller range of motion may be beneficial in sprinting. Therefore, these may not be sufficient for recovery and return to play. Additionally, standard performance tests may fail to evaluate the complex motor skills needed in sports. As a preliminary step in developing objective indicators for determining return to play, this study aimed to investigate the excitability changes in central nervous function (CNS) during muscle output regulation under different feedback methods among athletes, as well as to examine the characteristics of cases where athletes have not yet returned to play after a sports injury.

METHODS: The study involved 13 female university basketball players. Of these, 12 were participating in the sport without any issues, and 1 (Case), three months post hemilateral meniscal repair, was unable to run. Using the BIODEX System 4 (Biodex), participants were seated with the knee flexed at 60 degrees and were asked to maintain 25% of the maximum effort of voluntary isometric contraction of knee extension for 60 seconds. During torque maintenance, a mixed-nerve silent period (SP) was derived from the ipsilateral opponens pollicis muscle using a Neuropack (Nihon Kohden). SP was recorded 16 times by applying electrical stimulation to the median nerve at the wrist while the participant lightly held a rubber ball to induce slight contraction in the opponens pollicis muscle. The electrical stimulation conditions were a supra-maximal intensity, a frequency of 0.5Hz, and a duration of 0.2msec. Torque maintenance was performed under two conditions: visual feedback (A) and verbal instructions from the examiner (B), in the order of A-B-A. The duration of the 16 recorded SPs was measured, and their average was used as the representative value for each condition. Statistically, the Shapiro-Wilk test was used to confirm normality, followed by the Wilcoxon signed-rank test, with a significance level set at 5%.

RESULTS: SP (ABA) for the dominant leg were 109.5 ± 10.5 ms, 106.3 ± 7.5 ms, and 109.6 ± 7.3 ms, and that for the non-dominant leg were 104.9 ± 5.9 ms, 103.2 ± 6.5 ms, and 105.7 ± 6.6 ms, with no significant difference ($n=12$). In Case, similarly, the injured leg had SP of 113.3ms, 123.7ms, and 115.2ms, and the non-injured leg showed SP of 111.7ms, 110.8ms, and 103.3ms.

CONCLUSION: In this study, the excitability of the upper CNS in athletes did not change based on the feedback method, unlike a previous study where verbal instructions increased CNS excitability in non-exercising individuals. However, in Case A, where movement acquisition was delayed, the results differed not only from the athletes but were also the opposite of those found in non-exercising individuals in the previous study. The results of this study suggest that individuals who have not achieved smooth recovery post-sports injury may experience changes in CNS excitability dynamics during muscle output regulation. This indicates the potential of using neurophysiological tests, such as those involving evoked electromyography, as one indicator to evaluate recovery progress after sports injuries.

DOES THE EFFECT OF BODYWEIGHT RESISTANCE TRAINING ON THE 30-SECOND CHAIR STAND TEST RELATE TO MUSCLE STRENGTH, MUSCLE MASS, AND LOCOMOTIVE FUNCTION?

SAWADA, S., MU, J., LIU, Z., IMAI, K., NAITO, H., MACHIDA, S.

JUNTENDO UNIVERSITY

INTRODUCTION: The 30-second chair stand test (CS-30) has been reported to be useful for evaluating lower limb muscle strength and sarcopenia in older people [1,2], and we also reported at ECSS 2024, that the CS-30 score is associated with gait speed. We also have previously reported that 12 weeks of bodyweight-based resistance training improves muscle mass, muscle strength, and locomotive function [3, 4]. In this study, we aimed to verify the effect of resistance training on improving the CS-30 score and to clarify the relationship with changes in other factors.

METHODS: Fifty-two community-dwelling Japanese people aged ≥ 60 years (72.0 ± 5.4 years) were divided into a training (TR) group and a control (CTR) group. The TR group participated in a 12-week exercise class that included resistance training once per week and were instructed to perform the same training at home once per week. In contrast, the CTR group were instructed to maintain their daily activities.

Physical fitness measurements were performed before and after the 12-week intervention period, including the CS-30, maximum gait speed, isometric knee extension strength, and body composition assessment using the InBody 770. The body composition assessment focused on lower limb muscle mass and phase angle (PhA).

Two-way ANOVA was used to determine training effects and for multiple regression analysis, the rate of change in the CS-30 was used as the objective variable, and the rates of change in gait speed, isometric knee extension strength, lower limb muscle mass, and lower limb PhA were used as explanatory variables.

RESULTS: Two-way ANOVA revealed that time was a significant main effect for CS-30 ($p < 0.001$), but there was no significant main effect between groups ($p = 0.44$) or interaction ($p = 0.80$), and the TR and CTR groups improved. Multiple regression analysis revealed that the rate of change in isometric knee extension strength, corrected for lower limb PhA, was the only significant explanatory variable in the CTR group ($\beta = 0.50$, $p < 0.01$), with a statistically significant regression (adjusted R-squared = 0.22, $p < 0.01$). There was no statistically significant regression in the TR group.

CONCLUSION: CS-30 improved significantly in the TR and CTR groups before and after the 12-week intervention; however, the related factors are thought to be different. This suggests that improvement in the CTR group was influenced by an improvement in maximum muscle strength in isometric knee extension. Moreover, since no variables showed a significant association in the TR group, it is possible that the improvement in CS-30 due to resistance training using body weight involves changes in factors other than maximum muscle strength in isometric knee extension, muscle mass, and locomotive function.

IMPACT OF A 12-WEEK TRX-BASED MULTICOMPONENT EXERCISE PROGRAM ON SARCOPENIA IN OLDER ADULTS: A PILOT STUDY

EBRAHIMPOUR NOSRANI, S., REZAEI, S., MATEUS, A., BAUTMANS, I., TEIXEIRA, A.

1. UNIVERSITY OF COIMBRA 2. Vrije Universiteit Brussel

INTRODUCTION: Sarcopenia is undoubtedly one of the most defining aspects of aging, significantly affecting both health and quality of life. This condition is marked by a progressive decline in muscle mass and strength, which negatively impacts physical performance. Promoting healthy aging requires a focus on maintaining muscle mass and strength, with regular exercise being an effective prescription for improving physical function. It has shown that multicomponent exercise programs yield superior outcomes compared to concurrent exercise programs in older adults, enhancing various physical fitness measures [1]. To comprehensively address sarcopenia, it is crucial to incorporate a combination of aerobic, resistance, and balance training. In this context, we have developed a multicomponent exercise program that uniquely integrates TRX suspension exercises as a resistance training component. We hypothesize that a 12-week multicomponent exercise program will not only enhance daily physical performance but also improve appendicular skeletal muscle mass index (ASMMI) and grip strength in older adults with sarcopenia.

METHODS: This is a pilot study aimed at assessing the feasibility and initial effects of an exercise intervention on muscle quantity and quality. Twenty-one women (77.24 ± 9.53) were randomly assigned to two groups: the multicomponent exercise group (EG; $n = 12$) and the control group (CG; $n = 9$). Body composition and physical performance were evaluated before and after training using the Short Physical Performance Battery (SPPB), Timed Up and Go (TUG) test, and a Jamar hydraulic dynamometer. Body composition was assessed via the Akern 101 bio-impedance analysis system.

RESULTS: Univariate ANCOVA analyses, controlling for baseline measurements, consistently demonstrated that the exercise group outperformed the control group in SPPB ($F = 4.688$, $p = 0.046$, $\eta^2 = 0.227$), particularly in TUG performance ($F = 7.410$, $p = 0.014$, $\eta^2 = 0.293$) and walking speed (4-meter test) ($F = 8.031$, $p = 0.011$, $\eta^2 = 0.321$). Regarding sarcopenia indicators, including ASMMI and dominant grip strength, only grip strength showed a significant difference between the exercise and control groups after baseline adjustments ($F = 6.863$, $p = 0.019$, $\eta^2 = 0.271$). Notably, the control group experienced a decline in grip strength over time. The paired t-test revealed a significant increase in ASMMI in the exercise group, while the control group did not show any significant change.

CONCLUSION: In conclusion, this pilot study provides promising evidence for the efficacy of a 12-week multicomponent exercise program in improving both physical performance and sarcopenia-related outcomes in older adults. The incorporation of TRX exercises, proved to be an effective strategy and feasible with older adults.

HIGH-INTENSITY INTERVAL TRAINING ENHANCES OSTEOCALCIN LEVELS: A META-ANALYSIS OF EXERCISE EFFECTS ON BONE REMODELLING BIOMARKERS

BARNA, V., MAKOLLI, A., PÁSZTORNÉ BENYÓ, Z., ENGH, M.A., ZOLCSÁK, Á., TEUTSCH, B., SEYMOUR, V., HEGYI, P., PAPP, R., SYDO, N., FERDINANDY, P.

SEMMELEWS UNIVERSITY

INTRODUCTION: The relationship between biomarkers of bone remodelling due to regular exercise is unknown, it cannot be predicted what type and volume of exercise are optimal for bone remodelling. We aimed to quantify the effects of regular training on bone remodelling biomarkers, particularly osteocalcin and bone alkaline phosphatase in healthy adult populations.

METHODS: This study (PROSPERO: CRD42023483811) explored the effects of regular training through a systematic review and meta-analysis and included only randomized controlled trials examining different types (endurance, power, mixed) and intensities, frequency and duration of training. MEDLINE, Embase, and CENTRAL were searched on November 22, 2023. Risk-of-bias and quality assessment were performed by Cochrane RoB2 and GradePro.

RESULTS: 12,828 records were screened, and 22 studies with 1,126 participants were analysed. Endurance training showed no significant effect on osteocalcin level. High- and low-intensity endurance training also did not significantly affect osteocalcin. High-intensity interval training (HIIT) significantly increased osteocalcin levels (MD = 12.00; 95% CI: 8.40 to 15.50). Power training showed no significant change in osteocalcin level. Mixed training (endurance + power) did not significantly change osteocalcin level. Bone alkaline phosphatase showed no significant change following endurance training. Bone Mineral Density showed no significant changes following endurance and power training. Endurance training decreased body mass index, but the result was statistically not significant. The risk of bias for all outcomes was low. Grade assessment for osteocalcin in the HIIT group revealed moderate to low certainty.

CONCLUSION: This study is the first systematic review and meta-analysis that summarizes the results of the currently available randomized controlled trials, investigating the effects of regular training on bone biomarkers in healthy adults,

specifically osteocalcin and bone-alkaline phosphatase. Our study demonstrates that only HIIT significantly impacts osteocalcin levels, whereas other exercise types such as high-intensity, low-intensity, power, and mixed training do not. After the analysis of the training effectiveness in different training frequency and duration we also found that, osteocalcin synthesis is not dependent on duration or frequency but rather intensity. Specifically, we observed significant changes in osteocalcin levels exclusively with high intensity interval training, regardless of whether the training was of short or long duration. Our analysis showed similar patterns in the effect of training on bone-alkaline phosphatase level. Our findings highlight that when the synergistic effect of high intensity, dynamical loading, and rest periods during training were simultaneously present, we observed significant changes in bone metabolism markers, and a strong positive trend in the improvement of body mass index and bone mineral density.

OPTIMIZING BONE-LOADING INTENSITY FOR OSTEOPOROSIS PREVENTION: PROTOCOL FOR AN MHEALTH INTERVENTION IN POSTMENOPAUSAL WOMEN

SAÑUDO, B., TEJERO, S., DOMINGO, R., SÁNCHEZ, A., MARTÍNEZ-MAESTRE, M., FERIA, A., OVIEDO-CARO, M.A., CARRASCO, L., SÁNCHEZ-OLIVER, A., PECCI, J., SÁNCHEZ-TRIGO, H.

UNIVERSITY OF SEVILLE AND HOSPITAL VIRGEN DEL ROCÍO

INTRODUCTION: Osteoporosis poses a global health challenge, particularly in postmenopausal women, due to decreased bone density and increased fracture risk. Physical activity, specifically weight-bearing and impact-loading exercises, is a proven strategy to stimulate bone growth and prevent bone loss. However, identifying and sustaining the appropriate intensity of mechanical loading remains a challenge for individualized intervention. This study presents a protocol for a randomized controlled trial using an mHealth-based approach to assess the impact of exercise intensity on bone health outcomes in postmenopausal women.

METHODS: Participants are postmenopausal women (n=120) aged 50–65 years, randomized into intervention and control groups. The intervention group engages in structured daily physical activity incorporating weight-bearing and impact-loading exercises. Wearable accelerometers measure biomechanical loads, focusing on achieving optimal osteogenic thresholds ($\geq 3.9G$). Intensity and frequency data are personalized and monitored via an mHealth app, which provides real-time feedback and adaptive programming to enhance adherence. Bone mineral density, geometry, and strength are assessed via DXA scans and peripheral quantitative computed tomography (pQCT) at baseline, 6 months, and 12 months. Machine learning models analyze biomechanical data to refine individualized intensity thresholds.

RESULTS: Preliminary testing has validated the accelerometer-based approach to reliably capture impact-loading intensity. Pilot participants successfully maintained the target loading thresholds in over 80% of sessions, demonstrating the feasibility and acceptability of the mHealth platform. Bone-loading patterns correlated positively with improvements in surrogate markers of bone health, including markers of bone turnover.

CONCLUSION: This protocol emphasizes the critical role of personalized exercise intensity in driving osteogenic responses. By leveraging accelerometer technology and mHealth integration, it provides a scalable and adaptive model for osteoporosis prevention. Future results will contribute to the evidence base for individualized bone-loading thresholds, guiding clinical and public health strategies to reduce osteoporosis-related morbidity. This innovative framework highlights the potential of technology-driven interventions to enhance adherence and optimize health outcomes in at-risk populations.

SENIOR FITNESS TEST AS A PREDICTOR OF BONE HEALTH IN OLDER ADULTS

TÓTH, N.

UNIVERSITY OF PÉCS

INTRODUCTION: Osteoporosis poses a significant health risk in older adults, yet reliable and rapid screening methods remain limited. The Senior Fitness Test is widely used to assess physical fitness in older adults, but few studies have explored its relationship with bone mineral density (BMD) and osteoporosis risk. This study aimed to examine the association between Senior Fitness Test performance and BMD and compare BMD values among endurance-trained athletes, resistance-trained individuals, and inactive older adults.

METHODS: A three-year longitudinal study was conducted with 138 adults aged 65+, divided into three groups: endurance-trained athletes (SP, n=46), resistance-trained individuals (RT, n=46), and inactive older adults (IN, n=46). Participants underwent annual DEXA scans to assess BMD at the lumbar spine and femur and completed the Senior Fitness Test, including lower-body strength (Chair Stand Test), dynamic balance (8-Foot Up-and-Go Test), and aerobic capacity (2-Minute Step Test). Osteoporosis risk factors were assessed based on prior fractures and fall history.

RESULTS: A significant correlation was found between Senior Fitness Test performance and BMD. Chair Stand Test and 8-Foot Up-and-Go Test scores positively correlated with BMD ($r=0.68$, $p<0.01$), while flexibility tests showed no significant association ($p>0.05$). The RT group exhibited the highest BMD values, whereas no significant difference was found between the SP and IN groups ($p=0.12$). In the SP group, femur BMD was 7.1% lower compared to the RT group ($p<0.05$), particularly among those who did not incorporate resistance training into their regimen.

CONCLUSION: Our findings suggest that Senior Fitness Testm particularly Chair Stand Test and 8-Foot Up-and-Go Test, may serve as effective predictors of BMD and osteoporosis risk. This indicates that Senior Fitness Test could be a rapid and cost-effective screening tool for assessing bone loss in older adults. Furthermore, our results highlight that endurance training alone may not be sufficient for maintaining BMD, whereas resistance training appears to play a crucial role in bone mass preservation.

AGE RELATED-SEX DIFFERENCES IN CARDIOVASCULAR RESPONSES TO ECCENTRIC CYCLING : PRELIMINARY OUTCOMES OF THE SWEETEXC STUDY

CARLET, T., GARNIER, Y.M., MOUROT, L., SERONDE, M.F.

UR SINERGIES

INTRODUCTION: Endurance exercises are well-documented to improve cardiorespiratory fitness that reduces overall mortality, including in elderly and pathological populations. However, traditional exercises such as locomotor activities (e.g. walking, cycling) are mainly used in their concentric muscle contraction form, but may prevent deconditioned people from achieving sufficient levels of muscle mechanical tension. Eccentric cycling seems to be a promising alternative in a clinical context as it requires less oxygen uptake than traditional cycling for greater muscle stimulation. While the neuromuscular approach has been largely studied, the evolution of cardiovascular responses during eccentric cycling as a function of age and sex remains unexplored. We hypothesize that the rate pressure product (RPP = Heart Rate*Systolic Blood Pressure) is a reliable easy-to-monitor indicator for prescribing the intensity of eccentric cycling.

METHODS: 9 healthy young and old people have so far been included in this study (14 are currently included). The first visit was an incremental test to determine concentric maximal aerobic power on a semi-recumbent seated cycle (MAPCON). After familiarisation, eccentric cycling consisted of 5-minute stages at 5 intensities (40%, 55%, 70%, 85%, 100% of MAPCON) performed at 40 rpm. A non-invasive blood pressure device (Finapres Medical Systems, Chennai, India) and a 3-lead electrocardiogram were used to collect hemodynamic responses and heart rate, respectively.

RESULTS: The higher the intensity, the greater the hemodynamic responses and heart rate. All responses tended to be proportional to intensity, whether the heart rate (100%MAPCON : 110.2 ± 8.6 bpm; 70% MAPCON : 102.9 ± 10.4 bpm; 40%MAPCON : 82.8 ± 12.0 bpm), systolic blood pressure (100%MAPCON : 171.6 ± 12.6 mmHg; 70% MAPCON : 156.6 ± 16.2 mmHg; 40%MAPCON : 149.8 ± 8.4 mmHg), or cardiac output (100%MAPCON : 10.5 ± 2.9 L.min⁻¹; 70% MAPCON : 10.2 ± 2.2 L.min⁻¹; 40%MAPCON : 6.2 ± 0.9 L.min⁻¹). As a result, RPP showed a similar increase (100%MAPCON : 10.5 ± 2.9 L.min⁻¹; 70% MAPCON : 8.2 ± 1.7 L.min⁻¹; 40%MAPCON : 6.2 ± 0.9 L.min⁻¹), with no threshold since a linear increase seems to be apparent with the intensity increments ($R^2=0.988$).

CONCLUSION: These preliminary data do not allow further investigation or comparisons between groups. However, eccentric cycling appears to be a safe and tolerated alternative when performed at submaximal intensity. Its consideration in the clinical context may be relevant for population with severely limited exercise capacity.

OUTCOME DEFICITS IN FEMALE ATHLETES AT 8-12 MONTHS FOLLOWING ACL RECONSTRUCTION

PHAN, L., SOKOLOSKI, M., ANABLE, N., DOBSON, N., DOUTHIT, T., LAPLANTE, S., LOWREY, J., ABT, J.

CHILDRENS HEALTH ANDREWS INSTITUTE

INTRODUCTION: Female athletes face a 2-8 times higher likelihood of sustaining an ACL injury compared to their male counterparts. Reinjury rates following ACL reconstruction (ACLR) are notably high, ranging from 20-30%. Decisions on return to sports (RTS) are often based on time rather than objective measures. Current RTS testing for ACL injuries primarily assesses quadriceps strength and hop test symmetry, overlooking crucial performance gaps and asymmetries that are vital for athletic success. Rehabilitation and RTS protocols have predominantly been developed using male-centric models, which do not fully address the unique biomechanical and neuromuscular factors that influence recovery and performance in females. This study explored the differences between genders in ACL RTS testing, incorporating patient-reported outcomes (PROs), balance, strength, and single-leg (SL) jump performance metrics.

METHODS: Athletes who were 8-12 months from ACLR surgery and aged 15-17 years (N= 55; female = 31, male = 24) performed an ACL RTS test battery that included PROs (GRIT, IKDC, ACL-RSI), y-balance, SL hop, SL triple hop, SL counter-movement jump (CMJ) using force plates, and isokinetic dynamometry.

RESULTS: A Principal Component Analysis (PCA) identified key variables that differentiate ACLR athletes. Principal component one (PC1) explained 25% of the variance that was primarily driven by the involved limb in SL hop (female = 110.6 ± 26.83 cm; male = 151.6 ± 30.73 cm), SL CMJ jump height Imp-Mom (female = 8.9 ± 3.06 cm; male = 14.2 ± 4.37 cm), peak power (female = 22.2 ± 3.85 W/kg; male = 29.1 ± 5.65 W/kg), concentric impulse (female = 82.2 ± 18.76 Ns; male = 124.8 ± 26.09 Ns), and peak landing force (female = 29.7 ± 4.69 N/kg; male = 35.7 ± 5.82 N/kg). Uninvolved limbs, as well as isokinetic quad and hamstring strength (60 deg/s), and SL triple hop, contributed to a small proportion of the variance. There were no differences in PROs and y-balance.

CONCLUSION: Significant gender differences in neuromuscular performance extend beyond the affected limb, reflecting both local and systemic adaptations that occur 8-12 months following ACLR. Force plate testing revealed critical neuromuscular deficits that are frequently overlooked in standard RTS protocols for ACL rehabilitation that do not incorporate force plate testing. These deficits involve gender-specific variations with asymmetry across the sequence of a CMJ (concentric impulse, peak power, and landing force), implying training gaps in force application, propulsion, and landing mechanics. This may be a result of a younger training age in which these athletes have less experience with strength

training and plyometrics that would address neuromuscular control and proper biomechanics. Female athletes may require additional focused interventions during rehabilitation to address more aspects of neuromuscular performance due to their lower training ages and different levels of competition.

EXERCISE PREHABILITATION BEFORE ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION – A SINGLE-BLINDED RANDOMIZED CONTROLLED TRIAL

ABEL, R., NIEDERER, D., GLOWA, A., HANSEN, N., WILKE, C., OFFERHAUS, C.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Although the effectiveness of preoperative training before anterior cruciate ligament (ACL) reconstruction is well-established, there is ongoing debate regarding its optimal structure, including the specific components, degree of supervision (one-on-one guidance or self-administered training) and overall framework. This study evaluated the effectiveness of an individually tailored, adaptive, guided, structured, and criteria-based preoperative rehabilitation program in contrast to a non-guided, self-administered home training program in individuals with an ACL rupture.

METHODS: Participants with an unilateral complete ACL rupture, scheduled to an arthroscopic ACL-reconstruction with a hamstrings or quadriceps autograft in >3 weeks after inclusion were included. They were investigator-blinded block-randomised using an 1:1 allocation to one of the following groups: intervention group (structured, criteria-based, guided prehabilitation training) and comparator group (non-guided, self-administered home training). After ACL reconstruction, patients of both groups participated in a standard, postoperative rehabilitation program. Self-reported knee function (KOOS sum score) was the primary outcome and assessed at six specified time points: during the initial anamnesis in the hospital (t1), 1-7 days prior to ACL reconstruction (t2), and at 30 (t3), 60 (t4), 90 (t5), and 180 (t6) days postoperatively. The analyses were conducted based on an intention-to-treat basis, linear mixed models for the change scores to t1 were calculated.

RESULTS: In the 114 enrolled participants (mean age $M = 31.03$ years, $SD = 10.30$ years; 47% males, 53% females), the ACL rupture injuries occurred while playing football (37%), while skiing (26%), others (37%). After study commencement, 59 participants discontinued intervention or withdrew consent during the course of the study. The intervention group (KOOS score M1: mean = 46.04, 95% confidence interval = [45.07 to 47.02]; M2: 58.52, [57.51 to 59.54]) demonstrated a more pronounced preoperative improvement from t1 to t2 in the KOOS score compared to the comparator group (KOOS score M1: 51.01, [50.10 to 51.92]; M2: 59.18, [58.40 to 59.96]). The interaction (group*time) of the KOOS score reached significance for the change score from t1 to t3 ($p = 0.039$) and to t5 ($p = 0.039$).

CONCLUSION: An individually tailored, adaptive, guided, structured, and criteria-based preoperative rehabilitation program improved perceived knee function more than self-guided training. However, the evidence is limited as the effects are small. Self-administered training presents the challenge of maintaining self-motivation due to the absence of structured scheduling and personal guidance while guided training is more structured and more accountable.

MEDIAL MENISCUS EXTRUSION BEFORE AND AFTER 30-MIN RUNNING IN INDIVIDUALS WITH MENISCUS SURGERY, ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION, AND HEALTHY CONTROLS

KANG, E., KIM, J., PARK, J.

KYUNG HEE UNIVERSITY

INTRODUCTION: While medial meniscus extrusion (MME) is one of the potential contributors to developing knee joint complications, the relative degree of MME and its response to running in individuals with a history of knee joint surgery remain unclear. This study evaluated whether the MME in individuals with meniscus surgery, anterior cruciate ligament reconstruction (ACLR), and healthy individuals differ before and after 30-min of treadmill running.

METHODS: A total of 63 subjects (21 individuals each in meniscus surgery: 30.0 years, 172.5 cm, 74.4 kg, time since surgery: 47.9 months; ACLR: 27.0 years, 174.2 cm, 76.2 kg, time since surgery: 44.4 months; and healthy control: 24.9 years, 171.3 cm, 68.7 kg). Ultrasonographic images using a 12 MHz linear probe (gain: 20 Db; dynamic range: 50 dB; frame rates: 30 fps; depth: 3 cm) of the MME in the supine and standing positions [1] were obtained before and after 30-min of treadmill running at a self-selected moderate intensity (running speed to correspond to the Borg's Perceived Rate of Exertion of the 5-6 /10 scale) [2]. Running speed, heart rate, and step count were compared between groups to assess running intensity. Data were analyzed using analysis of variance and Tukey-adjusted post hoc tests ($p < 0.05$) with effect sizes (d).

RESULTS: MME in the supine position was different (group by time: $F_{2,60} = 8.00$, $p = 0.0008$) that individuals with meniscus surgery showed a 13% increase in MME after running ($p = 0.01$, $d = 0.57$). MME in the standing position was different (group by time: $F_{2,60} = 3.42$, $p = 0.04$), but Tukey-adjusted pairwise comparisons did not identify any statistical differences ($p > 0.16$ for all tests). Statistical trends were observed that individuals with ACLR showed greater MME than those with meniscus surgery (supine: -16%, $p = 0.09$, $d = 0.68$; standing: -11%, $p = 0.19$, $d = 0.56$) and control group (supine: -12%, $p = 0.10$, $d = 0.68$; standing: -14%, $p = 0.16$, $d = 0.69$) group before running. The running speed ($F_{2,60} = 1.16$, $p = 0.32$), heart rate ($F_{2,60} = 0.70$, $p = 0.50$) and step count ($F_{2,60} = 1.92$, $p = 0.16$) during 30-min treadmill running did not differ between groups.

CONCLUSION: While limited data are available on change in MME in response to functional movements, our results provide meaningful clinical insights into MME morphology, suggesting that (1) running activity may immediately induce further extrusion of the medial meniscus in individuals who have undergone meniscus surgery and (2) individuals with ACLR may have greater MME than those with meniscus surgery healthy controls.

CHRONIC EFFECTS OF RESISTANCE TRAINING ON FUNCTIONAL AND CLINICAL OUTCOMES IN INDIVIDUALS WITH PATELLAR AND ACHILLES TENDINOPATHY: A SCOPING REVIEW.

MANIEU SEGUEL, J., PATERNOSTER, F., KONRAD, A., TILP, M.
UNIVERSITY OF GRAZ

INTRODUCTION: Tendinopathy is a disabling and painful condition in athletes, with a prevalence of up to 45% in specific sports like running, basketball, and volleyball [1]. One of its predominant causes is mechanical overuse of the tendon tissue, which can result in repetitive strain beyond physiological limits, resulting in a degenerated and weakened tendon [2]. Eccentric training has been the gold standard of treatment; however, it is pain-provoking leading to maladaptive changes in the excitability and inhibition of the primary motor cortex, resulting in altered movement patterns of the affected muscles [3]. This study is part of a bigger scoping review, that aims to investigate the different outcomes of chronic eccentric training (ECC) and heavy slow resistance training (HSRT) regarding functional, morphological, and clinical outcomes in participants with patellar and Achilles tendinopathy.

METHODS: An electronic search was conducted in three databases (Pubmed, Scopus, and Web of Science). In total, 5460 studies were identified. After removing duplicates (n=1862), two researchers screened the remaining articles by title and, if necessary, by abstract. After extracting the data from the included studies, pain (VAS), VISA questionnaire (Patellar and Achilles), neovascularization, and strength of main muscles were assessed. Values are expressed as weighted mean changes (in percentage) and pooled standard deviation.

RESULTS: after a thorough screening process, 24 studies were included in the review. Eccentric training yielded the highest changes in neovascularization, with a $5.11\% \pm 0.04$ decrease in neovessels in the tendon (HSRT increased by 11.42%). On the contrary, HSRT showed higher gains in strength ($12.06\% \pm 0.14$ vs. 5.79% for ECC) and VISA questionnaire ($36.79\% \pm 0.04$ vs. 34.09% for ECC), and the greatest reduction in pain ($56.16\% \pm 0.06$ vs. 41.74% for ECC). Correlation analyses revealed a strong positive correlation ($r = 0.797$, $p = 0.01$) between neovascularization and pain, for ECC and HSRT combined.

CONCLUSION: Although ECC training showed a decrease of neovessels in the tendon, HSRT had a greater impact on performance and clinical outcomes, representing the main areas of interest in recovery for athletes. Therefore, ECC training seems to have a bigger influence on morphological parameters in the tendon. However, it does not seem to be the best option when returning to pre-injury levels regarding performance and absence of pain, which is the main goal for athletes during tendinopathy rehabilitation.

IMPROVING DECISION MAKING IN ACLR: SHAP ANALYSIS OF A SUPPORT VECTOR MACHINE

VOLMER, J., ROTT, P., HOLLAUS, B., ABERMANN, E., FINK, C.
MANAGEMENT CENTER INNSBRUCK

INTRODUCTION: Treatment of anterior cruciate ligament (ACL) injuries involves various decisions. Most obviously, the type of graft to reconstruct the ACL has to be chosen. In recent years, the lateral extra-articular tenodesis (LET)[1] is regaining more attention, introducing another decision to make. Opting for the LET increases knee rotatory stability and may reduce the re-rupture rate of the ACL [2], but it causes increased surgery and recovery time as well as an elevated risk of limited range of motion [3]. Hence, LET should only be performed when necessary. In this work we seek to develop a data-based recommendation system to aid in this decision-making process.

METHODS: The ACL treatment decision-making process was recorded in a dataset for 500+ patients treated at the Gelenkpunkt Medical Practice. The dataset contains 23 features per patient such as age, gender, posterior tibial slope, pivot shift test results etc. Expert level surgeons judged each patient's condition to determine which graft type should be used and if an LET should be performed. These decisions were stored in the database together with all input features. After normalising and splitting the dataset into training and test parts a support vector machine (SVM) was fitted to predict the LET decision based on the patient's input features. Using Shapley-based explanations, the resulting SVM was investigated to gain insight in the most important features.

RESULTS: The trained SVM obtained the following scores on the test dataset: accuracy: 78%, precision: 63%, F1: 65% and an area under the ROC curve of 86%. Using SHAP analysis the most important patient's features were found to be participation in competitive sports with an average value of 0.19, a high positive pivot-shift test with an average value of 0.17 and gender with an average value of 0.11. Upon inspecting the SHAP values, it is observed that most features contribute positively to the LET decision. Age at surgery is one of the few exceptions, which indicates a younger patient is more likely to receive an LET.

CONCLUSION: The performance of the SVM is satisfactory but leaves room for improvement. The developed methodology of fitting a machine learning model on the decision-making dataset proves promising and could help the development of

new decision-making tools for the LET procedure. These tools could for example be used to help more unexperienced physicians to make better decisions in the ACLR treatment process.

HOW GENU VARUM AFFECTS LOWER LIMB MUSCLE ACTIVITY AND ILIOTIBIAL BAND TENSION IN RUNNERS

KIM, D.

TOKYO SEITOKU UNIVERSITY

INTRODUCTION: Iliotibial band syndrome (ITBS) is the most prevalent running-related injury, characterized by lateral knee pain and affecting approximately 12% of runners annually (Taunton et al., 2002). Several risk factors contribute to increased ITB tension, including gender, knee malalignment, and altered muscle activation (Hamill et al., 2008). ITBS is influenced by both anatomical and neuromuscular factors, with genu varum alignment and impaired muscle activation playing key roles in increasing ITB tension. Understanding these contributing factors can aid in developing targeted prevention and rehabilitation strategies, such as correcting malalignment and optimizing muscle activation patterns to mitigate the risk of ITBS.

This study aimed to identify differences in muscle activity between runners with and without genu varum during running and to explore the relationship between ITB strain and muscle activation.

METHODS: Seventeen healthy recreational female runners participated in the study (genu varum group: GV = 8; normal alignment group: N = 9). Participants ran for 30 minutes while the muscle activity of the gluteus maximus (GMAX), gluteus medius (GMED), and tensor fasciae latae (TFL) was recorded every 10 minutes. ITB strain was measured before and after running. A repeated two-way ANOVA was conducted to examine differences in EMG data between the two groups.

RESULTS: Significant differences in muscle activation were observed between the groups. The GV group exhibited greater muscle activity in the TFL and GMAX compared to the N group. Additionally, only the GV group demonstrated a significant increase in ITB strain after running.

CONCLUSION: These findings suggest that genu varum alignment may lead to increased ITB tension due to greater TFL activation during running. The ITB is influenced by both the TFL and GMAX, as the TFL inserts into the ITB anteriorly, while the lower fibers of the GMAX contribute posteriorly. Genu varum-induced overactivation of the TFL may elevate ITB tension, thereby increasing the risk of developing ITBS. Given that excessive TFL activation may promote hip internal rotation and impose greater tensile stress on the ITB, our findings indicate that the increased ITB strain observed in the GV group was likely a consequence of heightened TFL activation during running.

COMPARATIVE ANALYSIS OF AUTOGRAFT CHOICES IN ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION: IMPLICATIONS FOR MUSCLE STRENGTH RECOVERY AND JOINT BIOMECHANICS

DHAHBI, W., ISSAOUI, W., DERGAA, I., EL OMRI, A., GHRAIRI, M., MOALLA, W.

UNIVERSITY OF JENDOUBA

INTRODUCTION: This study aimed to address critical gaps in the management of anterior cruciate ligament reconstruction (ACLR) by comparing the effectiveness of four autograft types—iliotibial band (ITB), ITB with hamstring tendon augmentation (ITB+HT), hamstring tendon (HT), and bone-tendon-bone (BTB)—on quadriceps and hamstring peak torque recovery (QPT and HPT) and evaluating their impact on knee stability and function through the hamstring-to-quadriceps (H:Q) ratio. We hypothesized that ACLR would improve isokinetic muscle strength six months post-surgery, with the HT graft offering the most balanced recovery.

METHODS: In this prospective cohort study, 42 physically active males (aged 18-40 years) with primary ACL injury underwent ACLR using one of four graft techniques: iliotibial band (ITB, n=16), combined ITB with hamstring tendon (ITB+HT, n=12), hamstring tendon (HT, n=7), or bone-tendon-bone (BTB, n=7). All participants completed a standardized four-phase rehabilitation protocol. Isokinetic muscle strength testing was performed at 60°/s, measuring quadriceps peak torque (QPT), hamstring peak torque (HPT), and H:Q ratio. Statistical analyses included one-way ANOVA, post hoc Holm-Bonferroni tests, effect size estimation, and Bland-Altman plots for agreement assessment.

RESULTS: Significant differences were observed between the BTB group and other groups in QPT (Cohen's d = 3.17-4.63, P < 0.001), HPT (Cohen's d = 1.79-2.66, P < 0.001), and H:Q ratios (Cohen's d = 1.16-2.03, P < 0.001). The BTB group exhibited the highest mean differences in QPT (+133.4 Nm) and HPT (+41.1 Nm) between healthy and injured legs, with substan-

tial limits of agreement. Pearson correlation coefficients between healthy and injured legs were high for QPT and HPT ($r = 0.66-0.88$, $P < 0.001$) but low for H:Q ratios ($r = 0.05-0.25$).

CONCLUSION: The study highlights significant variations in muscle strength recovery among different autograft types, with the BTB graft demonstrating the most pronounced deficits. While all graft types contribute to muscle strength recovery, the HT graft may offer advantages in balancing muscle strength and enhancing knee stability. These findings underscore the importance of individualized rehabilitation protocols tailored to specific graft types to optimize functional outcomes and mitigate re-injury risks. Long-term assessments are crucial for ensuring sustained muscle strength recovery and overall knee health following ACLR.

COMPARISON OF BAREFOOT AND SHOD TRAINING EFFECTS ON FOOT STRUCTURE, MUSCLE STRENGTH, AND SENSORY FUNCTION

HOSONO, S., KEIJI, K.

TOIN UNIVERSITY OF YOKOHAMA

INTRODUCTION: The structure and function of the human foot are critical for maintaining balance and generating propulsion during physical activities. Therefore, improving foot structure and function is essential for injury prevention and the enhancement of athletic performance. Several studies have investigated the effects of training on enhancing foot structure and function. For example, foot exercise training has been reported to alter arch morphology (Holowka et al. 2018) and enhance force-generating capacity (Koyama & Yamauchi, 2023) as well as sensory function (Maemichi et al. 2024). However, evidence suggests that these training effects may be influenced by footwear use. Specifically, individuals who habitually wear footwear that closely mimics barefoot conditions exhibit higher and stiffer foot arches and larger cross-sectional areas of the intrinsic foot muscles compared to those who habitually wear conventional shoes (Holowka et al. 2018). Therefore, differences in training outcomes may arise depending on whether foot-strengthening exercises are performed barefoot or while wearing shoes. Nevertheless, no studies have directly compared the effects of foot training on muscle strength under barefoot and shod conditions. This study investigated how footwear use during training influences foot structure, muscle strength, and sensory function.

METHODS: Healthy adults (20–50 years) participated. Foot length, arch height, toe flexor strength, and sensory perception were measured. Subjects were assigned to a barefoot training group (BARE), a shod training group (SHOD), or a control group (CON), matched for age, height, weight, and measurement variables. Training groups followed a foot and lower limb strengthening program (Koyama & Yamauchi, 2023) for 60 minutes, twice a week, for eight weeks. Measurements were taken once every two weeks. Foot dimensions were measured with a ruler in sitting and standing positions. Toe flexor strength was assessed with a dynamometer, and sensory perception with a Semmes-Weinstein monofilament at seven plantar and two dorsal sites. To control for body composition, arch height was normalized by foot length and toe flexor strength by body weight. Data were expressed as percentage changes from baseline.

RESULTS: After eight weeks, no significant differences were found between BARE and SHOD in most variables, except seated arch parameters. Neither group showed significant changes in arch-related variables or sensory perception. However, BARE significantly increased toe flexor strength at weeks 4, 6, and 8 from baseline and at weeks 6 and 8 from week 2. SHOD showed significant increases at weeks 4, 6, and 8 from baseline. In the CON, no significant changes were observed in any of the measured variables during the training period.

CONCLUSION: Training effects were similar between conditions, but barefoot training appeared more effective for enhancing toe flexor strength.

THE RELATIONSHIP BETWEEN JOINT RESTRICTION AND POSTURAL ADJUSTMENT PATTERNS IN DIFFERENT ANKLE TAPING METHODS

DAIKUYA, S., OKAYAMA, Y.

HOKURIKU UNIVERSITY

INTRODUCTION: For taping in sports, while some studies have evaluated taping effects using a single method, comparisons of different techniques are lacking. This study examined the relationship between taping methods and changes in joint restriction and postural adjustment patterns.

METHODS: This study involved 22 healthy participants classified based on ankle instability. Ankle taping was applied to the non-dominant side (side not kicking the ball) using two methods: a non-elastic tape method (Taping A) and Functional Taping™ (1988), which primarily uses elastic tape to restrict calcaneal inversion and foot supination (Taping B). Measured variables included ankle and foot range of motion (ROM), rearfoot alignment (RA), center of pressure (COP) sway, and %IEMG of the soleus (SOL) and tibialis anterior (TA) during a 10-second single-leg stance. Muscle activation latency (MAL) of SOL and TA in the non-dominant leg was assessed during rapid upper limb raising in quiet bipedal standing. Subjective discomfort of taping was rated using an 11-point Numerical Rating Scale (NRS).

RESULTS: In the group without instability ($n=13$), plantar flexion and dorsiflexion (DF) ROM decreased with both Taping A ($p=0.04$) and B ($p<0.001$) compared with no taping. Eversion ROM ($p=0.03$) and inversion ROM ($p<0.001$) decreased with Taping A compared with no taping. In non-weight-bearing, RA shifted toward eversion in both taping conditions ($p<0.001$). In weight-bearing, all conditions showed eversion, but Taping A ($p=0.01$) and B ($p=0.04$) reduced the eversion angle. NRS scores were higher for Taping A in both rest ($p=0.04$) and motion ($p=0.02$), but discomfort changes from rest to motion did not differ. No significant differences were found in COP sway, %IEMG, or MAL. The instability group ($n=9$)

showed following different results: DF ROM significantly decreased with Taping A compared with no taping ($p=0.001$). NRS scores showed no difference between taping types at rest and in motion. MAL of SOL was significantly prolonged in Taping A ($p=0.03$).

CONCLUSION: Notable findings include the following: In the group without instability, Taping A had a stronger restriction effect. For DF ROM, both taping methods restricted movement in the group without instability, but in the instability group, Taping B showed no restriction effect. For eversion ROM, in the group without instability, the greatest restriction was seen in Taping A, followed by Taping B, and then no taping. However, in the instability group, restriction effects between Taping A and B did not differ. These results indicate that although Taping A provides greater joint restriction, it may risk over-restricting normal motion. In the instability group, Taping A prolonged MAL of SOL, suggesting that it may negatively impact anticipatory postural control during standing.

NORMATIVE ISOKINETIC KNEE STRENGTH VALUES AND PREDICTION MODELS IN NON-ATHLETIC CHINESE ADULTS

LIU, K., MA, Y., HUANG, L.

SHANGHAI SIXTH PEOPLES HOSPITAL

INTRODUCTION: Establishing normative isokinetic muscle strength values and prediction models for knee joints in non-athletic healthy Chinese adults aids in clinical assessments, diagnosis, and rehabilitation. However, there has been limited research on these normal reference values, particularly involving large sample cohorts. Therefore, this study aimed to develop normative reference values and predictive models for knee joint isokinetic muscle strength across different age groups and genders in non-athletic healthy Chinese adults.

METHODS: A total of 2208 participants aged between 20 years old and 70 years old were included in the study. The participants were divided into two groups by gender and further divided into five age groups: 20–29, 30–39, 40–49, 50–59 and 60–69 years old, resulting in a total of 10 groups. Key parameters, including peak torque of knee flexors and extensors, relative peak torque, peak torque ratio of flexors to extensors, peak torque angle and work, were collected using an isokinetic dynamometer at angular velocities of 60°/s and 180°/s. Two-way analysis of variance was utilised to analyse the characteristics and differences of these parameters amongst different age groups and genders. Pearson correlation coefficients were calculated to examine the relationships between these parameters and gender, age, height, weight and body mass index. Predictive models were developed using linear regression and various machine learning techniques.

RESULTS: Males exhibited significantly higher knee isokinetic strength values than females across all age groups, with knee extensor strength 20.47%–38.01% higher and knee flexor strength 22.91%–43.42% higher at both 60°/s and 180°/s. Muscle strength showed a moderate negative correlation with age, indicating a decline with increasing age. Extension strength values were greater than flexion, and measurements at 180°/s were lower compared to 60°/s. The multilayer perceptron regressor demonstrated the highest predictive capability among the models tested.

CONCLUSION: This study provides comprehensive normative reference values and predictive models for knee joint isokinetic muscle strength in non-athletic healthy Chinese adults. The results highlight significant gender and age differences, offering valuable data for clinical assessments and personalized rehabilitation strategies to improve knee joint health and overall quality of life.

CP-MH28 Epidemiology of Injury

RISK FACTORS FOR LOWER EXTREMITY INJURIES IN MALE COLLEGE BASKETBALL PLAYERS

MATSUURA, Y., SUGIMOTO, S., KUMAZAWA, S., OHNO, K., FUJIMOTO, T.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: Basketball is associated with a high incidence of lower extremity injuries, affecting 55–63% of NCAA basketball players (1). Core stability plays a crucial role in injury prevention. For example, a study of Australian football players found that a smaller cross-sectional area of the multifidus muscle was associated with an increased risk of lower extremity injuries (2). However, it remains unclear whether trunk muscle area influences the incidence of lower extremity injuries in basketball—a sport with distinct competitive characteristics. Therefore, the aim of this study was to identify risk factors for lower extremity injuries in collegiate basketball players.

METHODS: Twenty-four male basketball players from a single club participated in the study. An athletic trainer collected sports injury data using injury management software from April to September 2024. Athlete exposure was quantified in “athlete-hours (AH)” (1 AH = 1 hour of practice or competition). Magnetic resonance imaging (MRI) was employed to measure the cross-sectional area of the trunk muscles at their maximal points (L5/S1 for the multifidus, L3/L4 for the quadratus

lumborum, and L4/L5 for the psoas major) (2). Logistic regression analysis was subsequently conducted to identify risk factors for lower extremity injuries.

RESULTS: A total of 23 injury and disability events were recorded, 18 of which involved the lower extremities. The incidence rate was 5.1 lower extremity injuries per 1,000 AH. Both AH and age were identified as significant risk factors for lower extremity injuries. Specifically, the odds ratio (OR) for AH was 1.08 (95% confidence interval [CI]: 1.017–1.167), while the OR for age was 0.35 (95% CI: 0.074–0.991).

CONCLUSION: Our findings suggest that a rapid increase in athlete exposure and younger age are key risk factors for lower extremity injuries among male university basketball players. Notably, 18-year-old athletes exhibited a particularly high injury rate, implying that insufficient adaptation to the competitive environment may contribute to the elevated risk. In contrast, trunk muscle cross-sectional area did not appear to be a significant risk factor for the development of lower extremity injuries.

INTRINSIC RISK FACTORS ASSOCIATED WITH MUSCLE STRAIN LOCATIONS IN JAPANESE FEMALE COLLEGIATE SOCCER PLAYERS

ODA, K., YAMAGUCHI, T., OGAKI, R., MURAKAMI, K.

SENDAI UNIVERSITY

INTRODUCTION: Football is a high-intensity sport involving rapid direction changes, sprints, and technical movements in both sexes.

Female players have higher rates of ACL injuries and ankle sprains than males, with a recent rise in thigh muscle strains. While males mainly sustain hamstring strains during sprinting, females more frequently experience quadriceps strains during kicking, along with hamstring strains. However, the link between strain location and intrinsic risk factors remains unclear. This study aimed to clarify this relationship in female soccer players.

METHODS: A prospective cohort study was conducted on a Japanese women's collegiate football team from 2017 to 2022, which competed in major national tournaments.

Muscle strains sustained during soccer matches and training sessions were recorded. Participants underwent a pre-season medical assessment, which included height, weight, body fat percentage, muscle strength, and flexibility, and injury history (knee ligament injuries, ankle sprains and muscle strains within the past year).

Participants were categorized based on the location of the muscle strain (quadriceps or hamstrings) and associations with pre-season medical assessments and injury history were analyzed. An unpaired t-test was used to compare physical characteristics between groups, while Fishers exact test was applied to analyze differences in injury history ($\alpha = 0.05$).

RESULTS: During the study, 22 quadriceps and 12 hamstring strains were recorded. A comparison of the physical characteristics between athletes with quadriceps and hamstring strains revealed that isokinetic knee flexion strength was significantly higher in the hamstring strain group ($p < 0.05$). Additionally, a history of ankle sprains was significantly associated with an increased incidence of thigh muscle strains ($p < 0.05$).

CONCLUSION: This study showed that players with hamstring strains had significantly higher knee flexion muscle strength. In soccer, hamstring strains may result from sprinting and hip rotational stress caused by ground reaction forces during turning movements. Therefore, strengthening knee flexor muscles, particularly during eccentric contractions, is crucial for preventing hamstring injuries.

Furthermore, the present study suggests that a history of ankle sprains is associated with an increased risk of thigh muscle strains. A history of ankle sprains may not only affect sprinting mechanics but also influence quadriceps function during the kicking motion. Further research is needed to investigate the long-term effects of ankle sprains on thigh muscle function, particularly in female soccer players.

MUSCULOSKELETAL INJURY CHARACTERISTICS AND ACUTE-TO-CHRONIC WORKLOAD RATIOS IN COLLEGIATE HANDBALL: A ONE-YEAR FOLLOW-UP PROSPECTIVE STUDY ACUTE-TO-CHRONIC WORKLOAD RATIOS IN COLLEGIATE HANDBALL

LIM, J., LEE, J., PARK, J.

KYUNG HEE UNIVERSITY

INTRODUCTION: This study aimed to: (1) report the incidence and characteristics of musculoskeletal injuries (body location, type, and mechanism) in Handball; and (2) examine the association between the injury incidence and the acute-to-chronic workload ratio (ACWR).

METHODS: A total of 17 Korean collegiate Handball players (21.8 years; 181.6 cm; 81.4 kg; body mass index: 24.6 kg/m²; playing experience: 10.4 years) were prospectively studied during the 2024 season. Injury rates per 1,000 hours were calculated for training, scrimmages, and competitions. An athletic trainer recorded exposure (duration of training, scrimmages, and competitions), rate of perceived exertion (RPE), and musculoskeletal injury (injury rate, body location, type, and mechanism) in real time using a spreadsheet programme. The RPE was obtained after each session on a 1-5 scale, where a score 3 indicated the average exercise intensity over the past four weeks. The ACWR was determined by multiplying the RPE by the session duration (min) for training, scrimmage, and competition. The calculation was performed using two different approaches: the rolling average (RA) and exponentially weighted moving average (EWMA) methods [1]. Calculated ACWR values were categorised as high (>1.5), relatively high (1.3-1.5), moderate (0.8-1.3), or low (<0.8) [2].

RESULTS: Among the 124 injuries recorded, the highest injury rate per 1,000 hours was during scrimmage ($n=47$; 33.9/1,000 hours), compared to competition ($n=6$; 17.3/1,000 hours) and training ($n=71$; 9.7/1,000 hours). Regardless of the session, the ankle was the most frequently injured body location ($n=21$; 17%), followed by foot/toe ($n=13$; 10%) and hand ($n=13$; 10%). Sprain ($n=34$; 27%) was the most frequent injury type, followed by strain ($n=19$; 15%) and laceration/abrasion/skin lesion ($n=14$; 11%). Contact with another athlete was the most predominant injury mechanism ($n=27$; 22%), followed by non-contact trauma ($n=23$; 19%) and overuse ($n=21$; 17%). Of the 91 injuries (injuries that required at least 4 weeks to calculate the ACWR), the 65 (71%) were recorded under the moderate ACWR when calculated using RA method, and 75 (82%) when using the EWMA method.

CONCLUSION: Contrary to previous findings in team sports (football: >1.5 [3]), the greatest number of injuries were recorded under the moderate ACWR range (0.8-1.3) in Handball. This highlights the need for sport-specific workload management and careful adjustment of ACWR thresholds to reduce the risk of injury.

POST-COVID-19 SYNDROME: SEVERITY, SYMPTOMS, AND ASSOCIATIONS WITH QUALITY OF LIFE AND IMMUNE BIOMARKERS IN MASTER ATHLETES—INSIGHTS FROM THE 2024 WORLD MASTERS ATHLETICS CHAMPIONSHIP

ZHANG, B., GRAU, M., PUTA, C., PESTA, D., FORBES, S.C., CHILIBECK, P., MCLAURIN, N., TANAKA, H., BÖCKER, J., PUSTOW-ALOW, W., ARZ, M., KAISER-STOLZ, C., MIYAMOTO-MIKAMI, E., ARVIDSSON, D., RITTEWEGER, J., BLOCH, W.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Post-COVID-19 condition (PCC) is a persistent, multisystem condition that significantly impacts well-being and quality of life, with a prevalence rate of 41.8% in the general population. However, limited evidence exists regarding its prevalence and effects in master athletes (MAs). Understanding PCC in this unique group is critical for developing targeted management strategies and exploring links between high physical fitness, immune function, and symptom burden. This study aimed to assess the prevalence of PCC in master track and field athletes and investigate its associations with quality of life and biomarkers of immune response.

METHODS: This cross-sectional study analyzed track and field MAs who competed in the 2024 Gothenburg World Masters Athletics Competition. A total of 237 MAs (48% females, age = 57 ± 12 years, BMI = 22.8 ± 2.7 kg/m²) reported their previous highest competition level and current training regimens via a survey. Post-COVID symptoms were assessed using the Post-COVID Syndrome Questionnaire (PCSQ), while health-related quality of life (HRQoL) was evaluated using the Short Form-12 Health Survey (SF-12). In a subgroup of MAs ($n = 118$, 51% females, age = 59 ± 13 years, BMI = 22.4 ± 2.5 kg/m²), fasting blood samples were collected to measure C-reactive protein (CRP) level as an immune status biomarker. Differences in PCC severity were analyzed across sex, athletic specialties (endurance, sprint, and strength/power), previous highest competition levels, immune status, training intensities and volumes (hours and days), and SF-12 physical and mental component summary scores between MAs with and without PCC.

RESULTS: A total of 51 (21%) MAs were identified with moderate to severe and clinically relevant post-COVID condition (PCSQ score > 10.75). Overall, 43% of MAs reported at least one symptom, with musculoskeletal pain being the most prevalent (22%). No significant differences were observed in training intensities or volumes among different PCC severities (all $p > 0.05$), nor were there differences in sex, athletic specialties or previous highest competition levels ($p > 0.05$). However, significant differences in subjective quality of life were observed: MAs without PCC exhibited higher physical (54.4 vs. 52.0, $p = 0.003$) and mental component summary scores (60.9 vs. 56.4, $p = 0.003$) compared to those with moderate to severe PCC. While no significant correlation was found between PCC severity and CRP levels, MAs with reported cardiac ailments or flu-like symptoms showed significantly elevated CRP concentrations (4.4 vs. 1.4 mg/L and 3.0 vs. 1.2 mg/L, $p = 0.027$ and $p = 0.003$, respectively).

CONCLUSION: Post-COVID syndrome is prevalent among track and field MAs, significantly affecting subjective quality of life despite no difference in training intensity, while elevated C-reactive protein levels in MAs with cardiac ailments or flu-like symptoms indicate distinct low grade inflammatory profiles and ongoing post-acute infection regulation.

THE MUSCULOSKELETAL CHARACTERISTICS OF RECURRENT SHOULDER PAIN IN COMPETITIVE SWIMMERS: A PILOT STUDY

CHUNG WEI, Y., SHIH, Y.F., HUANG, T.S.

NATIONAL YANG MING CHIAO TUNG UNIVERSITY

INTRODUCTION: Shoulder pain is the most common musculoskeletal injury for competitive swimmers and a primary cause of cessation from training and competition. A history of previous shoulder pain is one of the factors contributing to recurrent shoulder pain in swimmers, altering athletes physical characteristics and generating risk factors distinct from those of healthy swimmers. Previous studies have mainly focused on exploring risk factors for shoulder pain in healthy swimmers, but they have not investigated musculoskeletal characteristics related to recurrent shoulder pain.[1] The purpose of this study was to identify the musculoskeletal characteristics associated with recurrent shoulder pain in competitive swimmers.

METHODS: Eleven competitive swimmers from high schools and colleges were recruited. For the recurrent shoulder pain group, participants had experienced unilateral shoulder pain in two or more episodes during training or competition

within one year, with no symptoms during their most recent training session. The control group consisted of individuals with a history of shoulder pain but had not experienced shoulder pain within one year. The testing items of musculoskeletal characteristics included shoulder internal rotation, external rotation, and horizontal adduction range of motion (ROM); cervical and thoracic posture and thoracic spine ROM; trunk rotational ROM; latissimus dorsi and pectoralis minor muscle length; glenohumeral joint laxity and generalized joint hypermobility; shoulder and periscapular muscle strength and fatigue resistance; scapular dyskinesis; scapulothoracic and glenohumeral joint control ability, and upper quarter dynamic balance performance.

RESULTS: There were 8 participants in the recurrent shoulder pain group and 3 in the control group in this pilot study. Using non-parametric analysis, the results showed that the recurrent shoulder pain group exhibited a significantly smaller forward head angle (more forward head posture) compared to the control group ($p = 0.041$). No statistically significant differences were observed in the other parameters.

CONCLUSION: Excessive forward head posture may be associated with recurrent shoulder pain in competitive swimmers. More participants should be recruited to confirm the findings.

CAFFEINE INTAKE AND THE PREVALENCE OF LEG CRAMPS: CROSS-SECTIONAL STUDY

SAWADA, S., CHIDA, T., LEE, D.C.

WASEDA UNIVERSITY

INTRODUCTION: Caffeine is a stimulant, and it has been suggested that it may cause leg cramps. However, there are few studies that have investigated the relationship between caffeine intake and the onset of leg cramps. Therefore, we conducted a cross-sectional study of Japanese adult men and women who have experience of participating in sports in order to investigate the relationship between caffeine intake and the onset of leg cramps.

METHODS: This study was conducted using an Internet survey between September 1st and 6th, 2023 in Japan. The study participants consisted of 2,446 adults (mean age = 41.3 years, 50% women). The participants were asked about their daily caffeine intake (almost none, small amount [e.g. less than one cup of caffeinated drink], medium amount [e.g. 1–3 cups of caffeinated drink], large amount [e.g. 4 or more cups of caffeinated drink]), and the frequency of leg cramps (every day, several times a week, several times a month, several times a year, never). We then divided the participants into three groups: a non-intake group (almost none), a small-medium intake group (small or medium amounts), and a large intake group (large amounts). We also divided the occurrence of leg cramps into two groups: a high-frequency occurrence group (every day, several times a week, several times a month) and a low-frequency occurrence group (several times a year, never occurs). Multivariable-adjusted odds ratios and 95% confidence intervals (95% CIs) for the high-frequency occurrence of leg cramps were obtained using logistic regression models while adjusting for age, sex, sleep time, drinking habit and smoking habit.

RESULTS: The high-frequency of occurrence of leg cramps group was 684 (28%). Compared to the non-intake group, the odds ratios (95% CIs) were 1.82 (1.34 – 2.49) for small-medium intake group, and 2.12 (1.37 – 3.30) for large intake group, respectively (P for trend < 0.001).

CONCLUSION: This study showed that the group with a high frequency of caffeine intake had a high-frequency of leg cramps. A prospective study is warranted to further investigate this association.

ASSESSING THE RELATIONSHIP BETWEEN GRIP STRENGTH, HEAVY MANUAL LABOR, AND THE RISK OF NON-TRAUMATIC ROTATOR CUFF TEARS IN ADULT POPULATIONS

LAI, C., CHIEN, K., LIN, J., HSIAO, M.

INSTITUTE OF EPIDEMIOLOGY AND PREVENTIVE MEDICINE

INTRODUCTION: Rotator cuff tears are a prevalent condition that affects the upper extremities in primary care settings. The causal relationship between degenerative changes and rotator cuff tears remains largely unclear. Additionally, physically demanding occupations may contribute to the risk of rotator cuff tears, and the role of grip strength as an early predictor of these injuries has yet to be definitively established.

METHODS: This study is a prospective cohort analysis derived from the UK Biobank, encompassing participants aged 40 to 69 years. The primary outcome of interest was non-traumatic rotator cuff tears. Grip strength was measured using a Jamar J00105 hydraulic hand dynamometer. Information regarding job involvement in heavy manual or physical labor was collected, categorized as never/rarely, sometimes, usually, or always. The relationships between these variables and the occurrence of rotator cuff tears were analyzed using logistic regression.

RESULTS: A total of 400,321 individuals were included in the final analysis. The mean age of the participants was 55.2 (standard deviation: 8.0) years, and 53.2% were female. Over a median follow-up period of 14 years, 3,008 participants developed rotator cuff tears. Analysis revealed significant associations between grip strength and rotator cuff tear risk (odds ratio (OR) 1.18, 95% confidence interval: 1.12–1.25). Heavy manual or physical work was significantly associated with increased rotator cuff tear risk, with those reporting "Always" engaging in such work having an odds ratio of 2.00 ($p < 0.001$).

CONCLUSION: The analysis revealed significant associations between grip strength and rotator cuff tear risk, along with an elevated risk linked to engagement in heavy manual or physical work. These findings highlight the importance of considering both grip strength and physically demanding occupations when assessing the risk for rotator cuff injuries.

THE ASSESSMENT OF ANTHROPOMETRIC PROFILES OF FEMALE UNIVERSITY STUDENTS STUDYING SPORT SCIENCE AND PHYSICAL ACTIVITY AT TAIBAH UNIVERSITY, SAUDI ARABIA

ALAHMADI, G., ALAHMADI, M.

TAIBAH UNIVERSITY

INTRODUCTION: Physical activity offers significant benefits for health, economy, and culture, and the Saudi government is committed to promoting it. In 2018, the Sport Science and Physical Activity (SSPA) major was introduced for female students at several universities, including Taibah University in Madinah, western Saudi Arabia. To our knowledge, anthropometric profiles of Saudi Arabian female SSPA university students are not currently available. Therefore, the aim of this study was to provide the anthropometric profiles of SSPA female students at Taibah University in Saudi Arabia.

METHODS: The anthropometric profiles of 20 female university students from the College of Education at Taibah University were assessed. Body weight was measured using a digital scale (Seca) to the nearest 0.1 kg, and height was measured using a portable stadiometer (Seca) to the nearest 0.5 cm, with the head in the horizontal Frankfort plane. Eight skinfold thicknesses (biceps, triceps, subscapular, suprailiac, supraspinal, abdominal, front thigh, and medial calf) were measured using a skinfold caliper (Cescorfi). Six circumferences (relaxed and contracted arm, waist, hip, thigh, and calf) were measured using an anthropometric tape (Cescorfi). Three bone breadths (humerus, bi-styloid, and femur) were measured using a small sliding caliper (Cescorfi). All measurements were conducted by a trained female (accredited level 1 anthropometrist) following procedures established by the International Society for the Advancement of Kinanthropometry (ISAK). Repeated measurements were taken for each parameter to determine the technical error of measurement ($\leq 5\%$ for skinfolds and $\leq 1\%$ for all other measurements).

RESULTS: The mean and standard deviation ($\pm$ SD) for age, height, weight, and BMI were 21.65 ± 1.23 years, 160.17 ± 5.31 cm, 51.62 ± 6.59 kg, and 20.14 ± 2.59 kg/m², respectively. The percentage of fat mass and skeletal muscle mass were $28.80 \pm 4.99\%$ and $40.80 \pm 3.40\%$, respectively. The sum of the eight skinfolds was 81.25 ± 25.15 mm. Waist circumference and hip circumference were 64.05 ± 6.70 cm and 91.30 ± 3.37 cm, respectively. The waist-to-hip ratio and waist-to-height ratio were 0.70 ± 0.06 and 0.40 ± 0.04 , respectively. Mid-upper arm circumference was 25.08 ± 3.06 cm.

CONCLUSION: This study provides, for the first time, anthropometric data on a sample of SSPA female university students in Saudi Arabia. The results indicate that the participants exhibited normal values for key health indicators when compared to individuals from the general population.

BODY COMPOSITION EVALUATION: BIOIMPEDANCE, ULTRASOUND, ANTHROPOMETRY AND DIGITAL PHOTOGRAPH COMPARED TO iDXA

NICOTERA, C., GRIMALDI, A., CIONE, E., MONEA, F., LEVI-MICHELI, M., CANNATARO, R.

DR MONEA MEDICAL OFFICE

INTRODUCTION: Body composition evaluation is a research area that has gained much attention recently. On the other hand, for all the methods, these are indirect estimates since it is impossible to evaluate the quantity of adipose tissue directly; therefore, each method has advantages and disadvantages; in this work, we have compared four of the most used methods (Bioimpedance, ultrasound, pycnometry, and digital imaging) compared to what is currently considered the gold standard, iDXA; to provide an evaluation tool.

METHODS: 60 subjects aged between 19 and 60 (33 women and 27 men), without pathologies and not using drugs regularly, BMI range of 19,8 and 50. All subjects were tested on the same day, with a pause of at least 10 minutes between every test. Subjects were asked not to do any physical activity in the 24 hours preceding the test, not to eat in the 8 hours preceding the test, and not to drink any liquids in the 2 hours preceding the test. The devices used were for iDXA: Lunar GE HealthCare – California – USA, for Bioimpedance: BIA 101 BIVA Pro Akern – Florence – Italy, BIA Dex Mascaretti, Ancona – Italy and InBody 770 Seoul – South Korea; for Ultrasound: BX2000, BodyMetrix, IntelaMetrix, California – USA; Anthropometry: Lipowise Pro, Wisify Matosinhos - Portugal; Digital: FitYourOutfit Pixelcando Tenerife - Spain

RESULTS: Respect to iDXA in overall BIA showed a difference respectively of Akern -5%, Mascaretti -15% and InBody -10%, ultrasound -11%, anthropometry -0,1% and Digital +2%; if taken by sex in women we recorded BIA showed a difference respectively of Akern -4,3%, Mascaretti -13% and InBody -7%, ultrasound -10%, Anthropometry -3.6% and Digital -3.2%; in men we recorded BIA showed a difference respectively of Akern -6,5%, Mascaretti -18% and InBody -12%, ultrasound -12%, Anthropometry +6% and Digital +1%; if grouped by BMI we recorded: between 19,8 and 25 BIA showed a difference respectively of Akern -7%, Mascaretti -19% and InBody -15%, ultrasound -12%, Anthropometry +5,8% and Digital +2%, between 25 and 29,8 BIA showed a difference respectively of Akern -11,6%, Mascaretti -24% and InBody -16%, ultrasound -19%, anthropometry -8,7% and Digital -7,8%; and over 29,8 BIA showed a difference respectively of Akern +6,7%, Mascaretti -13% and InBody +4%, ultrasound -12%, anthropometry -2,6% and Digital +5,5%

CONCLUSION: From the results obtained, which certainly should be evaluated on a larger sample (and in fact, the study is continuing with the objective of a sample of 100 people), it can be noted that the percentage of fat is estimated acceptably

even in the worst cases, with an error of maximum 20%; the most reliable methods would seem to be the simplest and simplest and cheapest ones, namely visual and anthropometry; on the other hand, bioimpedance and also ultrasonography, in exchange for a higher cost, provide other data on muscle mass, hydration, and general fitness; from a sports perspective using at least two combined tools is probably the best choice.

ROLE OF MEDITERRANEAN DIET AND PHYSICAL ACTIVITY ON IMPROVING SALIVARY ANTIOXIDANT CAPACITY AND IN BODY RECOMPOSITION.

FUSI, J., FRANZONI, F.

VAT N. IT00286820501 UNIVERSITY OF PISA

INTRODUCTION: There is ample evidence that a Mediterranean-style diet and physical activity can reduce risk factors such as obesity, hypertension, and improve antioxidant defenses. Unfortunately, people drop out after a period of following a nutritional pattern or physical activity because of poor willpower or poor short-term results. The purpose of our study was to devise and observe the effects of combining a nutritional and motor plan that could coexist over the long term (1 year of activity), with the ultimate goal of reducing risk factors and teaching a proper lifestyle.

METHODS: 60 subjects (10 men and 50 women, between 20 and 50 years) overweight and with a sedentary lifestyle were recruited for the study. They underwent to nutritional, body composition (plicometry and anthropometry) and Total Antioxidant Activity on saliva samples (TOSC assay) evaluation. All subjects underwent a 1 year of personalized Mediterranean-style nutritional scheme characterized by periods of calorie restriction, alternating with periods of restitution, so as to teach a healthy diet and not induce metabolic damage. We also added a highly personalized motor scheme (45 minutes, 2 times a week). Both the motor and nutritional patterns were highly personalized in relation to the clinical needs of each individual subject. The motor protocol included exercises derived from different disciplines such as pilates, weight training, endurance, boxing. The exercises and the order of the latter were varied at each session so as not to bore the subjects. The real and only variable was represented by the recovery times, which turned out to be very low, about 10-20-30 seconds between sets and a maximum of 1-2 minutes between one exercise and another. The number of repetitions and exercise were varied each time, so as not to create an adaptation phenomenon.

RESULTS: At the end of 1 year of treatment, a significant decrease in weight was observed (90.99 ± 8.86 vs 73.44 ± 8.01 ; $p < 0.01$) and in waist, abdomen and hip circumferences ($P < 0.05$). In terms of body composition, there was a significant decrease in fat mass (38.12 ± 5.544 vs 27.05 ± 5.50 $p < 0.05$), with an increase of free fat mass ($p < 0.05$). In addition, we found an increase in salivary antioxidant capacity against the three radical species peroxyl (13.67 ± 3.16 vs 19.88 ± 2.02 $p < 0.01$), hydroxyl (3.48 ± 1.51 vs 5.96 ± 1.72 $p < 0.01$), and peroxynitrite derivatives (14.21 ± 3.43 vs 18.46 ± 2.58 $p < 0.05$). Only 3% of subjects dropped out of the study.

CONCLUSION: The purpose of the study was to understand how nutrition and motor activity could interact in the long run to improve health and teach a proper lifestyle. From our results, we can conclude how the combination of our nutrition and motor program can be sustained in the long run (pointing out that only 3 percent of subjects dropped out of the study) leading to both excellent compliance and a significant decrease in various risk factors (weight, circumferences, and antioxidant capacity).

ACUTE EFFECTS OF MEAL AND EXERCISE SEQUENCE ON POSTPRANDIAL METABOLISM IN HEALTHY ADULTS

WANG, Y., YANG, Y., CHEN, Y.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Exercise has been shown to improve metabolic health. However, the efficacy of meal-exercise timing on postprandial metabolism, such as glucose and triglyceride (TG) responses, remains not fully understood. This study aims to investigate the effect of different sequences of meals and exercise on postprandial glucose, insulin, and TG concentrations.

METHODS: 16 healthy and physically active individuals (8 men and 8 women; age: 25 ± 3.1 years; BMI: 22.8 ± 2.4 kg/m²) were recruited and randomly assigned to perform 30 min of brisk walking either before (EM) or after the breakfast (ME) in a repeated-measures crossover design. Blood (plasma) samples were collected at baseline, 30- (immediately post-exercise in EM or after the breakfast in ME), 60- (immediately post-exercise in ME or after the breakfast in EM), 75-, 90-, 105-, 120-, 150-, and 180-min and then at immediately, 15-, 30-, 45-, 60-, 90-, 120-, 150-, and 180-min following the lunch. The outcome was the incremental area under the curve (iAUC) over the 375-min sampling period, with separate analyses for the 0-180 min and 180-375 min periods (i.e., after the lunch).

RESULTS: No significant differences were observed in oxygen uptake (18.5 ± 1.9 vs 18.8 ± 2.0 mL/kg/min; $p = 0.394$) and rating of perceived exertion (10.7 ± 1.5 vs 10.5 ± 1.4 ; $p = 0.394$) between EM and ME during exercise. iAUC₁₈₀₋₃₇₅ for glucose was lower in the EM (2834 [95% CI = 3660, 2009] mmol/L) compared to ME (3641 [95% CI = 4751, 2531] mmol/L, Cohen's d = 0.55, $p = 0.043$). There were no differences in the glucose iAUC₀₋₁₈₀ ($p = 0.610$) and iAUC₀₋₃₇₅ ($p = 0.265$) between trials. iAUC₀₋₁₈₀ for TG was lower in the EM (822 [95% CI = 1342, 303] mmol/L) compared to ME (2022 [95% CI = 2663, 1381] mmol/L, Cohen's d = 0.83, $p = 0.005$). There were no differences in the TG iAUC₁₈₀₋₃₇₅ ($p = 0.754$) and iAUC₀₋₃₇₅ ($p = 0.251$) between trials. The iAUC for insulin across all three periods did not differ between trials (iAUC₀₋₃₇₅, $p = 0.345$; iAUC₀₋₁₈₀, $p = 0.598$; iAUC₁₈₀₋₃₇₅, $p = 0.098$).

CONCLUSION: EM (i.e., fasted-exercise) reduced postprandial glucose concentrations after lunch (iAUC180-375) and TG concentrations in the morning period (iAUC0-180) compared ME (i.e., fed-exercise). Our findings suggest potential benefits of pre-breakfast exercise in modulating postprandial metabolism.

CHARACTERISTIC OF BODY COMPOSITION CHANGES IN PHYSICAL ENDURANCE EXERCISES.

PLAVINA, L.

NATIONAL DEFENCE ACADEMY OF LATVIA

INTRODUCTION: The endurance training course is essential part of professional skills support for military personnel. The aim of the study is to provide an assessment of body composition characteristics changes in a group of well-trained individuals depending on level of BMI (standard and overweight) in pre-course preparatory phase, to endurance exercises, directly after endurance training and in four weeks after endurance training course

METHODS: The study group included 66 healthy persons in aged from 21 till 35 years. They participated in pre-course training (four month) and endurance training course (ten days long total 24hrs), with high intensity physical load that included aerobic and anaerobic training elements, in combination with related energy deficiency (RED). Participants were divided into two subgroups according BMI levels: with standard level and with overweight level. We fixed in both subgroups body fat (%), muscle mass(kg) four times: at the beginning of pre-course training (1) no RED; after four months of pre-course training, directly before endurance exercises (2)no RED, directly after endurance training course (3)with RED and four weeks after endurance training course (4)no RED. The median and interquartile range (IQR) described non-normally distributed variables, data analysis was provided by Friedman's test and by using IBM SPSS Statistics 29.

RESULTS: The results revealed changes of body composition characteristics in both respondents' subgroups with standard BMI level (≤ 24.9) as well with overweight BMI level (> 25.0). The median of body fat % had small changes during pre-course training (no RED) for respondents with standard BMI level ($p > 0.999$) and with the overweight BMI level ($p > 0.999$), the body fat % characteristics in third measurements directly after endurance course (with RED) decreased for respondents with standard BMI level ($p < 0.001$) and with the overweight BMI level ($p < 0.001$). These changes of body fat% were not stable that fixed in fourth measurement in four weeks after endurance course (no RED) for respondents with standard BMI level ($p < 0.001$) and with the overweight BMI level ($p = 0.079$). The median of muscle mass(kg) had changes during pre-course training (no RED) for respondents with standard BMI level ($p > 0.999$) and with the overweight BMI level ($p > 0.999$), then characteristic of muscle mass measured directly after endurance training course (with RED) shown that they jumped up (in group with standards BMI ($p < 0.001$) and in group with overweight BMI level ($p = 0.003$). These changes diminished in four weeks after endurance course (no RED) and last measurement fixed that muscle mass returned to in initial level in group with standards BMI $p = 0.623$ and in group with overweight BMI level ($p = 0.010$)

CONCLUSION: Body composition characteristics were affected by intensity physical load and combination with RED or no RED for participants of both subgroups with standard and overweight level of BMI level, but changes of body composition characteristics were not longtermly.

DETERMINANTS INFLUENCING THE UPTAKE OF A WEB-BASED HEALTH INTERVENTION FOR PATIENTS WITH TYPE 2 DIABETES AND/OR CORONARY HEART DISEASE

SCHOLL, M., APPELBAUM, S., BIALLAS, B., BRENK-FRANZ, K., FRANK, F., GAWLIK, A., GIESEN, L., HERBRÜGGE, M., KÜPPERS, L., LEHMANN, L., LENDT, C., REDAELLI, M., SCHNEIDER, L., VITINIUS, F., WILM, S., KONERDING, U.

GERMAN SPORTS UNIVERSITY COLOGNE

INTRODUCTION: Digital health interventions (DHIs), including web-based applications, provide personalised, location-independent and effective support. However, effectiveness of DHIs depends on use. Accordingly, appropriate application and/or targeted design of DHIs requires intervention developers to know which variables determine use (e.g., personality traits, health literacy). In particular, knowledge regarding the uptake, i.e., using the DHI at least once, is important. The objective of the study presented here is to investigate the determinants of uptake of a specific DHI.

METHODS: The DHI investigated is a web portal for promoting physical activity and healthy nutrition in patients with type 2 diabetes mellitus and/or coronary heart disease. This DHI is a component of a complex intervention for improving self-management in persons with at least one of these two diseases. This study is a secondary analysis of a randomised controlled trial (RCT) [1] and refers to 465 persons (49.9% female; 64.8 ± 10.2 years of age) who had been assigned to the intervention condition of this RCT. Possible determinants of uptake were extracted from register data of the study centre and from data of a baseline survey. These variables encompass gender, age, education, the Big Five personality traits, loneliness, emotional distress, health literacy, patient activation, intention regarding physical activity, and intention regarding healthy nutrition. The relationship with DHI uptake was investigated using logistic regression, both for each variable separately (univariate analysis) and for all variables together in one model (multivariate analysis).

RESULTS: Univariate analysis showed significant positive associations of uptake with higher education ($p < .01$), the Big-Five-dimension openness ($p < .01$), health literacy ($p < .05$), intention regarding physical activity ($p < .001$), and intention regarding healthy nutrition ($p < .001$). Of these effects, only those for intention regarding physical activity ($p < .01$) and intention regarding healthy nutrition ($p < .001$) remained significant in multivariate analysis. Patient activation, previously non-significant, emerged as a significant negative predictor ($p < .001$).

CONCLUSION: The findings suggest that uptake of the DHI investigated here depends on whether people believe the DHI to support them in performing a behaviour they would like to perform. Persons without distinct intentions regarding physical activity or healthy nutrition must be approached in different ways.

ASSOCIATION BETWEEN ADHERENCE TO 24-HOUR MOVEMENT GUIDELINES AND RISKS OF ALL-CAUSE MORTALITY AMONG ADULTS WITH TYPE 2 DIABETES: PROSPECTIVE COHORT STUDY

LUAN, H., GUO, X.

BEIJING SPORT UNIVERSITY

INTRODUCTION: The incidence and mortality rates of type 2 diabetes (T2D) are rising annually[1]. Prior research has demonstrated that adherence to the 24-Hour Movement Guidelines (24HGs) in the general population is associated with reduced all-cause mortality[2]. However, there is limited understanding of the potential health benefits in individuals with T2D. This long-term study aimed to investigate the link between the T2D patients adherence to 24HGs and their risk of all-cause mortality.

METHODS: This study included U.S. adults diagnosed with T2D, utilizing information from the National Health and Nutrition Examination Survey (NHANES) conducted from 2007–2008 to 08/2021–08/2023 cycle. The mortality data were provided by the National Center for Health Statistics (NCHS). The adherence of the 24HGs was evaluated through self-reported levels of moderate-to-vigorous-intensity physical activity (MVPA) during leisure time, sedentary behavior, and sleep, with scores ranging from 0 to 3. A multivariable Cox proportional hazards model was used to assess the association between adherence to 24HGs and all-cause mortality.

RESULTS: The study included 5,047 individuals with T2D (mean age: 61.3 years, SD = 13.6) and a median follow-up period of 84 months. During follow-up, the all-cause mortality events of 1, 151 (22.8 %) participants were recorded. After the adjustment of sociodemographic, healthcare factors, and lifestyle influences, compared with non-adherence, following one recommendation (HR = 0.72, 95% CI: 0.60–0.87, $P < 0.001$), two recommendations (HR = 0.60, 95% CI: 0.50–0.73, $P < 0.001$), or all recommendations (HR = 0.37, 95% CI: 0.27–0.49, $P < 0.001$) were associated with a reduced risk of mortality. Compliance with either the MVPA (2.4% of participants) or sedentary behavior recommendation (29.0%) was linked to a 62% (95% CI 21%-71%, $P = 0.002$) and 28% (95% CI 60%-88%, $P < 0.001$) decrease in mortality risk, respectively. Adhering solely to the sleep recommendation showed no significant association (HR = 0.79, 95% CI 0.71–1.01, $P = 0.06$).

CONCLUSION: Adherence to the 24HGs in individuals with T2D is associated with a reduced risk of all-cause mortality, with the recommendations for MVPA and sedentary behavior conferring the greatest benefits. To manage or control T2D, prioritizing compliance with the sedentary behavior recommendation—being the more achievable component of the 24HGs—may serve as an effective starting point. This research is significant for individuals with T2D, as adhering to the 24HGs can help manage the disease and potentially extend the lifespan.

LOSS OF COMPETITIVE ADVANTAGE – ACADEMY FOOTBALL HAS HIGH LEVELS OF ORAL DISEASE

KONVISER, S., NUREK, M., NEEDLEMAN, I., FINE, P.

UCL EASTMAN DENTAL INSTITUTE

INTRODUCTION: We have previously reported high levels of oral disease in professional senior team footballers in England and Wales and have linked poor oral health with a perceived negative impact on athletic performance. Good oral health is a basic human right and an essential determinant of general health, well-being and quality of life. Poor oral health is related to systemic disease. This study aimed to determine the prevalence of oral disease in professional academy footballers, to identify if problems start earlier and to inform health promotion strategies.

METHODS: Professional academy football clubs in England (16–18-year-olds) were invited to participate. Questionnaires were used to collect oral health behaviours and self-reported impacts and validated clinical outcomes to assess oral health. An oral health screening for dental decay, periodontal (gum) disease, dental erosion and dental trauma was undertaken on the volunteers at the clubs training grounds.

RESULTS: 160 academy footballers were recruited from 10 English academy football clubs, of which 86.8% (n=139) were male and 13.2% (n=21) female, with a median age of 16.9 years. High levels of oral disease were identified. 31.2% (n=50) had dental caries requiring treatment. 76.8% (n=123) had inflammation of the gums and 22.5% (n=36) periodontitis (gum disease). Tooth wear affecting up to at least 50% of tooth structure was present in 15.5% (n=25) of participants. 35.6% (n=57) of participants had experienced dental trauma with 10% (n=16) actively recalling that they received either a soft tissue injury (lips or tongue) or dental trauma during training or competition.

Whilst 76.2% (n=122) self-reported brushing their teeth twice per day, 15.5% (n=18) brushed once or less a day and 21% (n=34) had not attended the dentist for over 2 years. There was a general perception that oral health issues did impact the participants' sporting performance.

CONCLUSION: The prevalence of oral diseases amongst professional academy footballers in England is high and greater than found in national surveys of a similar age demographic. There is also poor oral hygiene routines and dental attendance. This is surprising given the attention given to achieving optimal health and wellbeing of this cohort. Urgent action is needed to embed oral health promotion in development and youth football, to reverse and prevent the disadvantages that will have lifelong consequences for treatment burden, quality of life and sporting performance.

ACUTE KETONE MONOESTER INTAKE IMPROVES BLOOD FLOW REGULATION IN FEMALES WITH POLYCYSTIC OVARY SYNDROME

BERBRIER, D., HUCKINS, W., DELAGE, S.I., VAN BERKEL, E.K., HANNAIAN, S.J., CHURCHWARD-VENNE, T.A., USSELMAN, C.W.
MCGILL UNIVERSITY

INTRODUCTION: Polycystic ovary syndrome (PCOS) is an endocrinopathy associated with vascular dysfunction and insulin resistance, resulting in an elevated cardiovascular disease risk. Exogenous ketone supplementation can decrease blood glucose concentration and has been suggested to improve vascular function via improvements in blood flow in individuals predisposed to cardiovascular disease, but has yet to be assessed in females with PCOS. Therefore, we tested the hypothesis that acute ketone monoester (KME) ingestion would improve glucose-stimulated increases in blood flow in healthy lean females with PCOS.

METHODS: Ten otherwise healthy females with PCOS (age: 27 ± 5 yr, body mass index: 23.8 ± 2.7 kg/m², physical activity: 229 ± 111 min/week), participated in a randomized, double-blind, placebo controlled, acute crossover intervention study. In the overnight post-absorptive state, participants consumed the KME (R)-3-hydroxybutyl (R)-3-hydroxybutyrate (0.45 ml/kg body mass) or a taste-matched non-caloric placebo 30 minutes prior to completing a 2-hour 75g oral glucose tolerance test (OGTT). Venous blood samples to assess beta-hydroxybutyrate (β -OHB) concentrations were collected at baseline, at 30-min after KME intake and concurrent with OGTT ingestion (time point 0), and at 15, 30, 60, 90, and 120-min post-OGTT. Blood pressure (measured via finger photoplethysmography calibrated to manual sphygmomanometry) was continuously recorded throughout the OGTT. Leg blood flow (LBF; duplex ultrasound, superficial femoral artery) and femoral vascular conductance (FVC; LBF/mean arterial pressure) were assessed at baseline and at 0, 15, 30, 60, 90, 120-min post-OGTT.

RESULTS: In the placebo trial, blood β -OHB concentration, LBF, and FVC remained unchanged throughout the OGTT (main effects of time all $P > 0.05$). In contrast, KME intake significantly elevated blood β -OHB concentration, reaching 3.1 ± 0.8 mM within 30 minutes and remained elevated throughout the OGTT (main effect of time $P < 0.01$). Additionally, KME ingestion led to a sustained increase in both LBF and FVC across all OGTT timepoints (main effects of time all $P < 0.01$). Notably, peak OGTT-induced increases in LBF ($+171 \pm 50$ vs. $+27 \pm 14$ mL/min, $P < 0.01$) and FVC ($+1.9 \pm 0.7$ vs. $+0.5 \pm 0.3$ mL/min/mmHg, $P < 0.01$) were greater in the KME compared to placebo trial.

CONCLUSION: These findings suggest that acute KME ingestion enhances glucose-stimulated vascular function in lean females with PCOS. Notably, this lean, physically active phenotype of PCOS is frequently overlooked in both research and clinical interventions, despite evidence suggesting it may represent the most severe form of the disorder. Given the heightened cardiovascular disease risk in this cohort, KME supplements may offer a potential therapeutic strategy in the managements and prevention of cardiometabolic disease risk in females with PCOS.

EFFECTS OF A PROBIOTIC-PLANT EXTRACT COMBINATION AND SPONTANEOUS PHYSICAL ACTIVITY ON INTESTINAL INFLAMMATION IN A MOUSE MODEL OF CROHNS DISEASE

DE CLERCQ, F., SIVIGNON, A., LECLAIRE, C., COUVERT, A., HOLOWACZ, S., PERRIERE, F., KEOCHLIN-RAMONATXO, C., GOUSTARD, B., CHASSAING, B., MARTIN, V., BOISSEAU, N.
UNIVERSITY CLERMONT AUVERGNE

INTRODUCTION: Crohns disease (CD) is an inflammatory bowel disease affecting over 2 million people in Europe, significantly impacting patients quality of life. In a preliminary study conducted in our laboratory, an in vitro screening of 17 probiotic strains and 3 plant extracts led to the identification of a promising combination capable of reducing the adhesion of Adherent-Invasive Escherichia coli (AIEC), a pathobiont bacteria involved in CD, to intestinal epithelial cells and mitigating inflammation. Building on these findings, the present study aimed to evaluate, in a mouse model of CD, the potential of a formulation combining two Lactobacillus strains and walnut leaf extract, together with the protective effects of spontaneous physical activity (PA), known to reduce systemic and tissue inflammation.

METHODS: Male C57BL/6 mice were initially assigned to either a normal diet (control) or a high-fat diet (HFD) for 11 weeks to induce obesity. Following this period, HFD-fed mice were further divided into four subgroups: two groups had access to

spontaneous PA (individually housed with running wheels) for an additional 11 weeks while the other two groups remained sedentary (with locked wheels), each condition receiving either the formulation or not. Mice received oral gavage of the formulation or placebo once daily, 5 days a week, for 5 weeks from the 7th week of PA. During the final two weeks before sacrifice, colitis was induced by adding 1% DSS to the drinking water, with or without an additional challenge with AIEC bacteria to mimic CD, resulting in the formation of eight distinct subgroups.

RESULTS: After the first 11 weeks, HFD-fed mice exhibited significantly higher body mass gain ($p < 0.0001$) than control. During the second phase, despite consuming significantly more energy ($p < 0.0001$), physically active mice gained less mass than their sedentary counterparts ($p = 0.0027$). A negative correlation ($r = -0.4704$, $p = 0.01$) was observed between total distance covered and weight gain. The combination of probiotics and plant extracts had no significant effect on body mass or PA levels. Neither PA, the formulation, nor their combination had a significant effect on post-mortem muscle mass (soleus, gastrocnemius, or tibialis anterior) or adipose tissue mass (epididymal or mesenteric). On the day of sacrifice, the Disease Activity Index score, measuring colitis severity, and fecal lipocalin-2 levels, an indicator of intestinal inflammation, remained unaffected across conditions.

CONCLUSION: The formulation, spontaneous PA, or their combination failed to show effectiveness in the primary prevention of acute intestinal inflammation induced by DSS or DSS + AIEC. Further analyses of serum and tissue inflammation, dysbiosis markers, intestinal permeability, and microbiota composition will complement these data for a better understanding of these findings.

HYALURONAN ENHANCES PROLIFERATION AND MYOGENIC DIFFERENTIATION OF C2C12 MURINE MYOBLASTS UNDER OXIDATIVE AND INFLAMMATORY STRESS

FERRINI, F., ANNIBALINI, G., BATTISTELLI, M., CAPPARUCCI, I., SEYEDEHMAHBOOBEH, M., SESTILI, P., BARBIERI, E.
UNIVERSITY OF URBINO

INTRODUCTION: Hyaluronan (HA) is a non-sulfated glycosaminoglycan widely utilized in medical and pharmaceutical applications, particularly in muscle tissue repair. Recent studies highlight its crucial role in muscle regeneration, demonstrating that HA activates muscle stem cells by promoting JMJD3-driven hyaluronic acid synthesis, facilitating adaptation to inflammation and initiating the repair process (1).

METHODS: In this study, we investigated the potential of HA in rescuing myoblasts exposed to oxidative and inflammatory stress using C2C12 murine muscle cells. We first performed a wound healing assay to assess cell monolayer repair at baseline (t0) and after 24 hours (t1), in the presence or absence of an HA blend (2–1000 KDa, 1 mg/ml, Regenflex T&M, Regenyal Laboratories SRL), with or without pro-inflammatory agents (IL-1 β , TNF- α , LPS) and oxidative stressors (H₂O₂), known to impair proliferation.

RESULTS: Results revealed that HA significantly improved reparative mechanisms even in the presence of inflammatory and oxidative stimuli. Additionally, we evaluated the myogenic potential of C2C12 cells treated with HA by analyzing the expression of key myogenic markers, including MyoD, Mrf4, myogenin, and IGF-1, under the same stress conditions. Preliminary findings indicate that HA exerts a strong pro-proliferative effect, enhancing wound healing within 24 hours post-injury. Moreover, HA treatment upregulated myogenic biomarkers, suggesting a positive impact on differentiation pathways.

CONCLUSION: These results support the potential use of this HA formulation as a promising therapeutic strategy for muscle tissue regeneration

PATTERNS OF DAILY ACTIVITY, SLEEP, DIET AND HORMONAL FLUCTUATIONS AMONG PREMENOPAUSAL WOMEN: A TWO-MONTH ANALYSIS

AGUIAR BONFIM CRUZ, A., JOHNSON, A., IRWIN, G., FREY, M., SCHWARTZ, M., BROWN, A.F.
UNIVERSITY OF IDAHO

INTRODUCTION: Despite growing recognition of potential interplays among female reproductive hormones, physical activity (PA), sedentary behavior (SB), sleep, and diet; a dearth of evidence exists examining how these behaviors interact. Existing literature is primarily cross-sectional and typically examines only a single hormonal cycle, despite well-known fluctuations in hormonal fluctuations between cycles. Further, most research often only includes naturally menstruating (NM) women, excluding women using hormonal contraceptives (HC). Therefore, the purpose of this study was to identify potential interactions between estradiol (E2), progesterone (P4), follicle stimulating hormone (FSH), luteinizing hormone (LH), leptin on PA, SB, sleep, and diet among NM and HC women across two hormonal cycles.

METHODS: Premenopausal women (N=16, HC=9, NM=7) completed weekly testing for 8 weeks including a serum blood draw and completion of the Simple Physical Activity Questionnaire (SIMPAQ), the Automated Self-Administered Dietary Assessment Tool (ASA-24), and the Pittsburgh Sleep Quality Index (PSQI). Body fat percentage (BF%) was assessed at baseline via a dual-energy x-ray absorptiometry scan. Data was analyzed using general linear mixed models with HC/NM and cycle phase as fixed effects and participant as a random effect.

RESULTS: BF% (28.4 ± 6.7) was positively related to leptin across all time points for all participants ($b=1.7$, $p<0.001$). Significant positive interactions were identified between FSH and carbohydrate (g) and added sugar (g) intake among all participants ($b=0.93$, $p=0.030$; $b=0.15$, $p=0.006$; respectively). A significant negative interaction was observed between LH and added sugar intake ($b=-1.91$, $p=0.006$). E2 and protein were positively related ($b=0.10$, $p=0.013$). A significant interaction between walking and cycle phase was identified ($b=1.26$, $p=0.002$), and walking was significantly higher in the mid-

follicular phase compared to menstruation ($p=0.007$). A significant interaction between sleep and cycle phase was observed in NM participants ($b=5.21$, $p=0.004$), with sleep differing between menstruation and luteal phase ($p<0.001$). Additionally, a positive interaction between leptin and sleep was observed ($b=0.124$, $p<0.001$). No other significant interactions between lifestyle behaviors and hormones were identified.

CONCLUSION: In a relatively healthy female population, carbohydrate, added sugar, and protein intake appear to be related to infradian female hormonal fluctuations. PA and sleep both appear to have cycle phase interactions among NM participants. In a relatively healthy population, leptin has a strong relationship with BF% and sleep. Additional research is needed to better understand these interactions, particularly within a larger and more diverse population to ensure generalizability.

ENDURANCE RUNNING IN ELDERLY: ITS EFFECT ON PRODUCTION OF SELECTED HORMONES DURING AGING IN MEN, WITH FOCUS ON CIRCADIAN RHYTHMS AND REPRODUCTIVE HEALTH

KUNDEKOVÁ, B., ORESKÁ, L., BUZGÓ, G., OLIVA, V., OKULIAROVÁ, M., ZEMAN, M., SEDLIAK, M.

COMENIUS UNIVERSITY IN BRATISLAVA

INTRODUCTION: Aging is associated with a gradual decline in biological functions across all body systems including hormone production and its daily rhythmicity. Regular exercise has been identified as important factor for maintaining healthy ageing, in contrast to a sedentary lifestyle. However, extensive endurance training may also negatively impact physiological functions, such as reproductive health. The main goal of our cross-sectional study was to assess the impact of long-term endurance activity on the secretion of selected hormones in men during ageing.

METHODS: We recruited 51 participants in total, who were divided into 4 groups based on their age and endurance running activity: young athletes (YA, 20-30 years), young sedentary (YS, 20-30 years), master athletes (MA, 65-75 years) and elderly sedentary (ES, 65-75 years). Two venous blood samples were collected (between 7:30–8:00 and 15:30–16:00). We analyzed the levels of SHBG, testosterone (T) and cortisol (C) using commercial enzyme-linked immunosorbent assay kits (ELISA, Cloud-Clone Corp., USA) from both samples ($n=11$ YA, 10 YS, 9 MA, and 10 ES). Additionally, the percentage of bioavailable testosterone (BT) was analyzed via commercial laboratory (Unilabs Slovensko, s. r. o.) from the morning samples ($n=13$ YA, 15 YS, 13 MA, and 10 ES). Data were analyzed by two-way ANOVA (for the factors of age and activity) with Tukeys post-hoc test, and mixed-design three-way ANOVA (with a repeated measure factor), followed by Sidak's post-hoc test.

RESULTS: We observed the elevating impact of both the age ($p<0.0001$) and activity ($p=0.006$) on SHBG levels. While both C and T production exhibited circadian rhythmicity with the levels decreasing in the afternoon samples ($p<0.0001$), T levels showed a negative effect of age on the decrease ($p=0.0422$). There was also an indication of interaction between the activity and age on the decrease ($p=0.0934$), as the MA group maintained the rhythm (4.43 ± 0.22 ng/mL to 3.17 ± 0.21 ng/mL, ($p=0.0003$)) whereas the ES group did not (3.97 ± 0.30 ng/mL to 3.58 ± 0.29 ng/mL, ($p=0.585$)). BT levels were impacted by age ($p<0.0001$) and activity ($p<0.0001$), but not their interaction ($p=0.747$). While the highest levels reached the YS group (compared with YA: $p=0.003$; MA: $p<0.0001$; ES: $p<0.0001$), the MA group reached the lowest levels (YA: $p<0.0001$; YS: $p<0.0001$; ES: $p=0.003$).

CONCLUSION: We found that both age and endurance activity negatively impact SHBG and BT levels, which may have consequences for reproductive health in men. On the other hand, while we did observe the negative effect of age on daily rhythmicity of T levels, there is a suggestion that long-term endurance running may have a beneficial impact on maintaining its circadian rhythmicity. However, a larger sample size is required for statistical confirmation.

The study was partially supported by the Slovak Research and Development Agency (grant no. APVV-21-0164).

ANALYSIS OF IRISIN AND BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) EXPRESSION IN SELECTED ORGANS OF RATS UNDERGOING VARIED PHYSICAL EXERCISE

CIALOWICZ, M., WOZNIEWSKI, M., PIOTROWSKA, A., MURAWSKA-CIALOWICZ, E., DZIEGIEL, P.

WROCLAW UNIVERSITY OF HEALTH AND SPORT SCIENCES; MEDICAL UNIVERSITY OF SILESIA, WROCLAW

INTRODUCTION: Regular physical activity induces adaptive molecular and physiological changes in various organs, contributing to improved health. Irisin is a myokine produced, among others, by skeletal muscles during physical exertion and plays a crucial role in regulating energy metabolism while also exhibiting neuroprotective properties. Brain-derived neurotrophic factor (BDNF) is a key neurotrophin involved in neuronal plasticity and cognitive functions, with its expression also modulated by physical activity. Despite the growing interest in the systemic effects of these two proteins, their expression in different organs remains insufficiently understood. This study aimed to analyze the expression levels of irisin and BDNF in selected organs of rats subjected to physical training of varying intensity.

METHODS: Female Sprague-Dawley rats were divided into a control group ($n=12$, no training) and an experimental group ($n=36$) subjected to an 8-week treadmill training program, followed by a 4-week period of voluntary physical activity. The control group was kept under standard conditions for 12 weeks. The exercising group was further divided into subgroups with low ($n=12$), moderate ($n=12$), and high-intensity training ($n=12$). The training was conducted 5 days per week on a mechanical treadmill, with intensity adjustments of $\pm 20\%$ relative to moderate load. After the experiment, the rats were euthanized following standard animal study procedures, and selected organs—liver, kidneys, and lungs—were collected for immunohistochemical (IHC) analysis of irisin and BDNF expression levels.

RESULTS: Expression of irisin and BDNF was detected in the selected organs in both control and trained groups. The highest expression of both proteins was observed in the liver of rats subjected to physical exercise. High-intensity physical activity induced the greatest increase in irisin and BDNF expression.

CONCLUSION: This study confirms that physical training modulates irisin and BDNF expression, which may contribute to a better understanding of the effects of myokines and neurotrophins in the analyzed organs. Further research is necessary to elucidate the precise molecular mechanisms underlying physiological adaptations to physical exercise.

CP-MH31 Exercise Therapy

EFFECTS OF TELEREHABILITATION-BASED MULTILEVEL OROPHARYNGEAL EXERCISES IN OBSTRUCTIVE SLEEP APNEA PATIENTS

ONG, J., LIN, C.Y., HUNG, C.H.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Obstructive sleep apnea (OSA) is characterized by recurrent upper airway collapse during sleep, leading to serious health consequences, including increased cardiovascular risk and cognitive impairment. Multilevel airway collapse, particularly at the soft palate and tongue base, is common among OSA patients. While oropharyngeal exercises have been proposed as a non-invasive treatment, traditional delivery methods face challenges such as poor adherence due to time constraints and lack of feedback. The efficacy of group-based telerehabilitation for oropharyngeal exercises remains largely unexplored. This study evaluates the effectiveness of group-based telerehabilitation in delivering multilevel oropharyngeal exercises for OSA management.

METHODS: A quasi-experimental, two-group design was employed. Thirty-nine participants diagnosed with OSA via polysomnography were enrolled. The telerehabilitation group attended one to two 45-minute online sessions per week, guided by a trainer, while the control group followed conventional instructions. Generalized Estimating Equations (GEE) were used to analyze the interaction effects between group and time on key outcomes, including Apnea-Hypopnea Index (AHI), sleep quality, and tongue muscle strength.

RESULTS: Significant interaction effects ($p < .05$) were observed in AHI, Hypopnea Index (HI), and AHI in supine position (AHI_S), with the telerehabilitation group showing greater reductions compared to the control group. Additionally, the telerehabilitation group exhibited significant improvements in snoring outcomes, tongue strength (depression, lateralization), and tongue endurance across five directions. While BMI, waist, and hip circumference showed no significant changes, a reduction in neck circumference was noted in the telerehabilitation group, possibly due to improved oropharyngeal muscle function.

CONCLUSION: Group-based telerehabilitation of multilevel oropharyngeal exercises demonstrates potential as an effective intervention for OSA by improving AHI, sleep-related outcomes, and tongue muscle function. Future studies with larger sample sizes and randomized allocation are recommended to further validate these findings and enhance exercise adherence monitoring.

ECCENTRIC CYCLING EXERCISE IMPROVES CARDIOPULMONARY FITNESS AND MUSCLE FUNCTION IN CHRONIC KIDNEY DISEASE

HUANG, Y., CHENG, H.C., LEE, H.Y., SUN, C.Y., TSAI, K.L.

INSTITUTE OF ALLIED HEALTH SCIENCES, COLLEGE OF MEDICINE,

INTRODUCTION: Chronic kidney disease (CKD) involves irreversible renal dysfunction and is linked to various complications that impair quality-of-life, increase mortality, and reduce exercise capacity. Regular physical activity contributes to overall health, with aerobic exercise particularly enhancing exercise capacity. However, conventional aerobic exercise may increase cardiac workload and hemodynamic stress, posing potential risks for CKD patients. Eccentric cycling (ECC), characterized by lower oxygen and energy demands, provides an alternative for individuals with exercise intolerance, enabling higher-intensity training with reduced hemodynamic stress. This study aimed to compare the effectiveness of ECC and concentric cycling (CON) in improving body composition, cardiopulmonary fitness, and respiratory function in CKD patients.

METHODS: This randomized controlled trial, conducted at a single center, included 45 CKD patients assigned to CTL, CON, and ECC groups. The CON and ECC groups underwent 8-week, 24-session cycling programs. The initial exercise intensity was set at 50% of the maximal output (Watts) while maintaining a rating of perceived exertion (RPE) level maintained at 13. Exercise intensity was progressively increased weekly by 5%–10. Outcomes were evaluated through body composition, cardiopulmonary exercise tests, and respiratory function tests (diaphragm ultrasonography, maximum respiratory pressure), assessed at baseline (pre-test), after 1-month exercise (mid-term test) and post-intervention (post-test).

RESULTS: The ECC group exhibited a significant group-by-time interaction in body composition compared to the CON and CTL groups, particularly in skeletal muscle mass (CTL vs. ECC: $p < 0.001$; CON vs. ECC: $p < 0.001$ /slope: CTL: -0.16, CON: -0.267, ECC: 0.343), bilateral upper hand grip strength (CTL vs. ECC: $p < 0.001$; CON vs. ECC: $p < 0.001$), and bilateral lower

limb knee extensor strength (CTL vs. ECC: $p < 0.001$; CON vs. ECC: $p < 0.001$). Regarding functional capacity, both the ECC and CON groups showed improvements in the Timed Up-and-Go and the 6-Minute Walk Test. Notable, the ECC group demonstrated significantly greater diaphragm excursion performance (CTL vs. ECC: $p < 0.001$; CON vs. ECC: $p < 0.001$ /slope: CTL: -6.037, CON: -8.006, ECC: 1.285). Furthermore, the ECC group reported a higher quality of life, as reflected in the SF-36 Mental Component Summary (MCS) domain.

CONCLUSION: Our study is the first to explore the effects of eccentric cycling exercise on body composition and cardiopulmonary fitness with CKD. The results indicate that ECC is a low-effort, high-benefit exercise modality significantly enhancing body composition, cardiopulmonary fitness, and quality of life in CKD patients. Importantly, no adverse effects were reported throughout the study. These results advocate its use as an innovative intervention for this population.

INFLUENCE OF RESISTANCE TRAINING ON INFLAMMATORY FUNCTION IN ANOREXIA NERVOSA: AN EXPLORATORY STUDY

COSCO, L., PAGADOR, A.V., MORÁN, E., ARIAS, L., COBO, A., SALCEDA, S., SÁNCHEZ, M.A., SUAREZ, L., FAEDO, C., DÍAZ-AZCANO, P., CRUZ-PIÑEIRO, M., EMERENZIANI, G.P., BUONO, P., IGLESIAS, E., OLMEDILLAS, H., FERNANDEZ-DEL-VALLE, M.
UNIVERSITY OF NAPLES PARTHENOPE

INTRODUCTION: Anorexia Nervosa (AN) is a psychiatric disorder characterized by a distorted body image, fear of weight gain and a high rate of chronicity associated with an increased risk of mortality [1]. The overall prevalence of AN is 3.6% in women and 0.3% in men [2], with peak onset around 15.5 years of age [3]. Recently AN was associated to Neutrophil/Lymphocyte Ratio (NLR), Monocyte/Lymphocyte Ratio (MLR), and Platelet/Lymphocyte Ratio (PLR) serum increase, suggesting a dysfunctional inflammatory response in this population [4,5]. Although Resistance Training (RT) has been explored as a complementary intervention to improve physical and mental well-being in individuals with AN [6], its effect on inflammatory markers remains unknown. Therefore, this study aimed to analyze the effect of 10-week RT program on NLR, LMR and PLR in serum samples from AN patients receiving day hospital care.

METHODS: A total of 20 AN patients (22.25 ± 8.6 years; BMI 16.32 ± 6.1 kg/m²) were enrolled and randomly assigned to either exercise (ANE = 10) or control (ANC = 10) groups. Blood samples were drawn at baseline (T0) and after 10-week training (T1) inflammatory markers were measured and NLR, MLR, and PLR ratios were calculated. Physical fitness assessment included body composition analysis using Tanita BC418 MA and circumferences and skinfold thickness measurements were evaluated at T0 and T1. The RT program consisted of a 10-week supervised program (three per week, 50–60 minutes/session), with progressive moderate-to-high intensity training that included exercises for large muscle groups [6]. A non-parametric U Mann-Whitney or a parametric Student's t-test was performed based on normality tests.

RESULTS: A significant time x group effect was found for neutrophil count, NLR, thigh circumference (TC), lean body mass (LBM) and skeletal muscle mass (SMM) ($p < 0.05$). The ANE group presented significantly lower absolute neutrophil count ($p = 0.010$) and NLR ratio ($p = 0.017$) as well as significantly increased TC ($p = 0.032$), LBM ($p = 0.06$) and SMM ($p = 0.047$) after the 10-week exercise intervention.

CONCLUSION: Results from this study revealed for the first time RT's contribution to the improvement of inflammatory markers in AN patients under day-hospital care. In addition to the improvements found in TC, LBM and SMM, these results show underlying positive effects of RT in regulating inflammatory function in AN.

A DELPHI SURVEY TO ESTABLISH THE CORE KNOWLEDGE AND SKILLS OF CLINICAL EXERCISE PHYSIOLOGISTS WORKING IN THE UK

CROZIER, A., OSIN, C., SADLER, I., GRAVES, L.E.F., RYCROFT, J., DAWSON, E., MILLER, G., NAYLOR, L., GREEN, D.J., ASKEW, C.D., JONES, H.
LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Registered Clinical Exercise Physiologists (CEPs) are recognised healthcare professionals in the United Kingdom (UK) and are registered through the Academy of Healthcare Science (AHCS). Their practice is guided by the Clinical Exercise Physiology UK (CEP-UK) standards outlined in their scope of practice and the accompanying curriculum framework. This study aimed to identify and reach consensus on the key knowledge and skills of a UK CEP to ensure that current standards and guidelines are fit for purpose in the UK.

METHODS: Two phases, (i) a scoping review of Medline, Web of Science, and Cumulative Index to Nursing and Allied Health Literature (CINAHL) databases. Key requirements were identified from analysis, the current CEP-UK scope of practice, curriculum framework, the AHCS standards of proficiency and good clinical practice. Based on evidence gathered in phase (i), a modified Delphi survey was administered as phase (ii), which contained CEP key knowledge and skills ($n=58$), health conditions that a CEP should be able to work with ($n=15$), and healthcare professions that a CEP should understand

the roles and expertise of (n=9). Academics (n=26), healthcare professionals (n=25), CEPs (n=10), service managers (n=6), and researchers (n=4) were identified through purposive sampling, public advertisement through social media, and snowball sampling. A 1-to-5 rating Likert scale was completed by participants based on the importance of each component for a CEP to practice effectively in the UK. A consensus was reached based on >65% agreement for each component.

RESULTS: Phase (i) identified 24 studies that contained relevant knowledge and skills data. During phase (ii) n=58 (82%) of participants completed the survey. All knowledge and skills identified from the scoping review, the CEP-UK scope of practice, curriculum framework and the AHCS standards of proficiency and good clinical practice (n=58) were accepted, with those in clinical practice (99%) deemed the most important. For CEP practice, 12 of the health conditions identified (80%) were accepted, with cardiovascular and respiratory diseases (100%) identified as the most important and eating disorders (54%) the least important. All healthcare professions (n=9) were accepted, with specialist exercise instructors (100%) being the most important and podiatrists (73%) the least important.

CONCLUSION: The final consensus list contains 58 key knowledge and skills, 12 health conditions and 9 healthcare professions that are important for CEPs to work effectively in UK healthcare. This study confirms that the current CEP-UK curriculum framework is fit for purpose with minimal changes required for the next iteration scheduled for 2025 based on consensus. Further research is required to understand how to best teach and assess these key knowledge and skills within academic institutions.

FROM THEORY INTO PRACTICE: INSIGHTS FROM A REAL-WORLD IMPLEMENTATION MODEL FOR TAILORED EXERCISE PRESCRIPTION IN CHRONIC DISEASES

DUREGON, F., QUINTO, G., VECCHIATO, M., BATTISTA, F., FAGGIAN, S., URRU, F., GUZZON, C., FANTIN, A., FABRIS, M., ERMOLAO, A., NEUNHAEUSERER, D.

UNIVERSITY OF PADUA

INTRODUCTION: Although physical exercise is an evidence-based treatment for patients with chronic diseases, providing benefits in terms of morbidity, mortality and quality of life, its implementation in real-world healthcare systems is still limited. Even when physicians recommend physical activity, compliance and adherence to exercise programs remain very low. This study aims to implement a real-world model for tailored exercise prescription (TEP) in an outpatient clinic to evaluate feasibility, effectiveness, compliance and adherence.

METHODS: A TEP was set for each participant, based on a complete clinical and functional evaluation including cardiopulmonary exercise testing and fitness test battery. Subsequent supervised training sessions (STS) were performed in the hospital gym for at least 6 weeks. Lastly, the TEP was adapted for an unsupervised out-of-hospital gym training. After 6 months functional evaluations were repeated during follow-up meeting, also assessing compliance with general recommendations and adherence to the prescribed exercise program.

RESULTS: A total of 312 patients (44% male) with a mean age of 52.1 ± 13.6 years were enrolled. The most frequent main chronic conditions were obesity (47%), solid organ transplantation (32%), primary cardiovascular diseases (8%) and cancer (4%). The initial STS program was completed by 85.9% of patients, all without adverse events. All analyzed tests in the whole population showed improvement after the initial STS period, with maintenance in the medium term. The compliance at the 6-month follow-up meeting was 53.2%, without differences between patients with different chronic conditions. In those patients evaluated at follow-up, the adherence to prescribed exercise in the 6 months was 65.7% (44.9% considering the whole population).

CONCLUSION: A real-world implementation model involving medical evaluation, tailored exercise prescription, and supervised training sessions is safe and effective in the short-term, also impacting medium-term follow-up outcomes.

Despite achieving a compliance rate of two out of three patients for a medical intervention program that includes exercise therapy, only half maintained adherence to exercise after 6 months.

Intervention strategies based on implementation science, behavioral change and motivation, are needed to foster greater adherence to physical exercise in the mid-to-long term.

HOW DOES AN AEROBIC AND RESISTANCE INTERVAL TRAINING PROGRAM SHAPE CYTOKINE PROFILES AND COGNITIVE FUNCTIONS?

SKUREWICZ-PALICKA, M., CHROBOCZEK, M.1, WINOWIECKA, N.1, JOST, Z.1, LASKOWSKI, R.1, OLEK, R.A.2, KUJACH, S.1,3
1 GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT; 2 POZNAN UNIVERSITY OF PHYSICAL EDUCATION; 3 MEDICAL UNIVERSITY OF GDANSK

INTRODUCTION: Growing evidence suggests that elevated pro-inflammatory cytokines may impair executive function by exerting neurotoxic effects on the prefrontal cortex (PFC). In contrast, prolonged systemic inflammation appears to make the hippocampus, crucial for memory, more susceptible to neurodegeneration. This suggests that inflammation could differentially affect brain regions, driving domain-specific cognitive decline. It has been also suggested that circulating inflammatory factors may penetrate the blood-brain barrier, triggering neuroinflammation that disrupts brain neurotransmission. Regular exercise reduces systemic inflammation by lowering pro-inflammatory and increasing anti-inflammatory cytokines. This dual action not only protects the PFC and hippocampus from inflammatory damage but also promotes neuroplasticity and synaptic resilience. Furthermore, exercise-induced factors called "exerkines" have been shown to counteract the detrimental effects of pro-inflammatory cytokines, supporting both executive function and

memory processes. The aim of this study was to determine the effect of 12-week aerobic and resistance interval training program on peripheral pro-inflammatory and anti-inflammatory cytokine concentrations and cognitive function among the elderly.

METHODS: The study involved 70 elderly. Participants were randomly assigned to Aerobic High-Intensity Interval Training (AHIT), Resistance Circuit High-Intensity Interval Training (HICT) or a control group (CON). The AHIT protocol involved eight 60-second cycling bouts at 80–90% HRmax with 30 seconds of passive rest. The HICT protocol consisted of eight body-weight exercises with a 30-second rest period. Before and after the 12-week intervention, participants completed cognitive tests assessing executive functions (Stroop Test, Trail Making Test Parts A and B) and memory performance (Visual Pattern Test). Venous blood samples were collected to evaluate pro- and anti-inflammatory cytokine concentrations using the ELISA method.

RESULTS: This study found that HICT significantly reduced the execution time in the TMT-B test. AHIT improved cognitive flexibility and inhibitory control, as indicated by a shorter Stroop Interference time. Additionally, both HICT and AHIT enhanced short-term memory, shown by better VPT scores. Interestingly, only HICT program significantly reduced pro-inflammatory cytokines (TNF, IL-5, IL-2, IL-7, IL-1B), demonstrating a strong anti-inflammatory effect.

CONCLUSION: This study shows that a 12-week interval training program significantly improved executive function and memory performance. HICT significantly lowered pro-inflammatory cytokines, while anti-inflammatory levels remained unchanged. Improvements in cognitive function highlight the broader benefits of HICT and AHIT for physical and mental health. No specific effects of aerobic or resistance training on cognitive domains were observed.

SKELETAL MUSCLE MITOCHONDRIAL DYSFUNCTION AS A POTENTIAL DRIVER OF EXERCISE INTOLERANCE IN PATIENTS WITH ADVANCED CHRONIC KIDNEY DISEASE

HOUTVAST, D., HENDRIKS, F., PETRICK, H., VAN DER SANDE, F., HOLLOWAY, G., KOOMAN, J., VAN LOON, L.
MAASTRICHT UNIVERSITY

INTRODUCTION: Patients with advanced chronic kidney disease (CKD) often present with fatigue and exercise intolerance, which limits physical functioning and reduces quality of life. Within skeletal muscle, mitochondria are essential for maintaining energy production and, as such, mitochondrial dysfunction may contribute to exercise intolerance in patients with CKD. This study assessed whether skeletal muscle mitochondrial respiration differs between individuals with and without advanced CKD and whether mitochondrial respiration is associated with whole-body aerobic capacity. Furthermore, we assessed the effect of one week of resistance exercise training on skeletal muscle mitochondrial respiration in patients with CKD and healthy controls.

METHODS: Twenty patients with CKD stage G3b-G4 (3F/17M, age 66 ± 13 y, BMI 30 ± 5 kg/m²) and twenty sex-, age-, and BMI-matched controls (3F/17M, age 65 ± 14 y, BMI 29 ± 4 kg/m²) participated in the current study. At screening, all participants underwent a cardiopulmonary exercise test (CPET) to assess aerobic capacity (VO₂peak). Next, throughout a 1-week intervention period, participants completed three resistance exercise sessions (day 0, 2, and 4) consisting of 4 sets of leg press and leg extension at 70-80% of one-repetition maximum (1RM). Skeletal muscle biopsies were obtained from the m. vastus lateralis in an overnight fasted and rested state prior to (day 0) and after the intervention period (day 7). Permeabilized fiber bundles were prepared from skeletal muscle tissue to measure mitochondrial respiration. Respiration experiments were performed in an Oroboros O2k respirometer with the addition of saturating ADP and complex I- and II-linked substrates.

RESULTS: VO₂peak was significantly lower in patients with CKD compared with healthy controls (21.3 ± 5.9 vs 30.3 ± 11.2 mL/min/kg, $P=0.004$). Maximal mitochondrial respiration at baseline was significantly lower in patients with CKD compared with healthy controls (376 ± 71 vs 443 ± 128 pmol/s/mg dry wt, $P=0.048$). Maximal mitochondrial respiration and VO₂ peak were significantly correlated in both patients with CKD (Pearson's $r=0.54$, $P=0.014$) and healthy controls ($r=0.72$, $P<0.001$). Following one week of resistance training, maximal mitochondrial respiration tended to increase in patients with CKD (376 ± 71 to 408 ± 94 pmol/s/mg dry wt; paired t-test, $P=0.058$) but no significant time*group interaction was observed ($P=0.453$).

CONCLUSION: Whole-body aerobic capacity in patients with advanced CKD is lower when compared with matched healthy controls. The lower aerobic capacity is, at least partly, attributed to lower skeletal muscle mitochondrial respiration. Further work is required to assess the ability of resistance exercise training to augment muscle mitochondrial respiratory capacity, increase aerobic capacity, and hence improve exercise tolerance in patients with CKD.

QUANTIFICATION OF STREPTOCOCCUS SALIVARIUS K12 ABUNDANCE IN SALIVA AFTER ORAL PROBIOTIC SUPPLEMENTATION AND FOLLOWING A HIGH-INTENSITY TRAINING (HIT) PROGRAM

FANELLI, F., ANNIBALINI, G., GERVASI, M., AMATORI, S., PERRONI, F., ROCCHI, M.B.L., SISTI, D., BERTUCCIOLI, A.
UNIVERSITÀ DEGLI STUDI DI URBINO

INTRODUCTION: The human oral cavity harbors over 700 bacterial species, making it the second most complex microbiota in the human body [1]. Streptococcus salivarius K12 is bacterial strain potentially implicated in the reduction of upper respiratory tract infections (URTIs) [2]. Here, we quantified K12 strain in eighteen young subjects before and after S. salivarius K12 supplementation and following an high-intensity training (HIT) program. Additionally, total oral bacterial abundance

and dominant bacterial Orders present in saliva were analyzed using real-time PCR along with salivary IgA and cortisol levels.

METHODS: Participants were administrated either a probiotic containing *S. salivarius* K12 (Bactoblis®, PharmExtracta S.p.A., Pontenure, Italy) or a placebo for 30 days. Following this supplementation period, participants discontinued probiotic intake and underwent a graded exercise test followed by five HIT sessions within three days. Saliva samples (1 mL) were collected at baseline, after 30 days of supplementation, and at 24h and 72h post-exercise. Relative abundances of *S. salivarius* K12 and the bacterial Orders Lactobacillales, Bacteroidales, Clostridiales, and Enterobacteriales, as well as total bacterial load, were quantified in saliva DNA using real-time PCR [2-3]. sIgA and cortisol levels were quantified using a lateral flow device (LFD). Statistical significance was determined using repeated-measures ANOVA.

RESULTS: At baseline, *S. salivarius* K12 was undetectable in both the placebo and the supplemented groups. After 30 days of supplementation, its relative abundance significantly increased in all supplemented subjects, though with a high inter-individual variability. *S. salivarius* K12 levels remained elevated for three days after supplementation but declined sharply thereafter. Total oral bacterial levels were unaffected by *S. salivarius* K12 supplementation or HIT sessions. Interestingly, the abundance of the Bacteroidales order decreased 24h post-exercise but returned to pre-exercise levels after 72h. In contrast, Clostridiales abundance increased 24h post-exercise. Notably, post-supplementation *S. salivarius* K12 abundance negatively correlated with salivary cortisol levels. Additionally, Bacteroidales abundance negatively correlated with IgAs level and positively correlated with cortisol level.

CONCLUSION: Real-time PCR quantification may serve as a simple method to assess the efficacy of *S. salivarius* K12 supplementation and its persistence in the oral cavity. A three-day intensive exercise training programme did not significantly alter total oral bacterial abundance; however, the observed changes in specific bacterial Orders suggest potential modifications of oral microbiome composition. Further studies are warranted to identify the species involved in these microbiome changes and their potential implication on URTI.

EFFECTS OF INTERGENERATIONAL AND PARTICIPATORY-DESIGNED EXERCISE INTERVENTIONS ON ACTIVITY LEVELS IN OLDER ADULTS: A SYSTEMATIC REVIEW

TRULL, R., PAREDES, X., FORT, A., SOLÀ, J., CAPELLÀ, I., JEREZ-ROIG, J., CARDON, G., GINÉ-GARRIGA, M.
RAMON LLULL UNIVERSITY BLAQUERNA

Background: Older adults are the most sedentary segment of the population, highlighting the need for sustainable interventions to promote lasting behavioral change. Intergenerational programs and participatory approaches have shown promise in enhancing adherence and maintaining longer term benefits.

Objectives: This study aimed to assess the effects of intergenerational and participatory-designed exercise-based interventions to reduce sedentary behaviour (SB) and/or increase physical activity (PA) in older adults.

Design: Literature searches were conducted up to February 2025 within PubMed, Scopus, Web of Science and Cochrane databases. The selected papers met the following eligibility criteria: interventions had to (a) target older adults aged 60 and above, along with younger participants of any age; (b) incorporate intergenerational connections; (c) be experimental studies utilizing a participatory approach; (d) evaluate the effects of an exercise- or SB-focused intervention; and (e) measure at least one PA or SB outcome in older adults, with both pre- and post-intervention assessments.

Measurements: Primary outcomes measured PA or SB in older adults, with assessments conducted before and after the intervention. Secondary outcomes included additional indicators of physical and emotional health, as well as perceived benefits, satisfaction, and intervention acceptability.

Results: A total of 1 out of 148 identified articles met these criteria. The study showed non-significant, but positive associations between intergenerational interactions and increased PA.

Conclusions: While both intergenerational exercise-based interventions and participatory-designed interventions have independently shown positive outcomes in older adults, further research is needed to explore the benefits of combining these approaches.

INVESTIGATING PHYSICAL EDUCATION TEACHERS ASSESSMENT LITERACY: PRELIMINARY FINDINGS OF A MULTI-STEP APPROACH

FISCHER, L., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Assessment literacy is crucial for teachers, enabling them to adequately assess their students' learning process and adapt their teaching accordingly. Teachers' assessment is influenced by multiple facets, e.g. cognitive ability and perception [1]. The framework of assessment literacy encompasses cognitive abilities, teachers beliefs regarding assessments and their navigation of the institutional context [2]. However, assessment literacy in the context of physical education (PE) remains to be elucidated. In a multi-step approach, it is aimed to develop and evaluate a reliable instrument, specifically designed to investigate assessment literacy of PE teachers.

Methods: At first, an international (i.e., AUS, CAN, ESP, NED, USA) panel of research experts (n=7) agreed to review and adapt ACAI [3] and KOSTA [4] to account for the unique context of PE. Secondly, PE teachers (n=10), serving as practitioner experts, review the adapted instrument. Subsequent to piloting, reliability and validity will be tested within international PE teacher cohorts.

Results: Preliminary findings from the expert panels and pilot testing (German cohort; n=87) indicate context adaptability of assessment literacy in PE, particularly concerning to Scenario 1 "You give your class a paper-pencil summative unit test with accommodations and modifications for identified learners. Sixteen of the 24 students fail." and Scenario 2 "You discover that a student has plagiarized some of their assignment (e.g., an essay, lab report)" from ACAI.

Discussion and Conclusion: The studies contribute to assessment literacy research by developing a reliable instrument specifically tailored to PE. Eventually, the instrument aims to foster a more comprehensive as well as culturally informed understanding of teachers' assessment and may allow cross-cultural analyses.

ENGAGEMENT IN PHYSICAL EDUCATION AS A MEDIATOR BETWEEN PSYCHOLOGICAL NEED SATISFACTION AND SELF-REPORT OUT-OF-SCHOOL PHYSICAL ACTIVITY: THE MODERATING ROLE OF GENDER

HARBICHOVÁ, I., SCHEIER, L., NOVOTNÁ, J., KOMARC, M.

CHARLES UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Physical inactivity among adolescents remains a global public health concern, with schools playing a crucial role in promoting lifelong physical activity habits. Self-Determination Theory (SDT) [1] suggests that satisfying students basic psychological needs for autonomy, competence, and relatedness in physical education (PE) fosters intrinsic motivation, enhancing engagement and long-term physical activity participation. However, how engagement in PE translates into out-of-school physical activity remains unclear, and potential gender differences in this relationship require further investigation. This study examines engagement in PE as a mediator between psychological need satisfaction in PE and self-reported physical activity outside school, while also testing whether gender moderates this mediation effect. Understanding these mechanisms can provide insights into how PE environments can be tailored to foster engagement and long-term physical activity in youth.

METHODS: Self-report instruments measuring basic psychological need satisfaction (BPNS) in PE (autonomy, competence, relatedness, 5 items each, $\omega \geq .66$), behavioral engagement in PE (5 items, $\omega = .81$), and out-of-school physical activity (2 items, $\omega = .91$) were administered online to N = 2,967 Czech high school students. Multi-group structural equation modeling tested gender differences in mediating effects of PE engagement on general PA separately for each psychological need.

RESULTS: We observed varying total effects on out-of-school PA across needs, with competence having the strongest effect for both males ($\beta = .52$) and females ($\beta = .39$). The mediating role of PE engagement varied, ranging from none/partial for competence to substantial/full for autonomy. Gender moderated the mediation for relatedness, where PE engagement fully mediated the effect in females but only partially in males.

CONCLUSION: Our findings emphasize the role of engagement in PE as a mediator linking psychological need satisfaction to out-of-school physical activity, with its influence varying across needs. While competence had the strongest direct effect on PA, engagement played a key role in translating autonomy and relatedness satisfaction into sustained physical activity behaviors. The gender-specific mediation pattern highlights the need for differentiated PE strategies. These results suggest that enhancing PE engagement—through autonomy-supportive, competence-building, and socially inclusive environments—could be key to promoting lifelong physical activity habits among adolescents. Future interventions should focus on strengthening engagement in PE as a mechanism for increasing physical activity beyond school.

THE INFLUENCE OF SPORTS COACHES' EMOTIONAL EXPRESSIONS ON STUDENTS IN EXTRACURRICULAR SPORTS CLUB ACTIVITIES OF JAPANESE JUNIOR HIGH AND HIGH SCHOOLS

SHIMIZU, Y., MIYAZAKI, M.

INTERNATIONAL CHRISTIAN UNIVERSITY

INTRODUCTION : In Japan, approximately 70% of middle school and 42% of high school students participate in sports clubs. Sports clubs play an important educational role as extracurricular activities run by schoolteachers. However, in recent years, many problems with inappropriate instruction in middle and high school club activities have surfaced. The underlying factor is the psychological burden on teachers who lead club activities. Therefore, this study examined how the "teacher's emotional control," which is a background factor for "inappropriate instruction" and "appropriate instruction" by teachers who lead club activities, affects the adaptation and performance of sports club members in terms of club activities.

METHODS : The study participants were 2,500 Japanese middle and high school students involved in school sports club activities (mean age: 15.23 years, SD: 1.739). They voluntarily responded to a questionnaire comprising items from the Coaching Emotion Control Scale (CEC), Inappropriate Guidance Scale (IG), Appropriate Guidance Scale (AG), Coaching Evaluation Scale (CE), Club Activity Engagement Scale (CAE), Maladaptive for Club Activity Scale (MCA), and Self-Growth for Club Activity Scale (SCA). All these scales were originally developed for this study and confirmed as having shown acceptable reliability and meaningful content validity. A covariance structure analysis was conducted to confirm the acceptability of the hypothetical model and relationships between the seven scales.

RESULTS : The results showed that our hypothetical model, having CEC as the determinant independent variable, SCA as the dependent variable, and IG, AG, CE, CAE, and MCA as mediators, yielded acceptable fit indices (GFI: 0.995, AGFI: 0.977, CFI: 0.997, RMSEA: 0.049). Direct effects were observed for CEC, IG, and AG (path coefficients: 0.53, $p < 0.001$, -0.14, $p < 0.001$, respectively). The indirect effects of CEC on SCA through AG, CAE, and MCA were statistically significant.

DISCUSSION : The hypothetical model predicted that teachers' emotional control would directly affect students' awareness of inappropriate and appropriate coaching. The study findings indicated that emotional coaching conditions indirectly affected students' club engagement and self-growth through mediating variables. These findings imply that sports club coaches should have opportunities to learn emotional regulation or participate in regular coaching consultations and counseling sessions with psychological specialists in teachers' seminars. Additionally, educational committee boards or governments should create a coaching system and program for school club managers.

PREDICTORS AND WELL-BEING OUTCOMES OF PSYCHOLOGICAL NEED SATISFACTION IN PHYSICAL EDUCATION: A LATENT CLASS ANALYSIS

KOMARC, M., SCHEIER, L., NOVOTNÁ, J., HARBICHOVÁ, I.

CHARLES UNIVERSITY

INTRODUCTION: According to Self-Determination Theory (SDT), psychological need satisfaction is key to motivation and well-being in physical education (PE). When students feel their autonomy, competence, and relatedness needs are met, they experience intrinsic motivation, leading to sustained participation, enjoyment, and improved mental health [1]. This study adopted a person-centered approach to identify typologies of high school students based on psychological need satisfaction in PE. We also examined whether motivational climates in PE, shaped by different socialization agents (parents, peers, and teachers), predict class membership and compared well-being outcomes across classes.

METHODS: Self-report instruments measuring basic psychological need satisfaction (BPNS) in PE (autonomy: $\alpha = .84$, competence: $\alpha = .89$, relatedness: $\alpha = .90$), empowering motivational climates (parents: $\alpha = .86$, peers: $\alpha = .86$, teachers: $\alpha = .91$), and well-being outcomes (happiness, optimism, depression) were administered online to $N = 2,967$ Czech high school students. Latent class analysis (LCA) identified the optimal number of classes based on 15 BPNS indicators, and a three-step method [2] examined predictors and outcomes of the latent typology.

RESULTS: LCA model fit indices (e.g., reduction in G^2 statistics) and parameter estimates supported a four-class solution for need satisfaction. The largest latent class (Low Satisfaction) included over 30% of participants with low response probabilities across all 15 BPNS indicators. Participants in this class reported significantly lower happiness and optimism and higher depression compared to others (all $p < .001$). Multinomial logistic regression showed that all three socialization agents fostering an empowering motivational climate were significant predictors of class membership—a more positive perception of the climate was associated with membership in a qualitatively better class.

CONCLUSION: Consistent with expectations and prior research using LCA, we identified four BPNS classes in PE. A significant proportion of students reported low need satisfaction, highlighting the need for interventions fostering supportive environments to improve well-being. Our findings underscore the importance of a holistic approach to shaping PE's motivational climate, as all socialization agents critically influence students' psychological need satisfaction and well-being.

EXPLORING THE IMPACT OF PLEASURE-ORIENTED EXERCISE ON MOTIVATION AND BEHAVIOR IN HEALTH CLUBS: RESULTS FROM A RANDOMIZED CONTROLLED TRIAL ANCILLARY STUDY

ANDRADE, A., BASTOS, V., PALMEIRA, A., TEIXEIRA, D.

FACULTY OF PHYSICAL EDUCATION AND SPORT, LUSÓFONA UNIVERSITY, LISBON, PORTUGAL; RESEARCH CENTER IN SPORT, PHYSICAL EDUCATION, AND EXERCISE AND HEALTH, LISBON, PORTUGAL

INTRODUCTION: The sustainability of exercise behavior has been consistently linked to pleasurable affective responses, highlighting a motivational hedonic approach as a promising strategy to reduce physical inactivity. This randomized experimental study aimed to compare two individualized methods of exercise assessment, prescription, and supervision—adjusted for intensity—on motivational and behavioral variables defined as secondary outcomes.

METHODS: A total of 46 apparently healthy, insufficiently active adults (Mage = 32 years, SD = 8.62) were randomly assigned to one of two groups: a control group (FIT; n = 23) and an experimental group (FIT-AFFECT; n = 23). Participants completed three training sessions over two weeks in a gym. The control group followed general exercise prescriptions aligned with the American College of Sports Medicine (ACSM) guidelines, while the experimental group received prescriptions tailored to enhance pleasurable feelings via: (1) consideration of individual preferences and tolerance for exercise intensity, (2) self-selection/regulation of intensity, and (3) repeated affective assessments. Motivational and behavioral constructs—including intention to continue exercising, exercise-related habit, perceived choice, perceived competence, intrinsic motivation, and subjective vitality—were measured subjectively and analysed using descriptive statistics, correlational analyses, and 2 (group) x 2 (time) split-plot ANOVAs.

RESULTS: Both prescriptions were associated with positive outcomes across time in motivational and behavioral variables, such as intrinsic motivation, perceived competence, subjective vitality, exercise-related habit, and intention to engage in physical activity. No relevant differences emerged between groups favouring the presented hypothesis.

Discussion: The present study demonstrated that both a structured and individualized pre-defined intensity as a pleasure-guided intensity prescription can support several motivational and behavior-related variables like intrinsic motivation, choice, competence, subjective vitality, exercise habit, and intention to be physically active. The absence of significant differences between groups indicates that the increased exercise frequency observed in the experimental group of this RCT may be independent of these motivational constructs. Nevertheless, considering the same results in the motivational constructs and the higher frequency experienced in the experimental group, there is no empirical justification for discouraging engagement in pleasurable activities or related prescriptions.

REDUCING SCHOOL ABSENCE THROUGH HEALTH PROMOTION: A QUALITATIVE STUDY ON SCHOOL STAFF'S EFFORTS TO IMPROVE WELL-BEING, MOTIVATION, AND PHYSICAL ACTIVITY AMONG SECONDARY SCHOOL STUDENTS

AUGUSTSSON, C., HÖGMAN, J.

DEPARTMENT OF EDUCATIONAL STUDIES

INTRODUCTION: An increasing problem among students in today's compulsory school is the reduced physical activity, poor psychosocial health, and an increased number of students with problematic school absences. Working on health promotion and early detection of signs of discomfort and school absence is of utmost importance in order to work preventively. The PIA project – (Promote Health, Important Choices and Attendance) is a three-year school project in three smaller municipalities and three secondary schools in the western parts of Sweden. The project aims to reduce school absence through health promotion, with a focus on enhancing well-being, motivation, and physical activity among students aged 13 to 16.

The aim of this study is to qualitatively evaluate the PIA project. The study seeks to answer the following questions; How do school staff describe the types of interventions that have been implemented? Do the school staff experience that the activities enhance well-being, school motivation and physical activity during the school day?

Method: The study involves qualitative interviews with school staff (n= 27) who are part of the student health teams in three schools. These teams include roles such as school nurse, health coach, special needs teacher, study and career counselor. The project is grounded in ecological systems theory, which highlights the importance of interventions at various levels within the environment to influence and change the socio-cultural processes of individuals and groups. Data was analyzed using thematic analysis, involving a thorough review of the material followed by grouping codes into themes to develop a comprehensive understanding of the data.

RESULTS: Three themes were constructed from interview data. 'Opportunities for Movement' highlights efforts to promote physical activity and mental health. 'Management of Absence' displays the teams' work to influence students' decisions to attend school. The theme 'Collaboration and Relationships' emphasizes the importance of cultivating and developing secure relationships with students in order to better engage them and involve them in the schools' health promotion work.

Discussion: The results illustrate how the health teams in the PIA project attempt to implement interventions at multiple levels within the school organization, both directly targeting students and within overarching structures. The results of the study can contribute to a knowledge base recommending methods for schools to use in preventing problematic school absences, psychosocial ill health and physical inactivity.

THE IMPACT OF MENTAL HEALTH EDUCATION THROUGH THE DELIVERY OF A STRUCTURED PLAY-BASED LEARNING CURRICULUM ON CHILDRENS' MENTAL WELLBEING

OREILLY, J., FENG, J., CHOW, R., SIT, C.H.P.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Engaging in regular physical activity (PA) offers numerous benefits for the mental health of children. Those who are physically active often experience greater well-being, higher self-esteem, and an improved quality of life (Kopp et al., 2024). PA interventions in children have shown a reduction in symptoms of depression, stress and anxiety. It is well established that involvement in team sports promotes a more active lifestyle, enhances physical fitness and improves clinical health (Hills et al., 2015). In addition, mental health education has been found to support children managing emotion regulation, which is a precursor to the development of mental health concerns in adolescence (Moran et al., 2024). Very few studies in Asia have placed emphasis on the use of team sports among youth groups as an intervention strategy to enhance emotional wellbeing and psychosocial status.

METHODS: 18 children participated in a 10-week programme of play-based rugby and mental health coaching. Psychosocial assessments were conducted pre- and post-programme. These included The Depression, Anxiety and Stress Scale - 21 Items (DASS-21); The Physical Self-Description Questionnaire (PSDQ); Connor-Davidson Resilience Scale (CD-RISC); Buss Perry Aggression Questionnaire (BPAQ). The programme was delivered by full-time rugby coaches and mental health professionals. Informed consent was obtained from all parents prior to the commencement of the study.

RESULTS: A total of 18 participants (mean age 9 ± 1.6 y) took part in this study. Post-test analysis of data identified a significant reduction in stress levels as measured by the DASS-21 (pre: 149 ± 19 ; post: 127 ± 50 ; $p=0.06$). At the same time, self-concept scores according to the PSDQ significantly increased over the same period (pre: 4.6 ± 1.3 ; post: 5.2 ± 1 ; $p=0.07$). In addition, non-statistically significant improvements in scores for depression (pre: 7.6 ± 6.9 ; post: 5.1 ± 5.1 ; $p=0.25$) and anxiety (pre: 190 ± 28 ; post: 116 ± 19 ; $p=1.6$) were also observed amongst the same cohort. No differences were observed in CD-RISC. Aggression scores were slightly increased post-test (pre: 7.2 ± 3.1 ; post: 7.6 ± 3.2 ; $p = 0.17$).

Conclusions

The current study shows that increased access to safe and inclusive sports activity in a structured learning environment can promote the wellbeing of children and equip them with the ability to manage their emotional health. This research can provide useful information for sporting and community organisations to assist policy makers in designing new positive exercise programmes through a systematic learning environment that prioritises mental and physical well-being.

TEACHING AND ASSESSMENT OF CLINICAL EXERCISE PHYSIOLOGISTS IN THE UK

MILLER, G., CROZIER, A., GRAVES, L.E.F., DAWSON, E.A., OSIN, C., SADLER, I., NAYLOR, L., GREEN, D.J., ASKEW, C.D., JONES, H.

LIVERPOOL JOHN MOORE UNIVERSITY

INTRODUCTION: Development of clinical skills in areas such as exercise risk stratification, testing, prescription, monitoring and outcome assessment are vital for patient safety and clinical effectiveness in clinical exercise physiology (CEP). This study explored how current CEP courses are being taught and assessed, and how current curricula are aligned with the real-world clinical requirements in the UK.

METHODS: Qualitative methods were employed to explore the thoughts of CEPs, academics and current students regarding the teaching and assessment of CEPs in the UK. Research design involved, (i) semi-structured interviews with students ($n=16$), and (ii) focus groups with academics ($n=8$) and CEP ($n=5$) stakeholders. Data obtained were audio recorded using a portable Dictaphone and transcribed verbatim, then thematically analysed manually using reflexive thematic analysis.

RESULTS: Three themes: (i) in situ learning / real world practice (working with patients and specialist practitioners); (ii) programme design (scaffold learning and integrated modules) and, (iii) teaching approach (simulated learning and research competency) were generated concerning teaching methods and approaches across CEP postgraduate degrees. The current use of simulated tasks for the delivery of taught content was identified as lacking effectiveness, with clinical placements identified as being the most important source of knowledge and skill attainment due to the real-world exposure to patients and practitioners. Clinical placements and simulated learning were recognised as the main two methods of problem-based learning (PBL) used to develop student knowledge, skills and competency to practice. Two themes (placement tariffs/assessors in situ and role play/simulation) were identified for the assessment of students.

CONCLUSION: Clinical placements remain the optimal method for developing the knowledge, skills and competency to practice for student CEPs. However, suitable placements remain limited and novel approaches such as university-led exercise services require consideration for student competency development. A standardized and accredited training pathway from undergraduate through to postgraduate level should be explored to allow student competency to be developed over a longer period, to enhance knowledge, skills and competency upon graduation and registration.

WORK INTENSITY IN INDIVIDUALS WITH RHEUMATIC AND MUSCULOSKELETAL DISEASES INSTRUCTED TO GET THE HEART RATE UP

HANSEN, E., JOSEPHSEN, L., JØRGENSEN, J., CLAUSEN, B., JUNEJA, H.

UNIVERSITY COLLEGE ABSALON - CAMPUS ROSKILDE: PROFESSIONSHOJSKOLEN ABSALON - CAMPUS ROSKILDE

INTRODUCTION: Persons suffering from rheumatic and musculoskeletal diseases are urged to do aerobic exercise to reduce the risk of cardiovascular disease and symptoms. A suitable case of exercise is constant exercise at an intensity causing the rate of perceived exertion to be 15, on the 6-20 point Borg scale [1,2]. But, the instruction "Now you need to get your heart rate up" is commonly utilised before aerobic exercise. Here, the following hypothesis was tested: Work intensity during ergometer cycling initiated with the instruction "Now you need to get your heart rate up" is lower than when a score of 15 on the Borg scale is targeted.

METHODS: This was a counterbalanced crossover study. Individuals (n=15) with rheumatic and musculoskeletal diseases participated. Familiarisation was followed by two test sessions termed reference session and exercise session. In the reference session, the relationship between Borg scale score [3] and intensity was established by a progressive protocol, which included cycling at a target score of 15 on the Borg scale. The protocol was initiated by 2 min of cycling at a target score of 7 on the Borg scale. It continued without interruption with 2 min of cycling at a target value of 8 etc. - until the last 2 min at a target of 16 was completed. In the exercise session, intensity was recorded over 20 min of cycling. The participant received the instruction "Now you need to get your heart rate up" in advance. During cycling, the participant could regulate the power output as preferred. Heart rate, power output, and cadence were noted every second min. Heart rate, as a percentage of maximal heart rate, was estimated as earlier [4]

RESULTS: Average values of power output, heart rate, and heart rate as a percentage of maximal heart rate, during cycling at a Borg scale value of 15 in the reference session amounted to 89 ± 40 W, 138 ± 19 (beats/min), and $86 \pm 9\%$, respectively. For comparison, the average values of power output, heart rate, and heart rate as a percentage of maximal heart rate, across the 20 min of cycling in the exercise session, were $7 \pm 13\%$, $5 \pm 7\%$, and 5 ± 6 percentage points, respectively, lower than during cycling at a target score of 15 on the Borg scale in the reference session ($p < 0.05$). Cadence was on average 77 rpm in each session ($p > 0.05$).

CONCLUSION: A value separating moderate and high intensity is 82% of the maximal heart rate [2]. Accordingly, the intensity after the instruction "Now you need to get your heart rate up" in the exercise session may be considered moderate. The intensity when targeting a value of 15 on the Borg scale in the reference session may be considered high.

In conclusion, work intensity during ergometer cycling, preceded by the instruction "Now you need to get your heart rate up", was lower than during cycling targeting a score of 15 on the Borg scale.

PIFIT - PHARMA IN FIT: EXERGAMES AS NONPHARMACOLOGICAL DRUG

GALLORO, M., VACCARO, M., DE SARRO, A., IONA, T.

UNIVERSITY MAGNA GRAECIA OF CATANZARO ITALY

INTRODUCTION: Physical activity is essential for health promotion and disease prevention. However, sedentary behavior remains prevalent, with one in four adults not meeting the WHO's recommended levels (WHO, 2016). Exergames, active video games combining movement with digital interaction, have emerged as innovative tools to promote physical activity among both healthy and no-healthy individuals, play a key role in enabling more frequent, comprehensive, and out-of-hospital follow-up. This systematic review analyzes the effectiveness of exergames in improving physical and cognitive health, evaluates their potential implementation in pharmacies to support medication reduction through physical activity.

METHODS: This review follows PRISMA guidelines, analyzing studies from the past five years in PubMed and Scopus. Studies focus on exergames use in healthy and pathological populations, assessing their impact on physical health, cognitive function, and quality of life. Studies were evaluated using PICO model; exclusion criteria were rehabilitation or lacking "systematic review" or "meta-analysis" in their titles were excluded. Data extraction was conducted via Microsoft Excel, and bias risk assessment followed AMSTAR2.

RESULTS: The review identified studies involving both healthy and pathological populations. Among healthy individuals, exergames improved fundamental motor skills in children, cognitive functions in the elderly, and physical education outcomes in students. In pathological populations, exergames aided in managing childhood obesity, reducing chronic pain,

and enhancing balance and coordination in patients with peripheral neuropathies and Parkinson's disease. However, some studies highlighted methodological limitations, necessitating further research to standardize interventions.

CONCLUSION: Exergames offer a promising strategy to promote physical activity across populations, with potential applications in pharmacies to support public health initiatives. Findings suggest that integrating exergames into pharmacies could reduce medication prescriptions by offering physical activity as an alternative therapy. Further studies are needed to refine their integration into educational and healthcare settings, fostering exercise medicine.

ONLINE STRENGTH TRAINING: IMPACT ON FIBROMYALGIA AND ASSOCIATED SYMPTOMS

ALBUQUERQUE, M., ALVAREZ, M., MONTEIRO, D., NEIVA, H.

UNIVERSITY OF BEIRA INTERIOR

INTRODUCTION: Physical exercise is recommended as an adjunctive treatment for fibromyalgia in several guidelines [1]. However, the effects of remote and online strength training in this population remain poorly studied. This study aimed to investigate the effects of online strength training on disease impact and associated symptoms in individuals with fibromyalgia.

METHODS: Thirteen participants (45.77 ± 12.82 years) completed 16 sessions of online strength training using seven body-weight exercises with adaptations where necessary [2]. Sessions were conducted via Google Meet and lasted 50 minutes (1-8 sessions: 3x8 reps) or 75 minutes (9-16 sessions: 5x6 reps), twice a week. Exercises were performed at maximum intended velocity during the concentric phase, with exertion monitored using the Borg scale. Disease severity was assessed before and after training using the Fibromyalgia Impact Questionnaire (FIQ), and symptoms of pain, anxiety, fatigue, mood, and sleep quality were measured using a visual analogue scale (VAS).

RESULTS: All participants showed improvements after the sessions. The total FIQ demonstrated a 23% reduction in disease impact, with domain reductions ranging from 7% to 44%. Pain, anxiety, and fatigue symptoms decreased by 33%, 31%, and 38%, respectively. Additionally, 24% of participants reported improved mood, and 50% noted better sleep quality during the intervention.

CONCLUSION: Online strength training, without external loads and using an adapted exercise protocol, appears to be beneficial for reducing disease impact and improving symptoms in individuals with fibromyalgia.

HEALTH RELATED FITNESS OF HUNGARIAN ADULT FEMALES

WILHELM, M., GORDOS, M.2, KAJ, M.3, SOÓS, R.1, GYEBROVSZKI, Á.2, TÉKUS, É.4

UNIVERSITY OF PÉCS

INTRODUCTION: Multifaceted challenges are faced in Hungary in terms of life expectancy and premature mortality, oppositely to global standards. There are several lifestyle factors modifying health, leading to early death, contributing to higher mortality and high ratio of circulatory system diseases, malignant tumors. Oppositely among many positive factors regular physical activity (PA) proved to be important in health, and it is rather low among Hungarian adults. The primary aim of our research was to investigate health related fitness parameters, physical condition and performance of adult Hungarian women, analyzing data of 194 participants. Assessing lifestyles with the European Health Interview Survey, measuring body composition and physical fitness with the aid of Senior Fitness Test were employed.

METHODS: Subjects were assigned into 4 groups: Group 1 (G1) the age range was of 45-55 years ($n=43$, mean age: 49.09 ± 0.58 y), in Group 2 (G2) from 55-65 years ($n=22$, 59.20 ± 0.82 y), Group 3 (G3) young mostly inactive university students ($n=16$, 23.85 ± 3.15 y), and G4 ($n=98$ healthy active women, 46.48 ± 9.26 y). In G1 and G2 and G4 the volunteers were physically active, regularly participating in recreational activities and sports throughout their life, but none of them ever participated in elite sports at least three times a week. PAs mentioned were cycling, hiking or walking in town, jogging. A six-minute walking test (6MWT) was conducted to measure aerobic capacity/endurance (Enright 2003). In G1 and G2 a spiro-ergometric Bruce protocol was also conducted to correlate 6MWT results and $\text{relVO}_{2\text{max}}$ measured using treadmill. In 6MWT besides distance covered in meters, expected distance was calculated, maximal Heart Rate (HR_{max}) and O_2 -saturation with a pulse oximeter was registered.

RESULTS: Results of 6MWT average in G1:583.5m, and G2:693m reached the calculated expected distance, while in G3 the covered distance was 666.94 ± 46 m, the expected (894m) was much higher, although the body composition profile, BMI was lower than in the older population. In G4 the covered distance 633.26 ± 64.4 m did not reach the expected one (742.6 ± 63.34 m). Their $\text{VO}_{2\text{max}}$ calculated according to Laskin et al. (2007) was in G1= 41.87 ml/kg/min, G2 42.18 ml/kg/min, while in G3= 37.05 ml/kg/min, in G4 was higher (38.52 ± 5.07 ml/kg/min) than that in the younger generation. No significant difference was found between the measured and calculated $\text{VO}_{2\text{max}}$. Calculating age matched performance by the 6MWT, most subjects in the older groups were in the excellent category, in G3 $\text{VO}_{2\text{max}}$ was below the average. Analyzing G3 data subjects had either a very low, or good/excellent aerobic performance. Intensity of the 6MWT

measured with HRmax were over 75% in G1, G2 and G3, while in G4 it was only $57.3 \pm 18.81\%$. O₂-saturation did not change significantly in any groups by the end of the walk.

CONCLUSION: Results of our study suggest that among Hungarian adult women younger sedentary subjects are in worse fitness and health status than the older active ones.

EFFECTS OF EXERCISE UNDER DIFFERENT FEEDING STATES (FASTED VERSUS FED) ON APPETITE AND FOOD PREFERENCE

YANG, Y., WANG, Y., CHEN, Y.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Carbohydrate availability (e.g., muscle and/or liver glycogen) in the human body might play a role in regulating subsequent energy intake. Compared to fed-state exercise, fasted exercise may significantly reduce endogenous glycogen stores, and it may potentially affect appetite and macronutrient choices. Up-to-date, most studies have only used a single ad libitum lunch to assess eating behaviour, and it is still unclear whether food preferences, choices, and dietary behavior in free-living may be affected.

METHODS: Twenty-four (12 females) healthy and physically active participants (age: 24 ± 4 yr; BMI: 21.3 ± 1.7 kg/m²; VO₂max: 47 ± 6 ml/kg/min) were recruited, and performed a 60-minute running exercise at 60% VO₂max in a randomized, counterbalanced order either after an overnight fasting (Fasted-Ex) or consuming breakfast (5.8 kcal/kg, Fed-Ex). Subjective appetite sensation (i.e., hunger, fullness, prospective food consumption and desire to eat) was regularly measured during trials (baseline, 30, 60, 120, 150 and 180 min), and food preference (i.e., fat and taste's explicit liking, explicit wanting, implicit wanting, and relative preference) was assessed at baseline and 180 min using computerized visual test (i.e., Leeds Food Preference Questionnaire). Free-living eating behavior (total energy intake and macronutrient consumption) was recorded using a weighed food diary for the remainder of the day.

RESULTS: No difference was observed for exercise intensity between Fasted-Ex and Fed-Ex ($60 \pm 2\%$ vs. $61 \pm 3\%$ VO₂max, $p = 0.058$). Compared to Fed-Ex, fat oxidation was higher during Fasted-Ex (27 ± 6 vs. 19 ± 5 g, $p < 0.001$), and carbohydrate oxidation was lower (62 ± 22 vs. 85 ± 26 g, $p < 0.001$). Subjective appetite (Δ tAUC₀₋₁₈₀: Fasted-Ex minus Fed-Ex) was greater in Fasted-Ex than in Fed-Ex (hunger: 2156, $p = 0.002$; fullness: -1791, $p < 0.001$; prospective food consumption: 1925, $p < 0.001$; desire to eat: 2242, $p < 0.001$). There were no differences in food preferences immediately after exercise or dietary behaviors (first meal and total intake) in the free-living conditions. Moreover, total daily energy, carbohydrate, and protein intake were lower in Fasted-Ex (1697 ± 685 kcal; 215 ± 100 g; 70 ± 27 g) compared to Fed-Ex (2340 ± 664 kcal; 293 ± 95 g; 100 ± 36 g, all $p < 0.001$).

CONCLUSION: While fasted-exercise increases subjective appetite, it does not acutely alter food preferences or eating behavior in free-living conditions in physically active adults. Total energy intake remains lower over a 24-hour period in the Fasted-Ex due to breakfast omission.

THE ACTIVE PREGNANCY GUIDE. BUILDING MULTILANGUAGE EDUCATIONAL RESOURCES TARGETING WOMEN, TO PROMOTE ACTIVE AND HEALTHY LIFESTYLES DURING PREGNANCY AND POSTPARTUM

OVIDO-CARO, M., SANTOS-ROCHA, R., PAJAUJIENE, S., SILVA, M.R., JORGE, R., SZUMILEWICZ, A.

UNIVERSITY OF SEVILLE

INTRODUCTION: Current official recommendations and substantive evidence supports the maintenance of an active lifestyle during pregnancy and postpartum, which is a multigenerational public health issue. Despite strong health benefits for both mother and fetus, most women reduce exercise frequency and intensity during pregnancy and postpartum, and also many do not meet recommended activity levels. Scientific literature shows that pregnant women perceive a lack of information on safe exercise as a key barrier, while support from healthcare and exercise professionals as a facilitator. Women's health literacy is crucial for better healthcare behavior, empowerment, and self-management. Thus, creating multilingual resources that incorporate women's perspectives is essential. The objective is to present the Active Pregnancy Guide (I) and analyze health care and exercise professionals' perceptions about its use in the promotion of physical activity during pregnancy.

METHODS: The guide was first built in the Portuguese and English languages involving multidisciplinary experts and including the perspectives and experiences of women. In the second stage, it was translated to other European Languages. All versions of the Active Pregnancy Guide are made available for free download on the ResearchGate platform and other social media. During the NEPPE training, 77 participants including health care and exercise professionals were asked to rate the usefulness of the educational materials from 1 little useful to 5 very useful.

RESULTS: The guide is an example of practical guidelines that highlight the importance of involving the perspectives and experiences of women in the promotion of a healthy life and safe training during pregnancy and postpartum. The accessibility to these guidelines makes it necessary that they be shown as a multilanguage resource to be available independently of women's country or region. It consists of ten chapters: the first four cover benefits, recommendations, health

screening, and exercise assessment; the next three focus on exercise prescription and safety; the last three address reducing sedentary behavior, promoting healthy diet and sleep patterns. A link to YouTube channel offers free Workshops, Webinars, Workouts, and Wikipicks. All versions are available for free download on the ResearchGate. Participants from the NEPPE training rated the usefulness of the educational materials provided by the guide with an average of 4.7 points, as well as the global satisfaction with the training with an average of 4.5 points.

CONCLUSION: The use of educational resources may address some physical activity and exercise barriers, promote health education, and deliver effective and scalable interventions. The use of the guide is very well rated by health care and exercise professionals. The integration of the guidelines contents in an App with videos and remote monitoring allow to guide pregnant women during exercise providing a cost-effective solution to increase physical activity.

EFFECTS OF AN 8-WEEK TOE FLEXOR STRENGTHENING PROGRAM ON JUMP PERFORMANCE

KOYAMA, K., SHUHEI, H.

TOIN UNIVERSITY OF YOKOHAMA

INTRODUCTION: The force-generating capacity of the foot is closely related to human physical performance. During the take-off phase of a jump, the heel lifts off the ground, and the forefoot supports the body while transmitting forces from the upper and lower limbs (Yamauchi & Koyama, 2022). Just before take-off, ground reaction forces increase, and toe flexor strength is associated with jump performance (Yamauchi & Koyama, 2020). This suggests that strengthening foot muscles may contribute to improved jumping ability. While cross-sectional studies have examined the relationship between toe flexor strength and jump performance, the causal link remains unclear. This study investigated the effects of an 8-week exercise program on toe flexor strength and jump performance and explored the relationship between their changes.

METHODS: Healthy adults aged 20–50 years were measured foot length, arch height, toe flexor strength, vertical jump height, and standing long jump distance. Subjects were assigned to either a training group (TR) or a control group (CON), ensuring no significant differences in age, height, body weight or any measurement values. The TR performed a multi-component exercise training (Koyama & Yamauchi, 2023) twice weekly for 60 minutes over 8 weeks. Measurements were conducted once every two weeks, for a total of four times. Foot length, arch height and toe flexor strength in sitting and standing positions were assessed using a ruler and a dynamometer, respectively. Arch height and toe flexor strength were normalized to foot length and body weight, respectively. Vertical jump height was evaluated using both counter-movement jump (CMJ) and squat jump (SJ) tests. Standing long jump distance was measured using a tape measure. All measurement variables were analyzed relative to baseline values recorded at week 0. A two-way repeated-measures ANOVA [time (four po

RESULTS: In the TR, toe flexor strength in the sitting position increased every two weeks until week 8, and in the standing position, it increased except between weeks 6 and 8. At all measurement points, both were significantly higher than in the CON. Arch height variables showed no significant changes or group differences. CMJ, SJ height, and standing long jump performance significantly improved in the TR throughout the training period. However, no significant differences were observed between the TR and CON for any jump performance variables at any measurement week. The improvement rate of toe flexor strength showed no significant correlation with the improvement rate of CMJ or SJ but had weak correlations with the improvement rate of the standing long jump at week 4 ($p = 0.091$) and week 8 ($p = 0.099$).

CONCLUSION: A toe flexor strengthening exercise training program enhanced force generation capacity of the foot and jump performance, potentially benefiting forward-directed jumps.

PROBIOTICS & PERFORMANCE: THE HIDDEN LANGUAGE OF EXOSOMAL HSP60 IN EXERCISE

PROIA, P., PALLADINO, L., CARUSO BAVISOTTO, C., PAGLIARO, A., ALIOTO, A., BOATTA, A., CAPPELLO, F., BARONE, R.

UNIVERSITY

INTRODUCTION: Heat shock proteins (Hsp), particularly Hsp60, play a crucial role in regulating the cellular stress response and have also been identified in plasma-derived exosomes (Barone et al., 2016), suggesting a potential function in inter-cellular signalling. Exercise, both aerobic and anaerobic, can modulate the release of Hsp60 through exosomes, thus influencing cellular communication. In our previous publication, we already described how *L. fermentum* influenced the NF- κ B signaling pathway, inducing the expression of Hsp60 (Paladino et al., 2023). This study aims to analyze Hsp60 levels in exosomes isolated from the plasma as well as anti and pro-inflammatory cytokines levels (e.g. IL-6, TNF- α , IL-10) of three groups of subjects: sedentary, runners, and CrossFit athletes, before and after a period of supplementation with probiotics.

METHODS: Fifteen males were enrolled in our study: a sedentary control group, a runner group, and a CrossFit group. All participants underwent basal blood sampling (T0) before and after an exercise session to assess the acute response to physical activity. Subsequently, each group received supplementation of probiotic blend for two months. At the end of the supplementation period, subjects were assessed again by blood sampling before and after an acute exercise session.

Plasma-derived exosomes were isolated using standardized ultracentrifugation protocols. The presence of exosomes was confirmed by detecting specific markers by western blotting. In addition, the expression of Hsp60 within the exosomes was analyzed. In parallel, the levels of inflammatory and anti-inflammatory cytokines were quantified using Mag-Pix® (ThermoFisher Scientific).

RESULTS: Preliminary results indicate variations overall in Hsp60 levels between groups, with differences between the activities, suggesting that the type of exercise influences the release of this protein through exosomes. Furthermore, it is hypothesized that exosome-mediated cellular communication may originate from muscle cells, contributing to the transport of molecular signals to other tissues. These results suggest that exercise may modulate the release of Hsp60 in plasma exosomes, and probiotic supplementation may play a role in regulating this response.

CONCLUSION: Further studies are needed to clarify the mechanisms underlying this modulation and its impact on intercellular communication, the inflammatory response, and the change in performance.

IMPACT OF SLEEP RECOVERY FOLLOWING 24-H TOTAL SLEEP DEPRIVATION ON APPETITE, ENERGY INTAKE AND FOOD PREFERENCES

CHARLOT, K., COCA, M., ERBLANG, M., SAUVET, F., BOURRILHON, C., BEAUCHAMPS, V.

INSTITUT DE RECHERCHES BIOMÉDICALES DES ARMÉES

INTRODUCTION: Sleep deprivation is well-known to induce an orexigenic behaviour that may lead to obesity and other metabolic diseases if these episodes became persistent. This problem mainly affects personnel used to work during nightshifts but could also concern athletes especially nearby and during competitions. These effects have been mostly measured at the breakfast but the impact on appetite during the total sleep deprivation (TSD) and the remaining of the day are unexplored. Moreover the effects of sleep recovery (partial, PSR or total, TSR) have never been assessed. The objective of this study was to follow the effect of TSD and investigate the efficiency of PSR then after TSR on energy intake (EI), subjective appetite, and food reward.

METHODS: 41 healthy participants lived in a laboratory designed like an apartment with 5 sleeping rooms during 4 consecutive days. After a night with normal sleep (NS, time in bed (TIB)=8 h), participants realized TSD, a night with PSR (TIB=3 h) and finally a night with TSR (TIB=8 h). During TSD and PSR, a buffet with ready-to-eat foods containing sixteen high-fat or low-fat and sweet or savory foods was proposed to participants. Subjective hunger was assessed using visual analog scales before and after each meal. Food palatability was assessed after each meal. Food reward was assessed before the night collation and the breakfast using the Leeds Food Preference Questionnaire (LFPQ).

RESULTS: Nocturnal collations were predominantly composed of fat (48 ± 17 of EI) and induced a supplemental EI of 511 ± 195 and 420 ± 183 kcal during TSD and PSR, respectively. No compensatory EI reduction was observed during the remaining of the day. Thus, 24-h EI was logically higher ($p < .001$) during TSD (2931 ± 578 kcal) and PSR (3019 ± 657 kcal) compared to NS (2519 ± 669 kcal) and TSR (2623 ± 638 kcal). Moreover, the impact of the nocturnal collations was marginal on subsequent subjective appetite. Indeed, although gastric fullness before breakfast was higher ($p < .05$) in TSR and PSR compared to NS, no other appetite-related dimensions was modified. In TSR, composite appetite score before breakfast was higher compared to TSD. Moreover, the quantities served at breakfast were estimated as lower during TSR compared to TSD ($p < .05$). These results may indicate that participants had higher appetite despite having fully recovered. Concerning food reward, appeal for high-fat foods before breakfast was increased during TSD and PSR compared to NS ($p < .001$).

CONCLUSION: These results indicate that individuals during TSD may be tempted to select foods with high-fat content during a nocturnal collation. Food reward was accordingly higher before breakfast after TSD and PSR. The collation consumption marginally impacted appetite the rest of the day and strongly increasing 24-h EI. Finally, even after TSR, persistence of high appetitive responses following TSD were observed at breakfast indicating that negative sleep deprivation on appetite may last after sleep recovery.

SIT-TO-STAND PERFORMANCE MEASURES AND THEIR ASSOCIATIONS WITH WALKING PERFORMANCE IN HIV PATIENTS

GONZÁLEZ FERNÁNDEZ, A., RIESCO, J., ESCRIBANO, A., PROTZEN, G., GIL, M., GUERRA, J.M., BOULLOSA, D.

UNIVERSIDAD DE LEÓN

INTRODUCTION: Advances in antiretroviral therapy (ART) have increased life expectancy in people living with HIV (PLHIV). However, long-term ART use and sedentary lifestyle [1] are linked to a rise in comorbidities in PLHIV, including frailty [2], which impact functional capacity and quality of life. Given that lower-limbs power is crucial for maintaining functional capacity in aging populations, identification of valid predictors of functional capacity is particularly relevant for PLHIV. Previously, sit-to-stand test (STS) completion time and power have been associated with the functional capacity in different clinical populations, however it remains unclear whether these measures are associated with functional capacity in PLHIV [3,4]. Therefore, this study aimed to analyze the relationships between STS time, absolute, and relative STS muscle power with walking performance in PLHIV.

METHODS: Twenty-seven PLHIV (48 ± 13 years) undergoing ART participated in the study. Muscle power was assessed through the STS. STS completion time was recorded, and absolute power, and relative power were subsequently calculated. The total distance covered during the 2-min walking test (2-MWT) was used as a measure of functional capacity. Normality was assessed and Spearman correlation analysis was conducted in R-Studio, with significance set at $p < 0.05$.

RESULTS: Spearman's correlation analysis showed that STS completion time did not correlate with total distance walked in the 2-MWT ($p > 0.05$). However, absolute STS power ($\rho = 0.494$, $p = 0.009$) and relative STS power ($\rho = 0.448$, $p = 0.019$) showed moderate significant correlations with walking performance.

CONCLUSION: Lower-limbs muscle power is a better predictor of functional capacity than time to complete STS in PLHIV. These findings support the use of power over time-based measures when evaluating functional capacity in PLHIV.

EFFECTS OF HELMET VENTILATION ASSISTANCE ON MUSCLE OXYGENATION IMPROVEMENT DURING ECCENTRIC EXERCISE IN COPD PATIENTS: AN EVALUATION USING NEAR-INFRARED SPECTROSCOPY

CHEN, H., CHEN, Y., HSU, H., WANG, J.

CHANG GUNG UNIVERSITY

INTRODUCTION: While eccentric exercise may cause muscle damage and inflammation, some studies suggest it does not necessarily impair oxidative function. Additionally, non-invasive ventilation (NIV) can enhance muscle oxygenation, prolong exercise duration, and increase oxygen uptake (VO_2). Further research is needed to clarify its direct effects on muscle oxidative function and the potential benefits of NIV in COPD patients.

METHODS: Patients diagnosed with COPD were recruited from outpatient clinics and randomly assigned to either the control group (CON, $n=14$) or the experimental group (EXP, $n=12$). Participants in the EXP group performed eccentric cycle exercise (ECE) with the assistance of non-invasive helmet ventilation. All participants engaged in 40-minute eccentric cycling sessions twice a week for a total of nine weeks, including a one-week familiarization period. The exercise intensity was set based on the peak oxygen uptake ($\text{VO}_{2\text{peak}}$) measured during a graded exercise test (GXT) before training. Measurements were taken during exercise sessions in the 2nd and 9th weeks to assess hemodynamic status and tissue oxygenation. Additionally, the Borg scale was used to record post-exercise leg fatigue and dyspnea levels.

RESULTS: In the CON group, O_2Hb and tHb in the vastus lateralis increased significantly from the first to the last session ($p=0.035$). No significant differences in muscle oxygenation were found between EXP and CON. However, in the first session, EXP had a greater increase in cardiac output ($p=0.036$) and stroke volume ($p=0.018$). EXP also reported higher dyspnea than CON ($p=0.013$), but leg fatigue was similar between groups.

CONCLUSION: After nine weeks, O_2Hb and tHb in the eccentric exercise group increased significantly. Tissue oxygenation remained stable in both groups, unaffected by helmet-assisted ventilation.

SEX-ASSOCIATED DIFFERENCES IN PHYSICAL ABILITY IN PATIENTS WITH SICKLE CELL DISEASE

NOGUER, M., MESSONNIER, L.A., FEASSON, L., MERLET, A.N., BARTOLUCCI, P., MESSONNIER, L.A.

UNIVERSITÉ SAVOIE MONT BLANC

INTRODUCTION: Sickle cell disease (SCD) is a genetic disorder leading to the production of abnormal haemoglobin (HbS). Deoxygenated HbS may polymerize, causing sickling of the red blood cell (RBC) and haemolysis. Patients are subjected to severe anaemia, endothelial dysfunction and often hypoxaemia. Because oxygen transport is seriously compromised, patients' physical ability is strongly reduced compared to healthy subjects. To date, no study investigated sex specificities in physical ability impairment in SCD. This question is of interest because females, with higher anaemia (lower HbS content), nitric oxide bioavailability, vasoreactivity and foetal haemoglobin (Gladwin et al., 2003), may display lower repercussions of SCD on their physical ability than males. Therefore, the aim of this study was to evaluate the sex-associated differences in physical ability in SCD patients.

METHODS: Thirty-three SCD patients (18 males and 15 females) were studied. They were subjected to i) a blood sampling to measure haemoglobin level, HbS and HbF percentages (HbS% and HbF%) and viscosity, ii) a submaximal exercise test to measure physical ability markers such as oxygen uptake at the lactate thresholds 1 and 2 expressed in percentage of theoretical values ($\text{LT1\%TheorValue}$ and $\text{LT2\%TheorValue}$, respectively) (Myers et al., 2017), and iii) a muscle biopsy (vastus lateralis) to analyse the microvascular network, muscle fibre size and energetic enzyme activities.

RESULTS: $\text{LT1\%TheorValue}$ was higher in females than in males ($p=0.020$) (a tendency was noticed for $\text{LT2\%TheorValue}$, $p=0.098$). Females also had lower muscle fibre perimeter ($p=0.025$). No significant sex-associated differences were noticed on the microvascular network, enzyme activities and blood characteristics excepted for haemoglobin level ($p=0.012$). In females (but not in males), $\text{LT2\%TheorValue}$ correlated with haemoglobin level ($p<0.001$, $r=0.770$), HbS% ($p=0.004$, $r=-0.720$) and viscosity ($p=0.033$, $r=0.552$) on the one hand, and with capillary cross-sectional area ($p=0.003$, $r=0.729$), perimeter ($p=0.001$, $r=0.766$), diameter ($p=0.007$, $r=0.683$) and length of contact capillary-fibre over fibre perimeter ratio ($p=0.001$, $r=0.779$). In males (but not in females), $\text{LT2\%TheorValue}$ was associated with capillary density ($p=0.005$, $r=0.628$) and number of capillaries in contact with one fibre ($p=0.018$, $r=0.558$).

CONCLUSION: Physical ability (in percentage of predicted value) has been found to be lower in males than females. In females, physical ability seems to be influenced by blood parameters (haemoglobin level, HbS% and viscosity) and mor-

phologic characteristics of capillaries (diameter, perimeter, area), whereas in males, physical ability was associated with microvasculature density. Even if the implicated physiological mechanisms remain to be explored, SCD repercussions on physical ability i) differs between males and females with SCD, and ii) does not seem to be limited by/associated to the same parameters.

AN EVALUATION OF THE FOOD, EXERCISE, STRESS AND SLEEP (FESS) ONLINE TOOL FOR SUPPORTING POSITIVE BEHAVIOUR CHANGE IN CLINICAL EXERCISE PHYSIOLOGY SERVICE DELIVERY

DAVISON, K., GOWER, B., MARTIN, M., LOWRY, D., SINGH HOWARD, R., BASTIAN, W., HARTEN, N.
UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: Lifestyle factors including diet, exercise, sleep and psychosocial stress are important for prevention and management of chronic disease. Health professionals such as Clinical Exercise Physiologists (CEP) can support people in making positive changes, however this can be time consuming and challenging. Online tools such as the Food, Exercise, Sleep and Stress (FESS) may be able to help educate people about key health behaviours and support positive change but there is limited research evaluating this approach. This study aimed to assess changes in key health behaviours in people accessing CEP services following 12 weeks of regular use of the FESS tool.

METHODS: This study used a pre - post single group design to assess changes in key health behaviours in response to accessing the FESS online tool that scores and supports change. People receiving Clinical Exercise Physiology services for treatment of existing chronic illness or injury were invited to access the survey comprised of 23 questions about their dietary intake, exercise participation, sleep hygiene and quality, and psycho-social stress on 3 - 7 days per week for 12 weeks. The survey platform provided real time scoring of their overall health behaviour and within each category and links to advice and supports to modify areas where the score was low. Scores were coded and change in median score analysed using a Wilcoxon signed-rank test.

RESULTS: Thirty-five participants (18 Female:17 Male; Age 60 +/- 14SD) completed the 12 week intervention. Overall the participant group scored well at baseline in most questions. Of the question that were not scored well at baseline, there were significant ($p < 0.05$) improvements in: number of serves of vegetables, likelihood of undertaking resistance training, hours of sleep, severity of stress experienced.

CONCLUSION: Twelve weeks of participation in a structured online health behaviour support tool was associated with improvements in a range of key health behaviours. These are encouraging data but need to be validated in a larger sample with a comparator control group to confirm causality. Online tools are a potentially cost effective means to support people make positive behaviour change leading to better disease prevention and management.

PROLONGED CHANGES IN FUNCTIONAL AND METABOLIC MEASURES AFTER ECCENTRIC EXERCISE INDUCED DAMAGE OF THE TRUNK EXTENSOR

KIM, A., JIEUN, L.2, JISUK, C.3, HOSEONG, L.2
DANKOOK UNIVERSITY

INTRODUCTION: Regular exercise reduces the risk of chronic diseases such as coronary artery disease and type 2 diabetes [1]. Resistance training, including both concentric (muscle shortening) and eccentric (muscle lengthening) actions, enhances muscle function and metabolic health [2]. However, the prolonged effects of eccentric exercise on functional and metabolic measures remain unclear. This study investigates the long-term impacts of eccentric training on muscle function and metabolic markers, hypothesizing that eccentric exercise induces beneficial adaptations.

METHODS: Eighteen healthy males, without eccentric training for six months prior, were randomly assigned to either an eccentric (ECC, $n=9$) or concentric (CON, $n=9$) training group. Each group performed a single bout of maximal voluntary contractions of the trunk extensor muscles per week for eight weeks. Measurements of muscle function, soreness, blood lipid profiles, and glycemic markers were pre-exercise, immediately post-exercise, and 48 hours post-exercise in weeks 1 and 8. Repeated measures ANOVA were used for analysis.

RESULTS: ECC participants showed increased muscle soreness and plasma creatine kinase (CK) levels in week 1, which significantly decreased by week 8, indicating adaptation. Both training types improved muscle function; however, ECC training led to significantly greater increases in resting isometric torque ($p < 0.05$). ECC training also reduced total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), and triglycerides (TG), while increasing high-density lipoprotein cholesterol (HDL-C) by week 8 ($p < 0.05$), whereas CON training improved only TG ($p < 0.05$). In terms of glycemic response, acute ECC exercise initially increased glucose, insulin, and homeostasis model assessment (HOMA) values in week 1. However, chronic ECC training significantly reduced fasting insulin, glucose, and HOMA values by week 8 ($p < 0.05$), along with decreased glycosylated hemoglobin (HbA1c), indicating improved insulin sensitivity. CON training did not significantly alter these metabolic markers.

CONCLUSION: Eccentric exercise has been demonstrated to enhance muscle function, lipid metabolism, and glycemic control. Despite the initial muscle damage that occurs, prolonged ECC induces adaptations that reduce soreness and improve muscle performance. These observations align with the findings of previous research, which demonstrated that eccentric training improves metabolic health via neuromuscular and molecular adaptations [3]. Future studies should explore ECC exercise in clinical populations to optimize training strategies for disease prevention and rehabilitation.

EFFECT OF AMILORIDE ON SALT TASTE SENSITIVITY DURING EXERCISE-INDUCED DEHYDRATION

IRIBE, Y., NISHIKAWA, Y., SAITO, A.

NATIONAL INSTITUTE OF TECHNOLOGY, ARIAKE COLLEGE

INTRODUCTION: This study examined the link between exercise-induced dehydration and salt taste sensitivity in humans, focusing on the role of epithelial sodium channels (ENaC). Previous studies suggested that increases in blood pressure and angiotensin II with exercise enhance the sodium (Na) uptake via ENaC, changing salt taste sensitivity in rodents. However, rodents differ from humans in salt taste mechanisms, requiring human studies for a definitive conclusion.

METHODS: Ten male subjects participated in a two-condition, single-blind, crossover study involving amiloride (AM), an ENaC inhibitor, and water. The measurements included salt detection and recognition threshold (DT, RT), urine specific gravity (UG), blood pressure (BP), heart rate, rating of perceived exertion (RPE), thirst, hunger, and taste of oral rehydration solution (ORS). DT, RT, UG, and BP were assessed before and after 40-minute running at 70% maximal oxygen uptake. Thirst and hunger were assessed 2 h before, immediately before, and after the exercise. ORS palatability was assessed 2 h before and after the exercise. Subjects were rinsed with 10 μ M amiloride hydrochloride solution between salt solution rinses for the DT and RT tests during the AM condition. The DT and RT were assessed using the whole-mouth method. The six salt solutions for the DT and RT tests ranged from 0.1-3.2 g/L. These solutions had arithmetic concentration gradients. After the exercise, the subjects drank 500 ml of ORS ad libitum.

RESULTS: Subjects lost $2.4 \pm 0.5\%$ of their body weight after the exercise. A decrease in DT was noted after the exercise ($p = 0.06$), but RT remained unchanged. Thirst significantly increased immediately before the exercise. Hunger increased before exercise but decreased after the exercise. ORS palatability significantly increased after the exercise.

CONCLUSION: No significant differences were found between the two conditions for any measured parameter, indicating that amiloride had no effect on ENaC. However, increased thirst and enhanced ORS palatability after exercise were likely related to increased thirst due to dehydration. A limitation of this study is that the assessment times were different to prevent taste interference between the salt taste threshold and the ORS. Future studies should design experiments that can evaluate these parameters simultaneously. This study suggests that 10 μ M amiloride does not affect salt taste sensitivity after exercise, but increased thirst after exercise enhances ORS palatability.

EATING DISORDERS AND EXERCISE THERAPY: A SCOPING REVIEW ON OUTCOME MEASURES IN EATING DISORDER AND EXERCISE RESEARCH.

MCMAHEN, C., KRAMER, B., WRIGHT, K., FURZER, B.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Exercise is increasingly recognised as a complementary therapy in Eating Disorder (ED) treatment, with high prevalence of dysfunctional exercise behaviours and emerging evidence of the psychological and physical benefits of exercise therapy in ED. Despite increasing access to exercise therapy in ED, there is currently limited guidance on implementing assessment within exercise therapy and ED. The aims of this scoping review are to 1) report on outcome assessments used in exercise research in ED, and 2) outline the general outcomes of exercise interventions in ED.

METHODS: This study employed a scoping review methodology with a literature search consisting of ED and exercise terms conducted on Embase, MEDLINE, and PsycINFO. Articles included at full text review were data extracted for study and intervention characteristics, aims, assessments implemented, and outcome change.

RESULTS: Twenty-six studies were included at full text review with diagnostic populations including Anorexia Nervosa (AN; $n=7$), Binge Eating Disorder (BED; $n=5$), Bulimia Nervosa (BN; $n=1$), and mixed diagnosis (e.g., AN plus BN; $n=13$). When examining broad health domains, body composition ($n=26$) and eating disorder psychopathology ($n=21$) were assessed at the greatest frequency in included studies, followed by subjective physical activity ($n=13$), exercise assessment ($n=12$)—including strength ($n=7$) and cardiorespiratory fitness ($n=7$), co-occurring psychopathology ($n=11$), exercise beliefs ($n=10$), and objective physical activity ($n=9$). For individual assessment tools, body mass index was the most frequently used body composition tool ($n=26$), followed by the Eating Disorder Examination ($n=13$) for ED Psychopathology. One repetition maximum ($n=5$) and the Balke protocol ($n=4$) were the most frequently implemented exercise tests, with actigraphy ($n=8$), the Compulsive Exercise Test ($n=7$), and the Beck Depression Inventory ($n=6$) the most frequently used tools for the assessment of objective physical activity, exercise beliefs, and co-occurring psychopathology. There were no reported adverse events in assessment in the included trials.

CONCLUSION: The results of this review outline that maximal and submaximal exercise assessment within ED contexts have been conducted safely and should be considered where appropriate within clinical practice. Comprehensive exercise assessment as part of therapeutic exercise interventions may provide additional health information beyond measures used in current practice to provide a greater holistic assessment of ED patient health and function. The results of this review, in addition to prior research indicate that exercise therapy in ED contexts can be effective in improving patient health and importantly, appears to be safe with no deleterious effects on weight status – a commonly held belief. The

results of this review may provide guidance on the appropriate assessment for exercise professionals to conduct within ED services.

PSYCHOLOGICAL RESPONSES TO THREE DISTINCT LOW-VOLUME INTERVAL TRAINING PROTOCOLS

TRUJILLO-BAAMEIRO, D., FERRARO-FARRO, D., BENÍTEZ-FLORES, S.

HIGHER INSTITUTE OF PHYSICAL EDUCATION, UNIVERSITY OF THE REPUBLIC

INTRODUCTION: Physical inactivity (PA) is a major public health issue, representing 7.2% of all-cause mortality (1). Time constraints and limited access to equipment are common barriers to exercise (2). Low-volume interval training, particularly sprint interval training (SIT) and high-intensity functional training (HIFT) are time-efficient alternatives (3,4). Various psychological factors are associated with long-term adherence to PA, and despite higher ratings of perceived exertion (RPE), interval training may induce better affective valence, self-efficacy, intention, and enjoyment than continuous training (5). However, its psychological responses are underexplored across HIFT regarding SIT. This study aims to compare psychological responses to three high intensity protocols.

METHODS: Fourteen adults (age: 25.6 ± 5.6 yr; body mass index: 24.5 ± 3.9 kg·m⁻²; VO₂max: 47.1 ± 7.9 ; males: 9 and female: 5) participated in the study. First day, they were familiarized with all protocols and validated psychological questionnaires (ie., RPE, Feeling Scale [FS], Self-Efficacy, Intention and Physical Activity Enjoyment Scale [PACES]). From the second to the fourth day, they performed the protocols (10 bouts × 5 s all out effort: 35 s passive rest) of SIT, burpee interval training (BIT) (6), and SIT+BIT in randomized order, with a 72–96 h of recovery. RMANOVA was used to compare responses across protocols. If interaction effect was significant ($p \leq .05$), Bonferroni post hoc tests were applied and effect size (ES) reported as Cohens d.

RESULTS: Significant protocol × time interaction presented in RPE ($p = .001$; $\eta^2 p = .399$); RPE was significantly higher in SIT compared to BIT only ($p < .01$; ES = .923), whereas BIT and SIT-BIT showed no difference ($p = .976$). Affective valence also showed a significant protocol × time interaction ($p = .01$; $\eta^2 p = .274$); FS scored lowest in SIT ($p < .04$; ES = .516), while BIT and SIT-BIT remained similar ($p = .181$). Self-efficacy, intention and PACES showed no significant protocol × time interaction ($p = .336$; .693; and .074, respectively). Finally, a strong preference emerged for SIT-BIT ($n = 10$, 71.4%).

CONCLUSION: The main results show that SIT being perceived as more strenuous and less tolerable than BIT or SIT-BIT. While, SIT-BIT emerged as the clearly preferred choice, further supporting multimodal training as a promising alternative for long-term adherence.

INDIVIDUALIZED EXERCISE PRESCRIPTION: HOW CAN THE SUBMAXIMAL TEST HELP US?

BRUSEGHINI, P., PITINGOLO, S., VIGNOLA, C., ARIA MANESH, D., PASTORE, A., VILLA, M., BORGONOVO, F., GALVANI, C.

UNIVERSITÀ CATTOLICA DEL SACRO CUORE

INTRODUCTION: Exercise intensity is the most critical component of the exercise prescription process. Different methods to determine exercise intensity, deriving from maximal or submaximal protocols have been critically compared¹. No studies have related an approach based on ventilatory thresholds (VT) with the corresponding intensity relative to reserve anchors. Therefore, the aim of this study was to understand how the exercise intensity at VT derived from a test to exhaustion (CPET) be equated to a workload derived from a submaximal test (SUB).

METHODS: Subjects included twenty-four healthy adults (14 M, 10 F; age: 23.2 ± 2.8 yrs; BMI: 22.1 ± 3.0 kg·m⁻²; RMR: 3.4 ± 0.5 mL·kg⁻¹·min⁻¹). Oxygen uptake (VO₂), heart rate (HR) and rate of perceived exertion (RPE, CR-10) were measured at rest and during SUB and CPET, both performed using a cycle ergometer and a metabolic cart. VO₂max was obtained: 1) at the end of the CPET ramp protocol (VO₂maxCPET), and the VO₂ at first and second VT (VO₂@VT1 and VO₂@VT2) was calculated, 2) by submaximal test (VO₂maxSUB), based on YMCA protocol, and extrapolated to predicted maximum HR (HRP, $208 - 0.7 \cdot \text{age}$). VO₂ reserve (VO₂R) was calculated considering resting VO₂, and %VO₂R corresponding to VO₂@VT1 and VO₂@VT2 was extrapolated.

RESULTS: No significant differences were found between estimated or measured variables (VO₂maxSUB 43.7 ± 9.3 , VO₂maxCPET 44.7 ± 8.7 mL·kg⁻¹·min⁻¹), $p = .444$; HRP 191.8 ± 2.0 , HRmaxCPET 187.8 ± 10.2 bpm, $p = .065$), except, as expected, for the RPE recorded at the end of each test (RPESUB 4.9 ± 2.1 , RPECPET 9.2 ± 1.6 , $p < .001$). The VO₂@VT1 (26.4 ± 4.9 mL·kg⁻¹·min⁻¹) and VO₂@VT2 (36.1 ± 7.8 mL·kg⁻¹·min⁻¹) corresponded to $54.4 \pm 13.9\%$ and $82.4 \pm 13.7\%$ of VO₂R, respectively.

CONCLUSION: To our knowledge, this is the first study which attempt to compare VT intensity from CPET to the corresponding percentage of VO₂R based on submaximal test. Exercise intensity at VT1 and VT2 can be considered as moderate and

vigorous, respectively, compared to the physical activity guidelines². This approach is important to enhance trainers and physicians' ability to understand and customize an effective exercise prescription in a non-clinical setting.

IMPACT OF DANCE CLASSES ON PHYSICAL FITNESS, BMI AND GUT MICROBIOTA IN PATIENTS WITH MULTIPLE SCLEROSIS

ŠIMIÁKOVÁ, M., NECHALOVÁ, L., OLEJ, P., HRIC, I., BIELIK, V.

COMENIUS UNIVERSITY IN BRATISLAVA FACULTY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: Sclerosis multiplex, or multiple sclerosis (MS) is a chronic disease of the central nervous system. Studies report that MS causes impairment in physical fitness, motor and cognitive function and shifts in gut microbiome. Therefore, the aim of this study was to investigate the effect of dance classes on the cardiovascular system and fitness of MS patients.

METHODS: In this randomized controlled trial, 42 patients were randomly divided into two groups: the experimental group (n = 21) and the passive control group (n = 21). Sports dance classes included the ballroom dances (waltz, tango, Viennese waltz, quickstep) and Latin American dances (samba, chacha, rumba, jive) were performed for 12 weeks at a frequency of three times a week. Body composition was measured by bioelectrical impedance machine and cardiovascular fitness was evaluated by bicycle spirometry before and after the intervention. Fecal microbiota were categorized using primers targeting the V3–V4 region of 16S rDNA.

RESULTS: Our results revealed significant differences in body composition weight (kg), body fat percentage (%) and body mass index (BMI) (kg/m²) compared to the control group. In the cardiovascular fitness assessment, we observed a significant improvement in max. load (W), VO₂/kg, ventilatory equivalent (VE), forced expiratory volume in 1 second (FEV1) and peak expiratory flow (PEF) compared to the control group. Furthermore, we observed, however, only a modest shift in gut microbiota composition.

CONCLUSION: Our randomized control trial investigating the effects of a 12-week dance class training program on MS patients revealed significant improvements in body composition and physical fitness. As a result, dance class training is likely to provide a variety of physical and psychosocial benefits, making it enjoyable for MS patients.

THE GUT MICROBIOTA IN COLLEGE ATHLETES INDUCES SPONTANEOUS ACTIVITY OF ITS FECAL TRANSPLANTED MICE

KONO, T., HAMADA, H., WATANABE, C., AOKI, T., KAWASHIMA, M., YODA, T., SAITO, T., OYANAGI, E., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE, KAWASAKI MEDICAL SCHOOL, TOTTORI UNIVERSITY

INTRODUCTION: Gut microbiota in humans comprises 100 to 1000 trillion microorganisms. It has been reported that these bacteria are implicated in a variety of diseases (inflammatory bowel diseases, obesity, diabetes, fatty hepatitis, systemic chronic inflammatory diseases, cardiac diseases and neurodevelopmental disorders) and behavioral disorders. On the other hand, it has been suggested that gut microbiota could be crucial for exercise performance in athletes. Also, exercise might produce changes in the gut microbiota, which may have health implications for athletes. Although changes in the gut microbiota and physical performance by FMT from exercise trained mice have been reported, their relevance to the gut microbiota from human athletes remains unclear.

To evaluate the functional role of gut microbiota in athletes, mice were colonized them with the fecal microbiota of the athletes or healthy control subjects, and monitored spontaneous and forced exercise performances.

METHODS: The athlete group (n=17, males, aged 19-22 years) and the control group (n=15 males, aged 19-24 years) were recruited. All subjects were asked to answer questions (height, weight, age, smoking habits, drinking habits, medical history, antibiotics taken in the past 6 months, International Standard Physical Activity Questionnaire (IPAQ), simple measurement of maximal oxygen uptake, etc.). Fecal samples were collected using a simple fecal collection kit, and then, to analyze the fecal microbiome of subjects, we use 16SrRNA gene next generation sequencing (NGS). Gut microbiota were identified using Qiime2 software (ver. 2023.2). Remains the collected fecal samples were used the next study. C57BL/6J male mice (4 weeks old, n=25) were treated with antibiotics for 7 days and then the mice were randomly divided into two groups: athletes fecal transplant group (ATP, n=13) and control fecal transplant group (CTRL, n=12). The fecal samples of the human subjects were transplanted once a week (for three times in total). Spontaneous wheel running (WR) and forced exercise on treadmill were assessed. After these exercise tests, the cerebrum and hippocampus in each of the mice were removed under anesthesia, and then analyzed for Bdnf expression using real-time RT-PCR.

RESULTS: Although physical activity level in Athletes was significantly higher than that in Control group, no significant difference between in Athletes and control groups was observed in both the characteristics of subjects. Alpha diversity and beta diversity were no different between the athletes and control subjects. However the αdiversities of fecal transplanted mice from ATP were showed lower than that of CTRL mice. Furthermore, the WR in the ATP group at 7 days was shown to be significantly higher than that in the CTRL group (p<0.05), but not forced exercise

CONCLUSION: Hence, changes in the gut microbiota in athletes may have an induction of spontaneous activity of fecal transplanted mice.

A SYSTEMATIC REVIEW OF EXERCISE, AEROBIC FITNESS AND THE NEUROACTIVE POTENTIAL OF THE GUT MICROBIOME: MINING MICROBES FOR GUT-BRAIN AXIS HEALTH

NUZUM, N., VALDERRAMA, B., KANON, A.P., GRABRUCKER, S., MUNUSWAMY, R., OSULLIVAN, O., CRYAN, J.F., CLARKE, G.
UNIVERSITY COLLEGE CORK

INTRODUCTION: The brain health benefits of exercise are increasingly appreciated as are the implications of the gut microbiome for the regulation of brain function and behaviour. While research has investigated relationships between exercise and the gut microbiome, results are variable and the interface between aerobic fitness, the gut microbiome (and its neuroactive potential) and brain health remain poorly understood. By systematically re-analysing prior exercise and gut microbiome research via *in silico* pipelines, we aimed to explore the relationship between the functions of the gut microbiome and aerobic fitness. Elucidating the details of the relationship between exercise and the gut microbiome can help uncover mechanisms of action and pave the way for increased uptake of exercise to support gut and brain health.

METHODS: This review (PROSPERO CRD42024480951) included human studies with gut bacterial data, VO₂max, or studies implementing an aerobic exercise intervention with pre-post data. 16 studies were included with 1,230 individual samples (473 females and 433 males; 27.8±10 y, 24.1±3.9 kg/m², VO₂max 40.4±11.5 ml/kg/min). Study data was downloaded and assessed via bioinformatics pipelines, with statistical analysis conducted in R covering bacterial diversity, abundance and functionality assessed via the gut-metabolic and gut-brain modules (predicted via PICRUSt2 on 16S samples).

RESULTS: While alpha-diversity was not related to VO₂max (all *p*>0.05), significant associations were observed between five gut brain modules and VO₂max (all *q*<0.05), including a positive association of 'Propionate Synthesis III', a short chain fatty acid of importance for gut-brain axis signalling [1]. 10 bacterial genera were also associated with VO₂max (all *q*<0.05).

CONCLUSION: This research indicates that VO₂max and functional gut bacterial measures, or relative abundance of specific genera, are related. Positive associations between VO₂max and propionate synthesis is consistent with prior research showing exercise induced lactate is converted by Veillonella bacteria to propionate, a feature associated with endurance performance in mice [2]. These data show that aerobic fitness may be associated with the metabolic and neuroactive potential of the gut microbiome. Further analyses of studies reporting the impact of aerobic interventions on gut bacterial composition and function over time are underway. Together, this information may be used to better inform the prescription of physical activity interventions towards enhancing performance and brain health.

MICROVASCULAR (DY)SFUNCTION CORRELATES TO HIGHER CARDIOVASCULAR DISEASE RISK

GIUSTI, L., PILOTTO, A.M., ANSALDO, M., NERI, M., RE, R., LAURETANI, F., ALCAZAR, J., BOTTER, A., FRANCHI, M., PORCELLI, S.
UNIVERSITY OF PAVIA

INTRODUCTION: Cardiovascular disease (CVD) is one of the major causes of death in the industrialized countries[1]. CVD results from the interaction of multiple genetic, behavioral, metabolic, environmental and socio-economic risk factors, including age-related alterations in the elastic properties and integrity of arterial walls[2]. Nitric oxide (NO) plays a pivotal role in the cardiovascular system and reduced NO bioavailability has been linked to increased susceptibility to atherosclerotic lesion progression, hypertension, hypercholesterolemia, thrombosis and stroke, suggesting microvasculature can contribute to the whole CVD process[3]. The objective of this study was to examine the microvasculature integrity of older individuals with different CVD risk, whilst also investigating the modulating effects of cardiorespiratory fitness and physical activity.

METHODS: Twenty-two healthy old adults (age:74±5yrs; 9 females) were recruited. CVD risk was assessed based on the American Heart Association Life's Essential 8 algorithm[4]. Blood samples and blood pressure (BP) were collected in resting condition. Habitual physical activity was monitored by accelerometry for 7 days. An incremental cycling test up to exhaustion was performed to measure peak oxygen uptake (VO₂peak). Microvasculature integrity was assessed by doppler-ultrasound on femoral artery during passive-leg movement (PLM) and by near-infrared spectroscopy (NIRS) on the vastus lateralis muscle during vascular occlusion test (VOT). Hyperemic response from PLM was quantified analyzing blood flow parameters as area under curve (AUC) and changes from baseline to maximal hyperemia (ΔPeak). The 10s change in tissue saturation index during the reperfusion rate from prolonged ischemia (Slope2) was used as index of microvasculature responsiveness.

RESULTS: Among all subjects 25% were smokers, 72% did not meet the recommendation to eat five fruits and vegetables per day, and 40.8% had a high level of sedentary behavior. Blood-related parameters and BP confirmed differences in CVD risk among the old individuals. VO_2peak ranged from 15.4 to 45.3 ml/min/kg. Average AUC and ΔPeak values were 175 ± 95 ml and 436 ± 115 ml/min, respectively. Slope2 ranged from 0.98 to 2.75%/s. PLM and VOT parameters were directly correlated with CVD risk ($r=0.45$ and $r=0.42$, respectively; all $p<0.05$) and VO_2peak ($r=0.59$ and $r=0.47$ respectively; all $p<0.05$). Adjusted for VO_2peak and sedentary time, CVD risk still correlated to indexes of microvasculature responsiveness.

CONCLUSION: In addition to clinical parameters classically used to estimate CVD risk, microvascular dysfunction assessed by passive-leg movement and NIRS correlates to higher CVD risk. Individual aerobic fitness correlated to indexes of microvasculature responsiveness, suggesting that during aging an active lifestyle can reduce CVD risk also through changes in small vessels.

EVALUATION OF SKELETAL MUSCLE VASCULAR FUNCTION AND HEALTH BY FAST TIME-DOMAIN NEAR INFRARED SPECTROSCOPY: A CASE STUDY

RE, R., CONTINI, L., CONTINI, D., AMENDOLA, C., SPINELLI, L., TORRICELLI, A.
POLITECNICO DI MILANO

INTRODUCTION: Physical exercise increases shear stress in the vasculature leading to better vasodilator and constrictor responsiveness, reducing arterial stiffness and oxidative stress. Acute hemodynamic adaptations to exercise lead to changes in both endothelial and vascular smooth muscle cell functions. Regular exercise training improves nitric oxide (NO) availability. We propose a method for evaluating the muscular tissue's vessel stiffness, endothelial and vasomotor function, based on the oscillations of the hemodynamic parameters measured by fast Time Domain (TD) near infrared spectroscopy (NIRS).

METHODS: A fast TD NIRS [1] acquisition on a healthy subject was performed employing a device previously developed at the Department of Physics, at Politecnico di Milano [2]. The tibialis anterior muscle was chosen due to its thin adipose tissue thickness (ATT), which allows to analyze data using the solution of the photon diffusion equation for homogeneous media. A subject was set down with the ankle fixed onto a holder and connected to a load cell for measuring the traction force exerted. He performed a 400 s long dorsiflexion, which was preceded and followed by 400 s of baseline and recovery, respectively. The protocol was chosen based on numerical simulations previously performed. The acquisition lasted 1200 seconds with an acquisition rate of 20 Hz and a 4 cm interfiber distance. The time course of the exerted force from the dynamometer was obtained to control the exercise execution. Absolute values for the time courses of oxy- (O_2Hb) and deoxy- (HHb) hemoglobin concentrations were obtained. A blood volume pulse (BVP) sensor located on the same muscle and a respiration band (RESP) were also employed to record physiological signals. After a 3rd order polynomial detrending, the power spectral density (PSD) was calculated for all the parameters. The mean power in six frequency bands related to peculiar physiological origin was derived [3]: Endothelial (VI), NO-related Endothelial (V), Neurogenic (IV), Myogenic (III), Respiratory (II) and Cardiac (I) activity.

RESULTS: During rest, most of the PSD power for the TD NIRS parameters is contained in the endothelial bands, in particular in band VI for HHb and band VI and V for O_2Hb . The PSD of BVP is similar to the one of O_2Hb and HHb , while a strong contribution to band II is found for RESP, as expected. During the contraction and the recovery, it is possible to notice clear differences in the power measured in bands VI, V and III for both hemoglobin, while in band II and I the changes are negligible.

CONCLUSION: In this pilot study we have verified the possibility to employ fast TD NIRS to underline skeletal muscle vascular functions during contraction and recovery, for what concern the endothelial and myogenic activity. We are acquiring more subjects (up to 20) to perform statistical analysis.

THE EFFECTS OF 4-WEEKS OF ISCHAEMIC PRECONDITIONING AT THE ANKLE ON THE OXYGENATION OF THE FOOT IN PEOPLE WITH DIABETES

FRENCH, C., ROBBINS, D., GERNIGON, M., GORDON, D.
ANGLIA RUSKIN UNIVERSITY

INTRODUCTION: 4.4 million people are living with diabetes in the UK, which can be associated with serious health complications including 184 lower-limb amputations per week. This typically stems from the development of diabetic foot, resulting in a loss of a vascularisation from damage to nerves and blood vessels. Diabetic foot is associated with a 25% chance of developing a diabetic foot ulcer within their lifetime for people with diabetes, with a 40% risk of reoccurrence within 1-year and long-term impacts on healthcare services. Therefore, this study aimed to apply a 4-week ischaemic preconditioning

tioning (IPC) intervention to assess the health of the foot in people with diabetes. IPC involves the application of repeated cycles of alternating occlusion and reperfusion, typically prior to exercise, which may improve the microcirculation and endothelial function.

METHODS: With institutional ethical approval, 14 participants volunteered (8 males, 6 females; 9 type 1 diabetes, 5 type 2 diabetes; age: 39.9 ± 24.1 years; height: 171.4 ± 6.5 cm; body mass: 80.6 ± 15.1 kg). Participants visited for a pre- and post-testing session involving an incremental step test performing 30 repetitions of isotonic plantar flexion and dorsiflexion at an increasing resistance on the isokinetic dynamometer. Participants were randomly assigned to one of two groups: IPC or SHAM. The training sessions involved 2 sessions per week for 4-weeks with three occlusion cycles of 5-minutes at an individualised arterial occlusion pressure (Mean $\pm$ SD: 190 ± 30 mmHg) for the IPC groups and 20 mmHg for the SHAM group. The health of the foot was assessed during every session using near-infrared spectroscopy to assess the oxygen saturation (SO₂), oxygenated (O₂Hb) and deoxygenated haemoglobin (HHb) in the abductor hallucis muscle.

RESULTS: There was a significant effect of time on SO₂max ($F(1,12) = 13.261$, $p = 0.003$), with post-hoc analysis showing a significant increase in SO₂max from $67.84 \pm 6.19\%$ to $72.86 \pm 6.74\%$ in the IPC group at post-testing ($F(1,6) = 11.539$, $p = 0.015$). There were no significant differences in peak oxygen uptake ($p = 0.085$), O₂Hbmax ($p = 0.513$), HHbmax ($p = 0.348$) or maximum torque ($p = 0.077$). The average O₂Hb showed a significant interaction effect between time and group at each workload increment ($p < .05$).

CONCLUSION: The aim of this intervention was to assess whether 4-weeks of IPC resulted in any improvement in NIRS-derived variables as an indicator of the health of the foot in people with diabetes. The results showed a significant increase in SO₂max evidencing an improvement in the oxygenation of the foot, which could have important health benefits in potentially limiting complications. This study is one of the first known to apply a repeated IPC intervention with an ankle occlusion, which offers an isolated foot intervention which could be an alternative for people living with diabetic foot who are unable to exercise or weight-bear.

EXPLORING THE COMBINED IMPACT OF TRPV4 ACTIVATION AND ENDURANCE TRAINING: A DUAL APPROACH TO BOOST MITOCHONDRIAL EFFICIENCY AND AEROBIC PERFORMANCE

MALKA, G., BERGDAHL, A.
CONCORDIA UNIVERSITY

INTRODUCTION: Angiogenesis, the formation of new capillaries, is a tightly regulated process involving numerous factors that promote the expansion of the microcirculation. Exercise drives angiogenesis through mechanical stimuli and shear stress, thus improving cardiovascular hemodynamics and metabolic activity. The increase in oxygen supply and delivery allows mitochondria to sustain a high level of aerobic respiration without relying on anaerobic pathways. Thus, supplementary stimulation of angiogenesis remains a crucial target for enhancing endurance performance and, more importantly, for preventing chronic diseases. Calcium ions (Ca²⁺) are essential as signal transducers in several cellular processes, including cell proliferation and migration. Transient Receptor Potential cation channel subfamily Vanilloid member 4 (TRPV4) is moderately permeable to Ca²⁺ and is highly expressed in endothelial cells, which form the inner lining of blood vessels. Activation of TRPV4 via channel-specific agonists (GSK1016790) has not been extensively studied. This study aimed to find a synergistic effect of endurance exercise and TRPV4 activation on angiogenesis to increase capillary density, thereby providing implications for enhancing functional aerobic capacity and mitochondrial efficiency.

METHODS: Two to three-month-old C57Bl/6 mice were randomized into a control, an agonist treatment (GSK), an exercise-only (EXCI) and a combined agonist treatment with exercise (GSK+) group. Exercise intervention groups underwent 6 weeks of moderate-intensity continuous training (MICT) 4 days a week on a treadmill after 2 weeks of acclimation. Intensity started at 60% of maximum aerobic capacity (MAC) for 40 minutes, with weekly increases of 5% in intensity and 5 minutes in duration. Baseline MAC was calculated using a functional aerobic capacity ramp test and was repeated bi-weekly to test aerobic capacity and adjust training intensity. Following the 8-week intervention, high-resolution respirometry was done using an Oroboros Oxygraph-2k with the vastus lateralis to assess cellular oxygen consumption using a substrate uncoupler-inhibitor titration (SUIT) protocol.

RESULTS: Compared to the baseline, the GSK+ group had an increase in mean maximal treadmill speed corresponding to a rise in MAC at weeks 4 and 6 (2.5 ± 0.14 km/h) relative to the control group (1.73 ± 0.23 km/h, 1.80 km/h). Additionally, an increase in mean maximal mitochondrial oxygen consumption in the GSK+ group at (27.10 ± 6.76 pmol/(s*mg)) relative to control (24.09 ± 6.66 pmol/(s*mg)), following the addition of ADP was observed.

CONCLUSION: This study provides compelling evidence that MICT coupled with TRPV4 activation can be a target for vascular remodelling via angiogenesis, offering valuable insights to advance cardiovascular function, oxygen consumption and exercise physiology. Current research aims to solidify the findings by analyzing capillary density via capillary staining and detecting specific angiogenic growth factors via immunoblotting.

MECHANISMS REGULATING CEREBRAL PERFUSION DURING EXERCISE: INFLUENCE OF FOOT-STRIKE INDUCED PULSATILITY OSCILLATIONS AND CO₂ REACTIVITY.

LAWLEY, J., PERKINS, D., CORNWELL III, W., HOWE, C., NIQUE, B., SIMPSON, L.
UNIVERSITY OF INNSBRUCK

INTRODUCTION: During running exercise, cerebral blood flow (CBF) does not exhibit the typical biphasic response observed with cycling. The mechanism(s) driving this divergent response to cycling are unknown.

METHODS: We assessed middle cerebral artery blood velocity (MCAv), end-tidal carbon dioxide (ETCO₂), and MCAv pulsatility variability at rest, during an incremental running test, and fixed workloads running under three conditions: 1) free running, 2) diastolic stepping, where the foot-strike was synced to the diastolic phase of the cardiac cycle, 3) Cerebral responses to hypercapnia and hypocapnia (i.e. CVRCO₂) at rest and during free running at a pace just prior to the decrease ETCO₂ observed during VO₂max testing. In a 2nd study, hypocapnic CVRCO₂ testing was performed at rest and during steady-state running exercise, and thereafter during steady-state cycling at an intensity whereby heart rate and mean arterial blood pressure (MAP) were matched. Finally, we had the opportunity to measure MCAv in a high level junior cyclist (VO₂max, 5.92 L/min) during a maximal exercise test.

RESULTS: STUDY 1. Young, healthy males (n=26) and females (n=17) exhibited progressive increases in MCAvmean during incremental running (BL, Females: 49.9±11.3, Males: 45.9±10.8; VO₂max, Females: 65.7±11.7, Males: 67.1 ± 13.0cm/sec; ANOVA P<0.0001) despite reductions in ETCO₂ at higher exercise intensities (BL, Females: 36.41±5.1, Males: 38.6±4.5; VO₂max, Females: 28.2±5.1, Males: 32.5±9.0 mmHg; ANOVA P<0.0001). Diastolic stepping reduced beat-by-beat variability in MCAv pulsatility (0.14±0.04 a.u.) compared to free running (0.29±0.09 a.u., P<0.0001); however, MCAvmean was not different (Free running: 56.1±8.1; Diastolic stepping 58.0±8.7 cm/sec; P=0.211). CVRCO₂ to hypercapnia increased from rest to exercise (1.26±0.29 vs 1.58±0.54 cm·sec⁻¹/mmHg; P=0.049), whereas CVRCO₂ to hypocapnia was reduced (Rest: 0.65±0.31 vs Exercise: 0.11±0.38 cm·sec⁻¹/mmHg; P=0.002). STUDY 2. At rest hyperventilation caused a reduction in ETCO₂ (33.9±3.4 vs 22.2±5.8, mmHg, P=0.02) and MCAvmean (56.3±10.4 vs 40.8±5.6, cm·sec⁻¹, P=0.02). During running (Δ14.7±2.9, mmHg, P=0.03) and cycling (Δ13.0±2.2, mmHg, P=0.02), the reduction in ETCO₂ was similar to rest, but the reduction in MCAvmean was blunted. Importantly, when exercising heart rate (running, 148±20 vs cycling, 150±17, bpm, P=0.26) and MAP (running, 106±17 vs cycling, 107±14, mmHg, P=0.74) were matched, the reduction in MCAvmean during hyperventilation was similar between running and cycling (Δ-9.6±5.5 vs -9.5±6.3, cm·sec⁻¹, P=0.02). CASE STUDY. MCAvmean increased during cycling (rest, 44.1; 40%, 59.9; 60%, 62.2; 80%, 63.6; VO₂max 62.2, cm·sec⁻¹) and did not show the bi-phasic pattern.

CONCLUSION: Foot-strike-induced oscillations in cerebral pulsatility do not influence MCAvmean responses. Cerebrovascular responsiveness to hypocapnia is blunted with exercise, but seems independent of exercise modality and likely dependant on the prevail MAP and magnitude of autoregulation.

TIME-SERIES ANALYSIS OF CEREBRAL CIRCULATION AND CARDIORESPIRATORY RESPONSES TO ACUTE CENTRAL BLOOD VOLUME REDUCTION

FEELEY, M., WATADA, T., ITO, G., SHIMADA, A., SAWAI, T., NAKATA, H., OTSUKI, S., MIYAMOTO, T.

OSAKA SANGYO UNIVERSITY

INTRODUCTION: Central blood volume (CBV) reduction challenges circulatory and respiratory homeostasis, particularly during the initial compensatory phase (0-2 min) where rapid physiological adaptations occur.

METHODS: This study examined dynamic cardiorespiratory response to CBV reduction using lower body negative pressure (LBNP) in eleven healthy males. Participants completed three standardized 2-minute LBNP trials at -45 mmHg, with respiratory variables assessed via flow measurement and breath-by-breath gas analysis, while cardiovascular and cerebral blood flow were monitored using ECG, blood pressure, and transcranial Doppler ultrasonography.

RESULTS: During LBNP exposure, an indicator of CBV reduction thoracic admittance decreased by 13.4% (p < 0.001), indicating significant CBV reduction. Time-series analysis revealed that mean blood pressure (Mean BP) temporarily decreased during the initial phase (0-30 s), while heart rate progressively increased (16.4%, p < 0.001). end-tidal PCO₂ showed a consistent reduction (5.9%, p < 0.001), and minute ventilation decreased by 9.3% (p = 0.041). Middle cerebral artery mean blood velocity (MCA Vmean) showed a slight decrease (-5.0%, p = 0.372). Analysis revealed a significant negative correlation between Mean BP and tidal volume (VT) (r = -0.78, p = 0.004) and heart rate and MCA Vmean (r = -0.68, p = 0.022) both in the first 30 s and VT and MCA Vmean (r = -0.62, p = 0.042) in the next 30 s.

CONCLUSION: These phase-specific correlations, together with individual variability, suggest rapid cardiorespiratory and cerebrovascular interactions during orthostatic stress, demonstrating dynamic cardiovascular and respiratory responses during CBV reduction, with distinct response patterns providing insights into physiological mechanisms maintaining homeostasis during gravitational stress.

TOBACCO SMOKING AS A BLOOD VOLUME EXPANDER

SOTIRIDIS, A., DARDAMANIS-AIDONAS, C., MAKRIS, A., GELADAS, N., KOSKOLOU, M.

NATIONAL KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Tobacco smoking is the worlds leading cause of avoidable premature mortality. Among the inhaled substances lies carbon monoxide (CO), a gas that binds to hemoglobin to form carboxyhemoglobin (COHb) and thus acutely reduce arterial oxygen content. Repeated exposure to CO has been shown to increase hemoglobin mass (HbM) in non-athletes (1). Whether regular tobacco smoking could accordingly act as an alternative erythropoietin-stimulating agent in trained individuals was examined in the present study.

METHODS: Thirty young males were split in four independent groups based on smoking status (CS- chronic smokers and NS- non-smokers) and aerobic fitness level (MT- moderately trained and UT- untrained) (CS-MT, CS-UT, NS-MT and NS-UT; n=8 for all but the first group). CS had been smoking >10 cigarettes/day for the last three years and scored a Fagerstrom test for nicotine dependence value > 4 (2). Peak oxygen consumption (VO₂peak) and running speed were evaluated using

an incremental running exercise test to exhaustion. An age-adjusted VO₂peak deemed as above “superior” or below “fair” was considered as a prerequisite for the participation in the MT and UT groups, respectively, according to the latest ACSM standards. The carbon monoxide-rebreathing method was performed using a fully automated instrument (OpCo; Detalo Instruments) to assess hemoglobin mass and intravascular blood volumes. %COHb was continuously monitored with participants connected to a pulse CO-oximetry sensor (Rad-57, Masimo). A two-way ANOVA was performed to detect differences in means.

RESULTS: Despite the fact that VO₂peak was only affected by fitness level ($p < 0.001$), smokers attained lower maximal running speed and higher HbM values (main effects of smoking status: $p = 0.004$ and $p = 0.001$, respectively). Specific differences were located in CS-MT (978 ± 147 g) demonstrating a higher HbM compared to NS-MT (800 ± 78 g, $p = 0.05$). When intravascular volumes were normalized to body mass, CS were characterized by a higher red cell volume ($p = 0.013$) reflected in CS-MT (37.2 ± 4.9 mL/kg) possessing marginally higher values compared to NS-MT (31.9 ± 1.7 mL/kg, $p = 0.08$). Total blood volume tended to be higher again in CS ($p = 0.06$). Main effects of fitness level ($p < 0.05$) but no interaction effects ($p > 0.05$) were noted for all investigated parameters.

CONCLUSION: Tobacco smoking and exercise training seem to act additively to enhance hemoglobin mass, red cell volume and total blood volume. A homeostatic regulation of hematocrit is implied in smokers. Given the observed deficit in aerobic performance, the described adaptive erythropoietic response could be alternatively serving to protect human body from CO poisoning.

EVALUATION OF VASCULAR RESPONSIVENESS AFTER PROLONGED ISCHEMIA: COMPARATIVE ANALYSIS BETWEEN CONTINUOUS WAVE AND TIME-DOMAIN NIRS DEVICES

MARCIANO, A., MOTTO, C.2, PILOTTO, A.1, CRECCHI, M.1, NERI, M.1, LACERENZA, M.2, PORCELLI, S.1

1. UNIVERSITY OF PAVIA, PAVIA; 2. PIONIRS S.R.L., MILANO

INTRODUCTION: Near-infrared spectroscopy (NIRS) is a non-invasive tool used to evaluate heme and other chromophores concentration changes occurring within biological tissue according to near-infrared light absorption and scattering [1, 2]. At skeletal muscle level, NIRS has been used to monitor changes of heme indexes during vascular ischemia and reperfusion, leading authors to draw conclusions about endothelial function with physiological and clinical significance [3]. However, changes in oxy-[heme] and deoxy-[heme] that occur during vascular ischemia and reperfusion affect tissue scattering characteristics, possibly worsening accuracy of NIRS indexes [4].

In this study, we compared parameters obtained by a time-domain (TD) NIRS device, which directly measures both absorption and scattering coefficients, with continuous wave (CW) NIRS, which assumes constant tissue scattering. The hypothesis to be tested is that absolute and functional indexes assessed during vascular ischemia and reperfusion could differ between NIRS technologies due to changes in tissue light scattering.

METHODS: Healthy active male participants ($n=9$; 23 ± 4 years, 79 ± 7 kg) with adipose tissue thickness values lower than 10mm were recruited. Tissue saturation index (TSI) of quadriceps muscle was monitored using CW (Train.Red Plus, Train.Red BV) and TD (NIRSBOX, PIONIRS srl) devices during the vascular occlusion test (VOT). Baseline (BAS), minimum (MIN), and maximum (MAX) absolute values were recorded. Desaturation rate (Slope_1) and reperfusion rate (Slope_2) were estimated. Differences between CW and TD estimates were evaluated by two-way RM ANOVA (time x device). Slopes were compared by paired student t-test. Statistical significance was declared when $p < 0.05$.

RESULTS: TSI determined by CW was significantly lower at BAS (CW: $67.4 \pm 3.9\%$; TD: $75.3 \pm 2.8\%$), MIN (CW: $34.7 \pm 11.5\%$; TD: $57.9 \pm 5.4\%$) and MAX (CW: $74.8 \pm 1.5\%$; TD: $79.9 \pm 2.3\%$), compared to TD (all $p < 0.05$). Slope_1 (CW: $-0.25 \pm 0.17 \%$.s⁻¹; TD: $-0.13 \pm 0.07 \%$.s⁻¹) and Slope_2 (CW: $1.97 \pm 0.60 \%$.s⁻¹; TD: $1.10 \pm 0.40 \%$.s⁻¹) resulted significantly different between devices (all $p < 0.05$), with TD values about 45% lower than CW.

CONCLUSION: Our findings show significant differences between CW and TD NIRS measurements, suggesting caution when both absolute values and functional outcomes obtained by different devices are compared. The present data confirm previous results comparing frequency domain NIRS data with those obtained by assuming constant tissue scattering characteristics [4]. Thus, it is essential to establish a reference framework that is specific to the instrument and that can reliably distinguish between physiological and altered values. This is particularly important when these indexes are used to identify endothelial dysfunction in ageing, disuse and clinical populations.

EFFECTS OF A PREBIOTIC GALACTOOLIGOSACCHARIDE ON EXOGENOUS GLUCOSE OXIDATION DURING EXERCISE IN TEMPERATE AND HOT ENVIRONMENTS

COLLINS, A., MORENO-CABAÑAS, A., BRADSHAW, L., HUTCHINS, K., MERRELL, L., GONZALEZ, J.
UNIVERSITY OF BATH

INTRODUCTION: Heat stress has been shown to decrease exogenous glucose oxidation rates during exercise by approximately 10%. There is some evidence that manipulating the gut microbiome via probiotic supplementation may increase exogenous carbohydrate oxidation rates during exercise. We aimed to assess whether a prebiotic galactooligosaccharide supplement can increase exogenous glucose oxidation rates during moderate-intensity exercise in either temperate or hot environments.

METHODS: 22 trained cyclists (14 males, 8 females; age = 43 ± 13 years; $\text{VO}_{2\text{peak}} = 50 \pm 8$ mL/kg/min) completed a preliminary trial (lactate threshold, $\text{VO}_{2\text{peak}}$ and 1-hour familiarisation) and four experimental trials. Participants supplemented daily with 3.65 g of maltodextrin placebo (PLA) or Bimuno-galactooligosaccharide (B-GOS) mixture for 4 wk (separated by a 4 wk washout period) in a randomised, double-blind, crossover design. After each supplement period, participants completed two experimental trials, which involved 2h cycling at 95% LT1 in 21°C (TEMP) and 35°C (HOT) ambient temperatures. A glucose drink containing [U-13C]-glucose was consumed every 15 min providing 90 g/h and exogenous glucose oxidation rates were determined over a 30-120 min period. Gastrointestinal (GI) symptom scores were recorded every 30 min during exercise and were analysed individually, grouped into upper (nausea, regurgitation, fullness & cramps) and lower (gas & urge to defecate) GI categories, and as mean total scores.

RESULTS: Total exogenous glucose oxidation was lower in PLA HOT vs. PLA TEMP (19 ± 11 g/h vs. 30 ± 10 g/h; $P < 0.001$, respectively). In contrast, there was no evidence B-GOS meaningfully increased total exogenous glucose oxidation (TEMP: PLA 30 ± 10 g/h vs. B-GOS 30 ± 9 g/h; $P = 0.512$; and HOT: PLA 19 ± 11 g/h vs. B-GOS 21 ± 14 g/h; $P = 0.081$). In TEMP, GI symptom scores for nausea ($P = 0.017$), upper ($P = 0.026$), and mean total ($P = 0.020$) were lower for B-GOS. No differences were evident for all other individual symptoms or lower GI ($P > 0.05$). Total carbohydrate and fat oxidation were not different between PLA and B-GOS ($P > 0.05$); however, total fat oxidation was lower in PLA HOT vs. PLA TEMP ($P = 0.023$). Plasma insulin concentrations were not different between PLA and B-GOS, or between temperatures ($P > 0.05$). Glucose and lactate concentrations were not different between PLA and B-GOS ($P > 0.05$), but lactate concentrations were higher in the heat ($P = 0.048$).

CONCLUSION: We provide evidence that heat stress can decrease exogenous glucose oxidation rates during moderate-intensity exercise by a greater magnitude (37%) than previously seen. Therefore, athletes and practitioners should carefully consider fuelling strategies in the heat, and explore approaches to mitigate reduced exogenous fuel availability in hot environments. Whilst B-GOS supplementation may provide some symptomatic relief in temperate conditions, other strategies will probably be required to address fuel availability limitations.

EFFECTS OF ACUTE EXERCISE FOLLOWING LATE-DINNER CONSUMPTION ON GLYCAEMIC RESPONSES THE NEXT MORNING

CHEN, Y., LI, Y., HSU, P., WANG, Y., YANG, Y.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Late-dinner eating (LD) impairs postprandial metabolism (e.g., glucose regulation and insulin sensitivity). Studies have indicated that a bout of moderate-intensity aerobic exercise can enhance glucose tolerance and/or insulin sensitivity; however, it remains unknown whether aerobic exercise can modulate the impaired metabolic responses due to LD. This study examined the effects of moderate-intensity aerobic exercise prior to LD on postprandial glycaemic regulation and gut hormone responses (GLP-1, PYY and GIP) the following morning.

METHODS: 14 young healthy men (age: 26.2 ± 4.9 years, BMI: 22.8 ± 2.5 kg/m²) completed 3 trials across 2 days including (1) regular dinner (RD at 18:00), (2) late dinner eating (LD at 21:30) and (3) 45-minute brisk walking at 60% $\text{VO}_{2\text{max}}$ + late dinner at 21:30 (ELD), in a randomized crossover study design. A 2-hour OGTT was conducted in the following morning, with blood (plasma) samples collected at baseline, and every 15 min following glucose ingestion. The primary outcome was total glucose area under the curve (tAUC) over the 120-min sampling period. One-way ANOVA were applied and the significant level is $\alpha = 0.05$.

RESULTS: In the ELD trial, exercise intensity was 62 ± 2 % $\text{VO}_{2\text{max}}$, with an average energy expenditure of 408 ± 61 kcal during 45 min exercise. The average heart rate reached to 143 ± 10 bpm, accompanying by a RPE of 12 ± 2 . During a 2-h OGTT, tAUC for glucose (833 ± 182 vs. 826 ± 133 vs. 859 ± 196 mmol/2 h/L, respectively) and insulin (27.2 ± 21.3 vs. 28.2 ± 15.7 vs. 28.9 ± 16.2 nmol/2 h /L, respectively) concentrations were not different between RD, LD and ELD trials (all, $p > 0.05$). In addition, GLP-1, PYY and GIP concentrations did not differ between 3 trials (all, $p > 0.05$).

CONCLUSION: In the healthy young males, late dinner eating did not acutely result in the impairment of glucose control and insulin sensitivity. Moreover, acute bout of exercise performed immediately prior to late dinner eating did not influence glucose control and insulin sensitivity next morning. Dinner timing with and without exercise did not affect gut hormone (GLP-1, PYY and GIP) responses.

ADJUSTED MEAL TIMING PRIOR TO TRANSATLANTIC TRAVEL DOES NOT MAINTAIN GLYCAEMIC CONTROL UPON ARRIVAL IN HEALTHY WOMEN AND MEN

MERRELL, L., THOMAS, J.E., SMITH, H.A., NAKAMURA, J., HICKMAN, J.A., AFMAN, G., BETTS, J.A.

UNIVERSITY OF BATH

INTRODUCTION: Long-haul flights involving transition between time-zones may misalign the human circadian timing system and impair metabolic regulation. We hypothesised that modifying meal patterns for 7 days before departure to match destination eating times would minimise metabolic disruption evident both one day and one week following arrival. This may have implications for the metabolic health of individuals traveling long distances, including athletes who regularly cross time-zones for international competition.

METHODS: Between May 2019 and May 2022, twenty-five young women (n=18) and men (n=7) who were lean and metabolically healthy (age = 21 ± 1 years, height = 1.70 ± 0.11 m, body mass = 67.9 ± 12.8 kg, body mass index = 23.3 ± 2.6 kg·m⁻²; means $\pm$ standard deviation) and residing in California, USA, were randomly allocated to adhere to one of two dietary patterns over the 7 days prior to a ~10.5 h transatlantic flight to the UK. The control group ate according to their local time zone (Pacific Daylight Time; PDT), with a typical breakfast consumed from 0600-0700 h, a typical lunch from 1200-1300 h and a typical dinner from 1800-1900 h; whereas the intervention group ate in the same pattern but with timings shifted by 6-8 hours to broadly match their destination time-zone (British Summer Time; BST), with a typical lunch therefore consumed from 0600-0700 h, a typical dinner from 1200-1300 h and a typical breakfast meal from 2300-0000 h (all local time; PDT). All participants went to bed at 2300-0000 h and woke at 0600-0700 h. Oral glucose tolerance tests were completed in California 12 days prior to the transatlantic flight, then 24-h and 168-h after arrival in the UK.

RESULTS: Both groups exhibited elevated glycaemic responses to the oral glucose tolerance tests upon arrival in the UK relative to their baseline assessments in California (ANOVA time effect $p=0.003$), but without any significant difference in the magnitude of this effect between experimental conditions (ANOVA interaction $p=0.093$). Specifically, the respective blood glucose concentration incremental area under curve for the control and interventions at baseline were 210 ± 65 and 216 ± 107 mmol·120 min⁻¹·l⁻¹, 24 hours after arrival were 295 ± 115 and 331 ± 102 mmol·120 min⁻¹·l⁻¹, and 168 hours after arrival had recovered to 193 ± 75 and 244 ± 83 mmol·120 min⁻¹·l⁻¹. Peak blood glucose concentrations followed similar numeric patterns, broadly reflecting an increase >0.5 mmol·l⁻¹ from baseline to 24-h (with partial recovery by 168-h), also with no difference between experimental conditions. Fasted glucose concentrations were relatively stable across all testing days in both groups.

CONCLUSION: This is the first study to examine changes in oral glucose tolerance before and after transatlantic travel, with significant impairment 24-h after the time-zone transition. This effect was not mitigated even by a relatively extreme schedule of eating according to the destination time-zone for a full week prior to departure.

THE EFFECTS OF THE COMBINATION OF HIGH-INTENSITY FUNCTIONAL TRAINING AND SELENIUM AND ZINC CO-SUPPLEMENTATION ON PHYSICAL FITNESS AND QUALITY OF LIFE PARAMETERS IN OVERWEIGHT AND OBESE PEOPLE

GIANNAKI, C., ZAVROS, A., ANDREOU, E., APHAMIS, G., SAKKAS, G., BOGDANIS, G.

UNIVERSITY OF NICOSIA

INTRODUCTION: Both high-intensity functional training (HIFT) (1,2) and the supplementation of selenium (Se) and zinc (Zn) (3) have the potential to enhance various aspects of physical fitness and health. The purpose of this study was to evaluate, for the first time, the combined effects of high-intensity functional training along with selenium and zinc co-supplementation in overweight and obese individuals following a hypocaloric diet.

METHODS: Sixteen individuals participated in a study where they were randomly assigned to either a group receiving zinc and selenium co-supplementation (n=8, involved in HIFT and supplements) or a control group (n=8, involved in HIFT and receiving a placebo). Throughout the intervention, participants engaged in HIFT sessions twice weekly while adhering to a hypocaloric diet that reduced their caloric intake by 500 calories below their total daily energy expenditure. Those in the supplementation group received 25 mg of zinc gluconate and 200 mcg of L-selenomethionine daily, whereas participants in the control group were given placebo tablets over a period of six weeks. Measurements of resting metabolic rate, thyroid function, body composition, cardiorespiratory fitness, functional capacity, sleep quality, and overall quality of life were conducted at both the start and the end of the study.

RESULTS: The results indicated improvements in functional capacity, quality of life, and sleep quality for both groups following the intervention. Concurrently, reductions were observed in body mass, body fat, and free triiodothyronine (FT3) levels. A significant interaction was found between group and time in relation to performance in the Timed Up and Go (TUG) test, sleep quality, body mass, and selenium serum levels, suggesting that supplementation had a beneficial impact on these parameters.

CONCLUSION: In conclusion, the integration of HIFT with Zn and Se co-supplementation led to enhancements in sleep quality and functional capacity among overweight and obese individuals. Moreover, this regimen effectively contributed to the reduction of body mass. These findings suggest that such a combined approach may serve as a beneficial strategy for improving health outcomes related to physical function and metabolic health in this population group.

RELATIONSHIP BETWEEN VISCERAL FAT AREA AND NUTRIENT INTAKES IN JAPANESE COLLEGIATE FEMALE ATHLETES

TANAKA-HASEGAWA, T., MARUYAMA, M., ZEMPO-MIYAKI, A., KUROSAKA, Y., MACHIDA, S.

JOSAI INTERNATIONAL UNIVERSITY

INTRODUCTION: Excessive visceral fat accumulation, which leads to lifestyle-related disease, causes the risk of cardiovascular disease. We have reported that the Visceral fat area (VFA) of Japanese collegiate female athletes had a negative correlation with HDL-cholesterol. Previous studies showed that nutrient intakes, such as dietary fiber, carotenoids, alcohol, and calcium, affected the accumulation of visceral fat. However, it is still unknown whether nutrient intakes have an effect on visceral fat accumulation in daily training athletes. Considering the prevention of health and lifestyle-related diseases after retirement, it is necessary for athletes to have dietary strategies that prevent the accumulation of visceral fat from the beginning of their professional careers. This study aimed to clarify the relationship between VFA and nutrient intakes in Japanese collegiate female athletes.

METHODS: The participants were 46 Japanese female collegiate athletes (rugby player = 23, Throwing Events player = 13, Softball player = 10). Body measurements were taken in the early morning after an overnight fast. The body mass index (BMI) was calculated based on height and body weight. The VFA and Waist Circumference (WC) were measured using abdominal bioelectrical impedance analysis (Panasonic, EW-FA90). The nutrient intakes were investigated using a digital photographic method with data obtained from 3-day dietary records. The study lasted three non-consecutive days: two days (training days) and one day (off day). Each variable was examined for normality using the Shapiro-Wilk test. Then, Spearman's correlation analysis was conducted to find the association between VFA and nutrient intake. Multiple regression analysis was performed for the determinants of VFA.

RESULTS: Aged 18-22years, the participants had a median (interquartile range) height of 161.3 cm (157.2 – 164.7 cm), body weight of 61.5kg (57.3 – 68.4 kg), BMI of 24.2 kg/m² (22.4 – 25.7 kg/m²), VFA of 45.0 cm² (35.0 – 54.0 cm²) and WC of 78.3 cm (75.2 – 83.0cm). Their VFA was most frequently distributed within the range of 40.0-59.9 cm², accounting for 47.8% (22/46 participants). The nutrient intakes of participants were 2,361 kcal/day (2,130 – 2,743 kcal/day), protein of 91.8 g/day (77.8 – 109.9 g/day), fat of 74.0 g/day (62.7 – 92.5 g/day) and carbohydrate 312.0 g/day (278.7 – 353.5 g/day). Negative correlations were found between VFA and energy, protein, dietary fiber, potassium, calcium, magnesium, iron, vitamin K, vitamin B2, vitamin B6 and folic acid, among which dietary fiber had the strongest correlation ($r = -0.56$, $p < 0.001$). Results of multiple regression analysis showed that protein ($\beta = -0.53$, $t = -3.16$, $p < 0.01$) and dietary fiber ($\beta = -0.58$, $t = -3.62$, $p < 0.001$) were significantly associated with VFA. (Adjusted R² = 0.43).

CONCLUSION: It is suggested that protein and dietary fiber may contribute to the accumulation of visceral fat in Japanese collegiate female athletes.

THE EFFECT OF AN OMEGA-3 RICH FOOD ON REDUCING IL-6 IN PEOPLE WITH ACHILLES TENDINOPATHY: A DOUBLE-BLIND, RANDOMISED CONTROL TRIAL.

MUSSON, D., HOLDEN, G., BRAAKHUIS, A., ELLIS, R., NAOT, D.

UNIVERSITY OF AUCKLAND

INTRODUCTION: Inflammation is fundamental in maintaining health, and important in many healing processes. However, unresolved inflammation has severe health consequences, particularly in performance and recovery. The role of inflammation in tendon disorders is well established, particularly in those with chronic Achilles tendinopathy. Achilles tendinopathy is incredibly common, and each year in New Zealand it affects 1 in 300 people, and costs the New Zealand healthcare system over \$25million NZD.

Studies have consistently demonstrated that increasing omega-3 consumption reduces inflammation across various disease conditions and in healthy people. Here, we explored whether consuming an omega-3-rich food product daily could reduce systemic inflammation in people with Achilles tendinopathy, and improve tendon healing and overall well-being.

METHODS: In this double-blinded, randomised, placebo-controlled clinical trial, participants with non-acute Achilles tendinopathy were randomised to consume a gel-based food product containing ~2.6g omega-3/day (n=20) or a control product where the omega-3 oil was replaced with vegetable oil (n=21). After 6 and 12 weeks of consuming the product daily, blood was taken to measure circulating levels of fatty acids, IL-6, IL-1, and TNF α , and self-reported questionnaires of tendinopathy severity (VISA-A), well-being (WHO-5), and stress and anxiety (DASS-21) were completed. A mixed effects model with post hoc Tukey's test was used to determine statistically significant changes with time and between groups.

RESULTS: Participants consuming the omega-3 product had significantly higher circulating levels of EPA, DHA, and total n-3 fatty acids after 6 weeks of treatment, which was maintained throughout the rest of the study ($p < 0.0001$). There was no change in the placebo group.

Circulating levels of IL-6 were significantly lower in the treatment group compared to the placebo group following 12 weeks of consuming the test product (0.9744pg/mL vs 1.728pg/mL, respectively, $p=0.0373$). There were no differences in IL-1 and TNF α across the treatment period, or between groups.

The severity of tendinopathy, measured through a self-reported questionnaire, improved in both the treatment and placebo groups across the study period ($p=0.0293$ and $p=0.0001$, respectively). There was no difference between groups.

There were no measurable changes in well-being or stress and anxiety in either group across the treatment period, or between groups

CONCLUSION: Overall, consuming ~2.6g omega-3/day reduced circulating IL-6 levels in people with Achilles tendinopathy. While no improvements in tendon healing were observed compared to the placebo product group, this study has again demonstrated the ability of omega-3 consumption to regulate systemic inflammation in people with disease. Increasing omega-3 consumption can therefore be considered a viable lifestyle alternative to managing unresolved chronic inflammation.

DARK CHOCOLATE SUPPLEMENTATION ATTENUATES ARTERIAL STIFFNESS INDUCED BY HIGH-INTENSITY RESISTANCE TRAINING DURING THE EARLY FOLLICULAR PHASE IN WOMEN

HE, C., YU, T.A., CHANG, W.Y., WANG, C.K., CHEN, L.Y., WANG, C.W., FANG, S.H., WANG, S.C.
NATIONAL CHUNG CHENG UNIVERSITY

INTRODUCTION: High-intensity resistance training (HIRT) enhances strength and muscle mass but may also increase arterial stiffness. Women in the early follicular phase of the menstrual cycle exhibit reduced vascular elasticity, potentially compounding these effects. Flavanol-rich dark chocolate has been shown to exert cardioprotective effects, yet its impact on vascular function during HIRT in this menstrual phase remains unclear. This study investigates whether 85% dark chocolate supplementation mitigates arterial stiffening induced by HIRT and the early follicular phase.

METHODS: Twenty-nine healthy eumenorrheic women (age: 21.17 ± 2.54 years) were randomly assigned to a placebo (PBO) or dark chocolate (DC) group. For four weeks, participants consumed 25 g of 85% dark chocolate or an equivalent placebo daily in a double-blind manner. The HIRT program included three exercises, performed at 75% of one-repetition maximum (1RM), with six repetitions per set, five sets per session, and three sessions per week. Vascular and cardiovascular parameters, including finger-toe pulse wave velocity (fPWV), arterial pressure-volume index (API), arterial velocity pulse index (AVI), heart rate (HR), systolic blood pressure (SBP), and diastolic blood pressure (DBP), were assessed at pre-intervention rest (pre-rest), post-intervention rest (post-rest), immediately post-exercise (post-T0), and 30 (post-T30) and 60 minutes (post-T60) post-exercise.

RESULTS: At pre-rest, there were no significant differences between the two groups in any parameter. After four weeks of intervention, fPWV significantly increased in both groups compared to pre-rest (DC: $p < 0.05$; PBO: $p < 0.001$), while only the PBO group showed a significant increase in AVI ($p < 0.001$). Additionally, post-rest HR was significantly higher than pre-rest in both groups ($p < 0.05$). Notably, fPWV and AVI were significantly lower in the DC group compared to the PBO group at post-rest, post-T0, post-T30, and post-T60 ($p < 0.05$). SBP, DBP, and API showed no significant changes between the groups.

CONCLUSION: HIRT-induced arterial stiffness was mitigated by 85% dark chocolate supplementation, suggesting a potential protective effect on vascular function during the early follicular phase. Future research should explore additional vascular markers (e.g., flow-mediated dilation, nitric oxide levels) and muscle adaptation indices (e.g., muscle cross-sectional area, 1RM). Further investigation into cocoa concentration, dosage, and supplementation timing may optimize dark chocolate's cardioprotective role while preserving strength adaptations, offering a non-pharmacological strategy for cardiovascular health in resistance-trained women.

HIGHER ENERGY-DENSE FOOD INTAKE IS LINKED TO COGNITIVE DECLINE IN SCHOOLCHILDREN: THE MODERATING ROLE OF CARDIORESPIRATORY FITNESS AND EMOTIONAL WELL-BEING (PACH STUDY)

RAUDENIECE, J., ZOLOVS, M., REIHMANE, D.
RIGA STRADIŠ UNIVERSITY

INTRODUCTION: Cognitive skills are essential for learning, problem-solving, and adapting to new information and daily life situations, allowing children to process and retain knowledge efficiently. Well-developed cognitive functions also contribute to emotional regulation, decision-making, and academic achievement, forming the basis for future personal and professional growth. This study aims to examine the effects of dietary habits, emotional status, and cardiorespiratory fitness (CRF) on cognitive functions in schoolchildren.

METHODS: Prospective longitudinal study involved 106 pupils aged 8-10 years (53.5% boys and 46.5% girls). Over 3 consecutive years dietary habits and emotional well-being were assessed by food frequency survey and revised childrens anxiety and depression scale 25 (RCADS25), accordingly. Cognitive functions were determined by Vienna test system tests – determination test (DT), visual pursuit test (VPT), reaction test (RT). For determination of CRF level pupils performed Kasch Pulse Recovery test. Latent growth curve model was used to test whether changes in cognitive functions over time are linear. Only cognitive function variables with a Comparative fit index of 0.90 or higher were included in the linear mixed model (LMM) analysis to identify influencing factors. Principal component analysis (PCA) was used to reduce food group dimensionality by creating principal components (PC). PCs were included in LMM.

RESULTS: PCA identified 2 PCs, where PC 1 represented energy dense foods, PC 2 – nutrient dense foods. LMM showed that PC2 had no effect on cognitive functions, while PC1 represented by food rich in carbohydrates showed to have an association. The increase of PC 1 score was associated with decreased correct responses in DT (mean estimate -5.72), but there was no effect on RT motor time ($p > 0.005$). RCADS25 score played a moderating role between PC1 and DT correct responses, and between PC1 and RT motor time. The increase of PC1 score was associated with decrease in VPT score (mean estimate -1.70). CRF was identified as moderator between PC1 and VPT score.

CONCLUSION: Higher consumption of energy-dense foods was associated with poorer results in most of the cognitive function tests and a decline in cognitive functions. CRF level and emotional well-being played a moderating role in relationship between PC1 and cognitive functions. Findings highlight the importance of prudent eating habits, CRF and emotional health management in early childhood to support cognitive development.

EXPLORING LOW SEX DRIVE, EATING DISORDER RISK AND EXERCISE BEHAVIOURS AMONG PROFESSIONAL AND ELITE MALE RUGBY UNION PLAYERS IN IRELAND.

SWEENEY, G., MCCARDLE, S., COLLINS, K.

TECHNOLOGICAL UNIVERSITY DUBLIN

INTRODUCTION: An athletes drive for muscularity and aesthetic satisfaction is a mediating factor of Eating Disorder (ED) symptomology and low sex drive. Rugby Union exhibits large variations in expected physique profiles norms across positional groups of backs (low body mass, low body fat) and forwards (high body mass, high body fat). The pursuit of established typical positional norms and physique ideals may increase body image concerns that could influence ED symptomology and risk exposure to Low Energy Availability (LEA). The aim of this research was to explore the prevalence of ED, low sex drive and exercise behaviours among male Rugby Union players.

METHODS: Participants were recruited from male professional Rugby Union teams and elite Rugby Union pathway squads in Ireland. Athletes were eligible for inclusion if they were over 18 years of age and training at least 4 times per week. Participants completed an online survey which included 71 questions (Q) comprising the Eating Disorder Examination Questionnaire (EDE-Q) (Q = 28), the Exercise Addiction Inventory (EAI) (Q = 6) and the sub-section relating to sex drive from the Low Energy Availability in Males Questionnaire (LEAM-Q) (Q = 4). A further 33 questions related to nutrition support (Q=8) and the participant background (Q=25) were also included.

RESULTS: 97 Rugby Union players participated (55% professionally contracted; 45% non-professional elite pathway players). The mean age of participants was 21.8 ($\pm$ 4.7) years. The highest competitive playing levels of participants included senior international (n=10), senior provincial (n=36), national age grade (n=55), national sevens (n=4), club adult (n=1) and university (n=1). Nine percent (n = 9) of participants scored above the threshold for the EDE-Q Global score of 1.68 indicating the presence of disordered eating risk. Twenty percent (n = 20) reported a low sex drive score. Sixteen percent (n=16) of participants scored above the cut off on the EAI suggesting the presence of exercise compulsion. All participants reported they had access to a professional nutritionist. Participants who played in the forwards, regardless of professional status, showed higher EDE-Q eating concerns (p = 0.03). There was no significant difference between professional status or position when determining sex drive status.

CONCLUSION: The practical application of these findings points to increasing the awareness of practitioners and stakeholders within the elite and professional rugby context to drive screening and intervention. Further research is needed to understand the contextual risk factors that may be associated with this symptomology in male Rugby Union players.

EFFECT OF DIETARY FIBER INTAKE ON MOTIVATION FOR PHYSICAL ACTIVITY

OYANAGI, E., WATANABE, C., HAMADA, H., KONO, T., AOKI, T., KREMENIK, M.J., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Although it is a well-known fact that exercise habits and a well-balanced diet are essential for the maintenance and improvement of health, it is very difficult to keep on regular exercise. One of the factors affecting human health involves the gut microbiota, which has also been shown to be affected by exercise. In addition, altered gut microbiota caused by exercise quickly returns to its level before exercise, suggesting that the gut microbiota, or the short-chain fatty acids (SCFAs) produced by the gut bacteria, may influence exercise motivation and exercise capacity. The purpose of this study was to investigate the effects of dietary fiber intake, which strongly induces the production of SCFAs derived from the gut microbiota, on the motivation to exercise in mice.

METHODS: Eight-week-old C3H/HeN male mice (n=24) were randomly divided into three dietary groups: non-fiber (NFD, n=8), 5% cellulose (Cellu, n=8) and 5% PHGG (PHGG, n=8). Body weights were measured weekly. They were measured by exercise motivation through voluntary wheel-running for 7 days and exercise capacity by forced treadmill exercise after each food-intake period. Then, we collected their fecal samples for analysis of the gut microbiota.

RESULTS: The change in body weight after 6 weeks of food consumption was significantly higher in PHGG compared with Cellu ($p<0.05$). Fecal pH, a measure of organic acid production by the gut microbiota, was significantly higher in Cellu compared with NFD, but showed no significant change with PHGG. The voluntary wheel-running in Cellu was significantly higher than that in both NFD and PHGG groups. The exhaustion time by forced treadmill running, however, was not affected by those dietary fibers. The alpha diversity of the gut microbiota in Cellu mice was significantly higher than that in NFD groups ($p<0.05$).

CONCLUSION: The increased voluntary wheel-running in Cellu might not depend on exercise capacity such as skeletal muscles and/or circulatory functions. It appears that the wheel-running requirement suggested a change in brain function. In other words, Cellu intake affects the formation of the gut microbiota, which acts on the brain via changes in SCFA production and influences the motivation to exercise. This may have stimulated gene expression in the brain, resulting in an effect on the amount of voluntary physical activity. This hypothesis may be consistent with the "gut-brain axis" hypothesis already proposed. We previously reported that ingestion of PHGG, a highly fermentable soluble fiber, leads to the formation of a characteristic gut microbiota and increased SCFA production. However, this study suggests that this may

have a negative effect on exercise motivation. In contrast, our collaborator already showed that wheel-running activity was increased by cellulose nanofiber intake. Accordingly, intake of cellulose, which is not easily metabolized by the gut microbiota, might be useful for keeping to a program of regular exercise.

EFFECTS OF CONCURRENT EXERCISE AND PROTEIN SUPPLEMENTATION ON WORKING MEMORY, BODY COMPOSITION, AND MUSCLE STRENGTH IN SARCOPENIC OVERWEIGHT WOMEN: A 12-WEEK INTERVENTION STUDY

WEN, H., MANI, H., CHEN, Y.Z., WANG, H.L.

TZU CHI UNIVERSITY

INTRODUCTION: The loss of muscle mass and cognitive function in sarcopenic overweight women is a public health concern. The relationship between exercise, protein supplementation, and cognitive function remains a key research area. This study examined the effects of concurrent exercise and high-protein supplementation on sarcopenic-overweight women.

METHODS: Forty women (mean age: 66.63 ± 7.23 years, BMI: 24.86 ± 2.64 kg/m², and waist circumference 83.16 ± 6.95 cm) participated in a 12-week intervention. They were randomly assigned to one of four groups: Exercise without supplementation (EG), Exercise with supplementation (ESG), Control with supplementation (CSG), and Control without supplementation (CG). Assessments included working memory (N-back task), body composition, and muscle strength (Biodex 4 Pro), measured pre- and post-intervention.

RESULTS: (1) Behavior performance of working memory: The study found that as task difficulty increased, reaction times became slower ($F(3,9) = 779.81$, $p < 0.01$), confirming that more complex tasks require more significant cognitive effort. No significant effect on reaction time or accuracy rate was found ($p < 0.05$). However, task-specific improvements were observed that SG improved in simple response tasks (N-back 0), reducing reaction time (638.85 ± 109.88 ms vs. 564.63 ± 62.38 ms, $p = 0.01$), while EG showed gains in high working-memory tasks (N-back 2) (1386.15 ± 311.99 ms vs. 1157.11 ± 337.75 ms, $p = 0.04$). (2) Body composition: The intervention significantly improved fat mass, fat percentage, and lean mass, with ESG achieving the best results. The most significant fat mass reduction (pretest 20.04 ± 8.61 vs. posttest 18.46 ± 7.43 kg, $p < 0.01$), fat percentage reduction (pretest $33.53 \pm 7.97\%$ vs. posttest $31.53 \pm 8.02\%$, $p < 0.01$), and the highest lean mass gain (pretest 21.01 ± 1.23 vs. posttest 21.57 ± 1.47 kg, $p < 0.01$) were found in ESG. BMI and total weight remained stable, suggesting muscle gain may have balanced fat loss. (3) Muscle strength showed significant improvement over time for flexion ($p < 0.01$, partial $\eta^2 = 0.38$) and extension strength ($p < 0.01$, partial $\eta^2 = 0.28$), particularly in ESG, while it showed the most significant gains (knee flexion: pretest 23.96 ± 10.93 Nt, posttest: 43.01 ± 12.93 Nt; knee extension: pretest 45.50 ± 16.87 Nt, posttest: 66.07 ± 20.35 Nt).

CONCLUSION: Concurrent exercise with supplementation effectively reduced fat mass, increased lean mass, and improved muscle strength in sarcopenic-overweight women. While the behavioral performance of working memory did not show substantial overall improvement, supplementation enhanced reaction speed, and exercise improved working memory. Targeted interventions integrating concurrent exercise and supplementation may optimize body composition and muscle strength. Future research should examine long-term metabolic and neurocognitive effects to refine strategies further.

The study was funded by National Science & Technology Council (NSTC 112-2410-H-320 -001 -MY2).

TOTAL PROTEIN AND BRANCHED-CHAIN AMINO ACID INTAKE ARE ASSOCIATED WITH LEAN MASS, SKELETAL MUSCLE FUNCTION AND STRENGTH IN ADULTS WITH MUSCULAR DYSTROPHY

LEAVER, M., MORSE, C., ORME, P., FLANNERY, O., KOLIC, P., HODSON, N.

MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: Muscular dystrophinopathies (MD) are a heterogeneous group of inherited neuromuscular disorders characterised by progressive declines in skeletal muscle strength, size and function. Despite progress in potential drug treatments in pre-clinical models, few have transitioned to widespread clinical usage. As such, identifying interventions that maintain and/or slow declines in function and quality of life (QoL) are essential. Nutritional interventions, including protein and creatine supplementation, have shown efficacy in specific MD populations i.e. paediatric Duchenne MD [1]; however, little is known about the dietary habits of the broader adult MD population [2, 3]. Therefore, the aim of this study was to evaluate nutritional status and habits in adults with MD and probe for associations between nutritional outcomes, functional/physiological parameters and QoL.

METHODS: Adults with MD ($n=39$; FSHD=8, LGMD=9, Other=22, body mass index (BMI) 26.8 ± 5 kg/m², 61 ± 14 yrs) and non-dystrophic controls (CTRL) ($n=15$, 28.5 ± 5.9 kg/m², 38 ± 12 yrs) completed: (1) 2x three-day food diaries, separated by 8 weeks, (2) a set of validated questionnaires assessing perceived functional ability and QoL; (3) strength and functional testing comprising body composition, forearm muscle thickness, elbow flexor, arm abduction and grip strength, and muscle function (10m walk, timed up and go). Group differences were probed using independent t-tests or Mann-Whitney

U and associations were tested using Pearson's *r* or Spearman's Rho tests, depending on normality. Values are reported as mean $\pm$ SD and significance was set at $p < 0.05$.

RESULTS: No differences between CTRL and MD were found for BMI or self-reported physical activity ($p > 0.05$). MD reported a lower protein intake (PI) as a percentage of recommended daily intake (%RDI) (0.76 g/kg/day) [4] when compared to CTRL ($150 \pm 35\% \text{RDI}$ vs $186 \pm 15\% \text{RDI}$, respectively, $p = 0.022$), while reporting a higher overall energy intake (MD = $139 \pm 48\%$, CTRL = $114 \pm 32\%$, $p = 0.023$). PI (g/kg/day) was positively associated with lower limb function ($r_s = 0.43$), Barthel Index (ability to perform daily tasks) ($r_s = 0.43$) and elbow flexor strength ($r_s = 0.37$) in the MD group (all $p < 0.05$). MD also reported lower branched-chain amino acid (BCAA) intakes (CTRL = $8225 \pm 961 \text{ mg}$, MD = $6274 \pm 474 \text{ mg}$, $p = 0.049$) which were associated with lean mass% ($r = 0.45$, $p = 0.015$) and arm abduction strength ($r = 0.37$, $p = 0.036$).

CONCLUSION: These data show MD adults have reduced total protein and BCAA intake compared to the average UK adult, whilst consuming a greater relative energy intake. Importantly, protein and BCAA intake were associated with various measures of muscle strength and function, suggesting interventions targeted at increasing such intakes may benefit this population.

RELATIONSHIPS AMONG SKELETAL MUSCLE CROSS-SECTIONAL AREA, INTRAMUSCULAR ADIPOSE TISSUE CONTENT, AND PROTEIN INTAKE IN YOUNGER AND OLDER ADULTS

SANDO, E., KITAGAWA, F., KOIKE, T., TANAKA, N., AKIMA, H.
NAGOYA UNIVERSITY

INTRODUCTION: Skeletal muscle size decreases and intramuscular adipose tissue (IntraMAT) content increases with aging, which induces decline of skeletal muscle strength and physical function (Goodpaster et al, 2006; Tuttle et al, 2012). IntraMAT content is known to be associated with metabolic diseases such as type II diabetes (Goodpaster et al, 2000). Therefore, it is important to take measures to prevent the decrease in skeletal muscle size and the accumulation of IntraMAT. One of the factors that may affect changes in the amount and proportion of skeletal muscle and adipose tissue is habitual dietary intake. It has been clarified that protein intake helps maintain and increase skeletal muscle size; however, it is not well known how protein intake affects adipose tissue. Previous studies examined the relationships among skeletal muscle cross-sectional area (CSA), IntraMAT content, and protein intake (Sjoholm et al, 2016; Dicks et al, 2020); however, a consistent consensus has not been observed in these relationships. A possible cause of the inconsistency in these relationships is the difference in age. Therefore, the purpose of this study was to clarify the relationships among skeletal muscle CSA, IntraMAT content, and protein intake in younger and older adults.

METHODS: Twenty-three young women (19.9 ± 1.6 years) and 25 older women (72.4 ± 3.2 years) participated in this study. Skeletal muscle CSA and IntraMAT content (%) of the quadriceps femoris (QF), hamstrings (HM), adductors (AD), and total thigh (i.e. sum of QF, HM, and AD) at the mid-thigh were measured using magnetic resonance imaging. The percentages of energy from protein were assessed using a simple self-administered dietary history questionnaire. Protein was classified into total protein, animal protein, or plant protein.

RESULTS: No significant correlations were observed between skeletal muscle CSA and percentage of energy from protein (i.e. total protein, animal protein, and plant protein) in both groups. In younger group, IntraMAT content of the QF significantly correlated with the percentages of energy from total protein ($r = 0.528$, $P < 0.05$) and animal protein ($r = 0.484$, $P < 0.05$). In older group, IntraMAT content of the three skeletal muscle groups (i.e. QF, HM, and AD) and the total thigh were inversely correlated with the percentages of energy from plant protein ($r = -0.538$ to -0.455 , $P < 0.01$).

CONCLUSION: These results suggest that the relationship between IntraMAT content and protein intake varies with age, and particularly in older group, a higher percentage of energy from plant protein affect reduce the accumulation of IntraMAT content.

EFFECTS OF ANIMAL AND PLANT FOOD INTAKE ON FATIGUE AND SATIETY DURING VOLLEYBALL PRACTICE

YURI, A., KAYO, K., KANNA, I., MONEKA, S., AYANA, N., HITOMI, I.
JAPAN WOMAN'S COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: Practicing volleyball involves various exercises and requires sufficient calorie intake. Fats are energy-loaded macronutrients both in plants and animals. Plant-based (PB) foods are rich in unsaturated fatty acids, which reduce LDL cholesterol accumulation in the blood, while animal-based (AB) foods have high saturated fatty acid levels. Consuming PB foods before exercise reportedly reduced arterial stiffness and increased maximal oxygen uptake in adult men. Thus, consuming PB foods before volleyball practice facilitates exercising during practice and affects fatigue. This study aimed to determine how PB foods before volleyball practice affect satiety, fatigue, and ease of movement.

METHODS: We involved eight womens volleyball club members and conducted measurements from July to September 2024. We applied a crossover method and a one-week washout period. The energy intake and fat-to-energy ratio of the PB and AB meals were 661 and 601 kcal and 50 % and 49 %, respectively. The measurement items included physical characteristics, energy consumption during practice by acceleration sensor, and feelings of fatigue and fullness. We

measured the following physical characteristics: height, weight, and body fat percentage. Fatigue and fullness were assessed using a Visual Analog Scale (VAS). The fatigue items included difficulty in breathing and heaviness in the legs. We assessed the feeling of fullness seven times: right after eating, 20, 50, 80, 140, 200, and 260 min. We assessed fatigue after warming up. We used paired t-tests to compare the energy expenditure, and fatigue levels when consuming PB and AB foods. We compared satiety between time, PB, and AB using repeated measures two-way ANOVA. When we identified significant differences, we assessed time using multiple comparisons and the differences between the PB and AB groups using paired t-tests.

RESULTS: On average, the participants were 158.8 cm tall and weighed 54.8 kg with a body fat percentage of 21.7%. There was no significant difference in exercise intensity or energy expenditure during the four-hour volleyball practice in this study. The energy expenditure was about 893 Kcal and the exercise intensity was about 3.7 METs. In terms of fatigue, there was no significant difference between the groups in the vas of PB and AB (difficulty breathing: about 4.3, feeling heavy in the legs: about 6.5). We observed no significant differences between the PB and AB groups with respect to leg heaviness or breathlessness during practice. Feelings of fullness was significantly r in the PB group (compared to the AB group) at 140 min and 260 min postprandial.

CONCLUSION: These results suggest that when performing moderate-intensity exercise, ingesting PB before exercise gradually reduces the feeling of fullness, reduces the feeling of hunger even in the latter half of exercise, and although the legs feel a little heavy, it is possible to concentrate on high-intensity exercise from 2 hours after eating.

EIGHT-DAYS OF FAVA BEAN PROTEIN SUPPLEMENTATION IMPROVES THERMOREGULATION WITHOUT EXACERBATING GASTROINTESTINAL SYMPTOMS DURING EXERCISE IN A HOT ENVIRONMENT

WALDRON, M., AITKENHEAD, R., CONWAY, G.E., HORNER, K., HEFFERNAN, S.M.

SWANSEA UNIVERSITY

INTRODUCTION: Exercise in hot environments can lead to gastrointestinal disturbances, which may impair performance (1). Single amino acid supplementation has been reported to attenuate gut damage (2) and enhance exercise tolerance (3); however, the effectiveness of amino acid blends from plant-based proteins remains underexplored. With increasing interest in plant-based protein sources as a sustainable option for athletes, further research is crucial to understand their potential to reduce markers of exercise-induced gastrointestinal syndrome (EIGS). This study aimed to investigate the effects of an eight-day supplementation with a novel fava bean-derived plant protein and amino acid blend on thermoregulation, endurance performance, and EIGS during exercise in a hot environment.

METHODS: Twelve, healthy, euhydrated, non-heat acclimated participants (7 females, 5 males; 31 ± 5 years) completed an eight-day supplementation protocol with either fava bean protein (ATURA; 60 g/day) or a placebo in a randomised, double-blind, placebo controlled cross-over design. On day eight, participants walked on a treadmill for 10 min, followed by a 40 min run at a fixed heat production (H prod), followed by a graded exercise test to exhaustion (35°C , relative humidity 40%). Whole-body sweat rate (WBSR), local sweat rate (LSR), pulmonary gas exchange, skin temperature, core temperature, and perceptual responses were monitored. Venous blood-samples were collected pre- and post-exercise.

RESULTS: Whole-body sweat rate (WBSR; 11%; $p=0.03$) and back LSR (11%; $p<0.001$) was higher in the ATURA condition compared to placebo. Core body temperature was lower in the ATURA condition (ATURA; $38.8 \pm 0.5^{\circ}\text{C}$, placebo; $38.7 \pm 0.5^{\circ}\text{C}$; $p=0.04$). There was no effect on mean skin temperature ($p=0.61$), ratings of perceived exertion ($p=0.91$) or thermal comfort ($p=0.12$); however, thermal sensation was greater in the ATURA condition ($p=0.05$). Gastrointestinal symptoms were 34% lower in the ATURA condition, but not significantly different ($p=0.257$). There were no differences in time to complete the graded exercise test and peak oxygen consumption ($p>0.05$). The pre- to post-heat shock protein 70 difference was higher in the ATURA group (12%, $p=0.05$), and no difference for pre- to post-interleukin-6 (ATURA; 29%, placebo; 51%; $p>0.05$).

CONCLUSION: Fava bean protein supplementation increased WBSR and LSR, as well as core body temperature during exercise, suggesting enhanced thermoregulation. Importantly, the supplement did not exacerbate gastrointestinal symptoms, indicating tolerance of fava bean protein during exercise. Whilst no improvements in exercise performance were observed, further investigation into the mechanisms underpinning the enhancements in thermoregulation, gastrointestinal function, and exercise adaptation is warranted.

COLLAGEN PEPTIDE SUPPLEMENTATION REDUCES POST-EXERCISE ENERGY INTAKE IN FEMALES

CLIFFORD, T., REYNOLDS, K.M., HANSELL, E.J., THORLEY, J., FUNNELL, M.P., THACKRAY, A.E., STENSEL, D.S., BAILEY, S.J., JAMES, L.J., PRAWITT, J., VIRGILIO, N.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Dietary protein ingestion via a single bolus or over several days has been shown to decrease energy intake through increased subjective fullness and/or increased concentrations of satiety hormones. To date, research has focused on the effects of complete proteins (e.g., whey and casein) and not those with different amino acid profiles. Collagen peptides (CP) are rich in glycine, proline and hydroxyproline, and are increasingly consumed by physically active populations for health, recovery, and performance benefits. However, the impact of CP on post-exercise appetite regulation is unknown. Thus, the primary aim of this study was to examine whether consuming CP influences subjective appetite, plasma hormone responses and ad libitum energy intake after a bout of exercise in healthy active females.

METHODS: In a randomised crossover design, 15 physically active females (23 ± 3 y; 60.5 ± 10.1 kg; 41 ± 8 ml/kg/min $\dot{V}O_{2\max}$) completed two experimental trials following 6 days of supplementation (15 g/day of CP or a flavour-matched placebo (water; CON)), with a ≥ 7 -day washout between trials. On day 7, participants cycled for 45 min at $\sim 55\%$ $\dot{V}O_{2\max}$, before consuming their final dose of the supplement. 60 min post intake an ad libitum meal was provided, and energy intake recorded. Subjective appetite and satiety were measured daily for 6 days (pre- and 30 min post-supplement), and pre (0 min) to 280 min post-exercise on day 7. Blood glucose and plasma hormone concentrations (total ghrelin, leptin, insulin, total glucagon-like peptide 1 (GLP-1), total peptide YY (PYY), cholecystokinin (CCK), dipeptidyl peptidase-4 (sDPP-4) were measured fasted at baseline (day 0), then pre-breakfast (0 min), post-exercise (100 min), post-supplement (115, 130, 145, 160 min) and post-meal (220, 280 min) on day 7.

RESULTS: Ad libitum energy intake was $\sim 10\%$ lower in the CP trial (CP 356 ± 125 kcal; CON 397 ± 120 kcal; $P=0.037$). There were no differences in heart rate (CP 153 ± 18 bpm; CON 152 ± 18 bpm) during exercise ($P \geq 0.682$) and no differences in gastrointestinal symptoms or subjective appetite and satiety throughout the trial ($P \geq 0.412$). Post-exercise intake of CP increased GLP-1 (area under the curve 0-280 min; CON: 6369 ± 2330 ; CP: 9064 ± 3021 pmol/L; $P < 0.001$) and plasma insulin concentrations (130-160 min; $P < 0.001$). Plasma ghrelin was $\sim 6\%$ lower and leptin $\sim 7\%$ lower in the CP trial on day 7 (condition effect; $P \leq 0.032$). PYY, CCK, sDPP-4 and glucose were not different between conditions ($P \geq 0.100$). There were no between condition differences in subjective appetite or hormones in the 6 days prior to the exercise trials ($P > 0.05$).

CONCLUSION: A 15 g bolus of CP consumed post-exercise increased circulating insulin and GLP-1 concentrations and reduced ad libitum energy intake in physically active females after exercise. These findings suggest that if consuming CP after exercise for health or recovery benefits, there may be a compensatory decrease in energy intake at the next meal.

POLYPHENOL SUPPLEMENTATION ATTENUATES ACUTE EXERCISE INDUCED INCREASE IN GLUTAMINE AND ACYL-CARNITINE AFTER RESISTANCE TRAINING: PRELIMINARY RESULTS

REIHMANE, D., FLENSTED-JENSEN, M., DELA, F., BERZINA, A., LEJNIECE, K., KLAVINS, K.

RIGA STRADIŅŠ UNIVERSITY

INTRODUCTION: While resistance-based training (RBT) is recognized for its role in mitigating the decline in physical function, its impact on inflammation, oxidative stress, and mitochondrial function in older adults remains less well understood. The aim of this ongoing study is to investigate the effects of RBT and polyphenol supplementation on systemic blood metabolites in individuals at the onset of aging.

METHODS: Forty subjects (20 males, 20 females) between 55 and 70 years of age (mean: 61.3 ± 4.3 years) were randomly assigned to either a polyphenol supplementation (PS) or placebo (PLA) group. All participants underwent a 12-week RBT protocol. Before and after RBT, subjects performed a 45-minute cycling test at $70\% \dot{V}O_{2\max}$. Blood plasma samples were collected at baseline and during the final minute of the acute exercise session.

Metabolite analysis was performed on plasma samples. Metabolite extraction followed a methanol-based protocol, and quantification was carried out using a liquid chromatography-mass spectrometry (LC-MS) workflow. Separation was achieved via hydrophilic interaction liquid chromatography (HILIC), and detection was performed using a high-resolution Orbitrap Exploris 120 mass spectrometer. Over 70 metabolites were quantified using external standard calibration curves and isotopically labeled internal standards. Preliminary data from 12 subjects (six from each group) are presented.

RESULTS: Plasma concentrations of several metabolites changed in response to the acute cycling test. Notably, a significant increase in glutamine and acetylcarnitine concentrations was observed ($p < 0.05$). After 12 weeks of RBT, the increase in glutamine during the acute cycling test was less pronounced in the PLA group, whereas in the PS group, glutamine levels remained elevated. A similar trend was observed for acetylcarnitine, a marker of mitochondrial fatty acid oxidation. Specifically, after 12 weeks of RBT, the increase in acetylcarnitine during the acute cycling test was attenuated in the PLA group, while it remained more pronounced in the PS group.

CONCLUSION: Polyphenol supplementation during 12 weeks of resistance-based training attenuates the acute exercise-induced increase in metabolites, most notably glutamine and acetylcarnitine, in the blood. The possible mechanisms, along with data from all 40 subjects, will be explored in the coming months and presented in greater detail at the congress.

MUSCLE MATTERS: A CASE STUDY ON RESISTANCE EXERCISE AND PROTEIN INTAKE TO PROTECT LEAN MASS DURING WEIGHT LOSS

BELFIELD, A., KORZEPA, M., ROGERS, L., WADDELL, A., QUINLAN, J., BREEN, L.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Energy restriction-induced weight loss can accelerate lean mass decline in older adults with obesity, contributing approximately 25-35% to total weight lost. This reduction in lean mass during weight loss in older adults has implications for muscle strength and physical performance deterioration and poorer metabolic health. Combined resistance exercise training and a higher protein intake may attenuate energy restriction-induced lean mass loss, but data in older adults with obesity are limited.

METHODS: In this case study analysis of an ongoing larger randomised, parallel groups clinical trial, an older female (aged 68 y) with obesity underwent four weeks of energy restriction-induced weight loss ($\sim 30\%$ estimated energy requirement) with partial (50%) controlled food provision. Our participant completed supervised exercise (3 x/week), including whole-body resistance exercise and high intensity aerobic training on a stationary bike. Protein intake was 1.5 g/kg/day,

including twice daily whey protein supplementation (2 x 0.3 g/kg/day). Body composition (via dual-energy X-ray absorptiometry), resting energy expenditure (via indirect calorimetry), strength, and physical performance were assessed before and after weight loss.

RESULTS: Body mass index (BMI) at baseline was 30 kg/m². After the four-week intervention, body weight and BMI decreased by 3.1 kg and 1.2 kg/m², respectively. Fat mass decreased by 2.0 kg and lean mass decreased by 0.3 kg, contributing 11.0% to total weight lost. Resting energy expenditure modestly decreased from 1786 to 1717 kcal/d. Chest press 1-repetition maximum (1RM) and knee extension 1RM increased by 10.4% and 30.0% from baseline (24 vs. 27 kg and 37 vs. 49 kg), respectively. Chair stand test performance improved by 25.7% (10.1 vs. 7.5 sec) while handgrip strength increased by 16.7% (24 vs. 28 kg) from baseline.

CONCLUSION: This case study highlights multi-modal resistance exercise training and a higher dietary protein intake as a strategy with the potential to optimise 'healthy' weight loss in older adults with obesity during short-term energy restriction.

INDICES OF HYDRATION STATUS AND PHYSICAL FUNCTION CAPACITY VARY BY ETHNICITY AMONG A CROSS-SECTIONAL COHORT OF AMERICAN WOMEN

EVAN, B., MOULTON, C.

UNILEVER

INTRODUCTION: There are well-understood ethnic differences among Americans in hemodynamics and metabolic health, while NHANES fluid intake data suggests certain ethnic groups are at greater risk for hypohydration. Recent evidence suggests that young African American (AA) adults may be more likely than young Caucasian adults to be hypohydrated, with reduced urine output, increased urine specific gravity, and elevated copeptin (1). It is generally accepted that dehydration is associated with diminished exercise performance, but less is known about the potential impact of hypohydration on non-exercise physical exertion. Therefore, we evaluated physical function capacity, hydration status and Quality of Life indicators in a multi-ethnic cohort of American women.

METHODS: Healthy women (n=114) aged 19-70 yrs were enrolled from the San Francisco metropolitan area without preference for ethnicity. Health was defined as absence of chronic disease and no recent use of associated medications (e.g., insulin, diuretics, corticosteroids). Vitals were measured, and participants completed the PROMIS-29 QoL questionnaire. Fasted blood was collected and glucose, ADH, and copeptin were analyzed. Twenty-four-hour urine volume was collected, and urine was analyzed for osmolality, specific gravity, and creatinine. A two-way ANOVA was used to detect differences in means between ethnicities. All data are expressed as mean ± SEM.

RESULTS: The cohort was comprised of Asian (n=51), African American (n = 24), Caucasian (n=21), and Hispanic (n=18) ethnicities. AA women had the highest BMI (33.25; p<0.0001) and highest systolic BP (124.54±3.18 mm Hg), while there were no differences in glucose or urine volume. There were group effects for ethnicity on PROMIS Physical Function (p=0.007), urine specific gravity (p=0.007), urine creatinine (p<0.0001), and ADH (p<0.001). AA women had the lowest aggregate score on the physical function domain (13.58±1.63), indicating more difficulty with activities of daily living. AA women had higher urine specific gravity (1.02±0.01) and markedly elevated urine creatinine (161.11±19.77 mg/dL). AA women had elevated ADH (27.31±2.53 pg/mL), and while not statistically significant, the highest mean level of copeptin.

CONCLUSION: In this cross-sectional sample, AA women reported the lowest physical function capacity, while displaying multiple indicators of hypohydration and possible renal insufficiency. These findings could be in part related to differences in body composition. Hydration interventions targeted to specific ethnicities may have potential to improve free-living hydration status, kidney function, and capacity for physical activity.

DRINKING BEHAVIOR AND HYDRATION EFFECTS OF WATER, CARBONATED WATER, AND SPORTS DRINK CONSUMPTION FOLLOWING EXERCISE IN THE HEAT

FUJII, N., TAKAHAGI, M., HASHIMOTO, H.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Several studies have examined the effects of hydration, identifying optimal solutions for maintaining hydration status. However, these studies controlled the amount and timing of fluid intake, thereby excluding the behavioral component. In real-world situations, drinking behavior plays a crucial role in determining fluid intake patterns, ultimately influencing hydration efficacy—yet this aspect remains insufficiently explored. In this context, our previous research demonstrated that carbonated water ingestion can alter perceptions such as exhilaration, sleepiness, and/or stimulating feeling both at rest (Fujii et al., 2022) and following exercise (Kajiki et al., 2024) in the heat. These perceptual changes may influence drinking behavior and, consequently, hydration effectiveness. However, this relationship has not been directly investigated.

METHODS: Eight healthy young adults performed repeated 10-min cycling bouts at 50% peak oxygen uptake in a hot environment (35°C), interspersed with 3-min passive recovery periods, until a 2% reduction in body mass was achieved. Twenty min after the exercise, participants were transferred to another room maintained at 25°C. They then freely consumed one of three beverages: (1) water, (2) carbonated water, or (3) a sports drink, over a 30-min period. Each beverage trial was conducted on separate days and the order was randomized and counterbalanced. Venous blood samples were collected pre-exercise, immediately post-exercise (0 min), and at 30 and 60 min after the commencement of drinking. Urine samples were obtained pre-exercise, immediately post-exercise, and at 30 min, 1 h, 2 h, 3 h, and 4 h following the onset of drinking.

RESULTS: During the initial 5 min of the 30-min ad libitum drinking period, the volume of beverage consumed was lower for carbonated water compared to the other two beverages. Similarly, the total volume ingested over the entire 30-min period tended to be lower for carbonated water than for water or the sports drink. Despite the differences in fluid intake, no significant differences were observed in urine output, plasma volume, plasma osmolality, or vasopressin levels among the three beverage conditions at any time point.

CONCLUSION: In healthy young individuals, carbonation of beverage reduces initial beverage consumption, likely due to sensory effects associated with carbonation (e.g., oral stimulation). However, despite this attenuation in early fluid intake, hydration efficiency appears comparable to that of water and sports drinks. Carbonated water may serve as a potential strategy to mitigate overhydration, particularly in individuals with lower sweat rates, though this hypothesis requires further investigation.

IMPACT OF CAFFEINE AND ELECTROLYTE LEVEL ON MEASURES OF HYDRATION OVER A 4HR PERIOD IN HEALTHY MEN AND WOMEN

LELKO, M.

LIQUID I.V.

INTRODUCTION: The Beverage Hydration Index (BHI) allows comparison of fluid retention profiles for different beverages relative to water. The impact of caffeine with and without electrolytes on hydration status over 4 hours is not well characterized. The effects of commercially available caffeinated beverages were compared to water (W) on hydration measures to understand the impact of various formulations on hydration status over 4 hours in a sedentary & euhydrated state. This study aimed to provide more clarity on the impact of different caffeinated products and their ability to promote fluid retention or diuresis.

METHODS: 28 healthy adults (14M/14F; age 22.6±3 y) participated in a BHI protocol. Participants arrived to the lab in a euhydrated state which was confirmed by urine specific gravity. Beverages were then administered in a randomized order of four 250mL aliquots over 30min: 500ml of caffeinated beverage (CAF) with 280mg, CAF of 280mg plus electrolytes (CAF+E) or CAF with 100mg+E & carbohydrates (CAF+CE) along with 500ml W (1st & 4th aliquot). Urine output was recorded over 4hr.

RESULTS: W & CAF+CE averaged a more positive net fluid balance (NFB) ($p < 0.001$, 0.001) compared to CAF & CAF+E, ranging from 120 to 175ml greater overall fluid balance. From 60–240min, CAF+CE exhibited significantly higher NFB when compared to CAF & CAF+E ($P < 0.05$). From 120–240min, CAF+CE had significantly higher BHI scores when compared to CAF & CAF+E ($P < 0.05$). CAF+CE had significantly lower urine output when compared to CAF & CAF+E from 90–240min ($P < 0.05$).

CONCLUSION: A low carbohydrate-electrolyte beverage with moderate levels of caffeine (CAF+CE) had similar hydration properties compared to water and both were significantly greater than CAF and CAF+E. Based on BHI, CAF+CE retained ~10 and 15% more fluid when compared to CAF+E and CAF, respectively, which has practical implications for caffeine containing products. This data suggests that a low -carbohydrate- electrolyte beverage with added caffeine may attenuate diuresis in a hydrating energy drink solution.

POST-EXERCISE REHYDRATION: A COMPARISON OF A NATURAL FRUIT-BASED BEVERAGE, A GLUCOSE-BASED SPORTS DRINK, AND WATER

JUETT, L., VAN DER WOLF-ONG, J., PUGH, C., CODD, E., FUNNELL, M., HOUGH, J., VARLEY, I., CLAYTON, D.

NOTTINGHAM TRENT UNIVERSITY

INTRODUCTION: Exercise-induced hypohydration may negatively affect aerobic performance, cognitive performance, and mood. Effective rehydration after exercise is paramount, with previous research demonstrating beverage retention can be improved by including carbohydrate and electrolytes. Fruit-based hydration beverages could provide comparable concentrations of carbohydrate and electrolytes to sports drinks, whilst also providing beneficial antioxidants and phytochemicals. The present study compared the effectiveness of a fruit-based hydration beverage (FRU), versus a glucose-based sports drink (SPO), versus water (WAT) at rehydration, following exercise-induced hypohydration.

METHODS: After familiarisation, six active males (age: 21 ± 1 y; W_{peak} : 209 ± 53 W) completed three experimental trials in a randomised cross-over design. Participants cycled in the heat (~35°C) at ~50% W_{peak} to induce ~2% body mass loss (dehydration phase), and then rehydrated with a water volume equivalent to 150% of body mass losses from either FRU (per 100 mL: 5.9 g carbohydrate, 1 g protein, 0.04 g salt, 135 mg potassium), SPO (per 100 mL: 6.3 g carbohydrate, 0.12 g salt, negligible protein and potassium), or WAT. Drinks were consumed in four equal aliquots, evenly distributed over a 1 h period, and participants then rested in a laboratory (~20°C) for another 4 h (5 h rehydration phase). Blood glucose con-

centrations were measured from fingertip blood samples (0, 0.25, 0.5, 0.75, 1, 1.5 and 2 hours after rehydration) and all urine produced was collected. Parametric data are reported as (mean $\pm$ SD), whereas non-parametric data are reported as (median [interquartile range]).

RESULTS: There was no effect of trial on body mass losses at the end of the dehydration phase (FRU: $-1.99 \pm 0.22\%$, SPO: $-1.96 \pm 0.19\%$, WAT: $-1.95 \pm 0.18\%$; $P = 0.560$) or the water volume provided by each drink (FRU: 2173 ± 506 g, SPO: 2118 ± 458 g, WAT: 2115 ± 381 g; $P = 0.563$). There was no effect of trial on total urine volume produced during the rehydration phase (FRU: $1025 [929-1586]$ g, SPO: $1039 [962-1561]$ g, WAT: $1427 [1118-1783]$ g; $P = 0.115$). Whilst, there was an effect of trial ($P = 0.030$) on water retained from the drinks at the end of the rehydration phase, post-hoc tests revealed no significant differences between trials (FRU: $46 [33-58]\%$, SPO: $39 [33-48]\%$, WAT: $26 [23-41]\%$; $P = 0.129$). There was an effect of trial ($P < 0.001$) on blood glucose area under the curve following consumption of the drinks (FRU: 9.94 ± 0.52 mmol/L/2h, SPO: 12.60 ± 1.79 mmol/L/2h, WAT: 8.08 ± 0.31 mmol/L/2h), with FRU and SPO both greater than WAT ($P < 0.01$) and SPO greater than FRU ($P = 0.033$).

CONCLUSION: The results from this preliminary analysis of an ongoing study currently suggest that a fruit-based hydration beverage, a glucose-based sports drink, and water are equally effective for post-exercise rehydration but produce differential blood glucose responses, with a fruit-based beverage producing lower blood glucose concentrations than a sports drink.

TRAINING SWEAT LOSSES, FLUID INTAKE, BODY MASS CHANGES, AND WAKING HYDRATION STATUS IN MIXED MARTIAL ARTS ATHLETES ACROSS A SIX-DAY TRAINING WEEK

REALE, R., WANG, J., RITCHIE, D., FRENCH, D., HU-STULL, C., AMASINGER, D., WANG, R.

UFC PERFORMANCE INSTITUTE

INTRODUCTION: Large data sets exist for typical sweat rates, fluid intakes, and daily hydration status of athletes across a wide variety of sports. Despite this, few data in combat sports, and none in mixed martial arts (MMA) are available. With the importance of hydration status in both performance and health contexts, combined with the intentional dehydration practices combat athletes use to facilitate acute weight loss to 'make weight', detailed investigations are warranted.

METHODS: Thirteen professional male MMA athletes took part in a study across a normal training week (Monday to Saturday, including different technical and non-technical sessions), which assessed waking hydration status (measured via urine specific gravity (USG)) alongside training sweat losses, fluid intake, and net body mass (BM) changes. Additionally, we compared training sweat losses to a typical hot water immersion (HWI) protocol (20 min at 41 C, followed by 20 min wrapped in towels) used to induce sweat losses, to understand differences in active vs passive dehydration modalities (both commonly used to make weight). Comparison of daily USG, fluid balance variables between training sessions, and HWI vs sweat losses, were analyzed using one-way repeated measures ANOVAs.

RESULTS: Average hourly sweat losses, fluid intake, and BM changes were 1.30 ± 0.38 BM%, 898 ± 244 mL, and $+0.12 \pm 0.28$ BM%, respectively. Significant differences with large effect sizes ($d > 0.8$) in sweat rate and fluid intake between some sessions were found ($p < 0.0125$), however no differences in BM changes were found between sessions. Average USG was 1.025 ± 0.004 , with a significant linear trend found for USG to increase across the week ($p = 0.025$). Differences between active and passive sweating were significant ($p < 0.00001$). When comparing HWI to athlete's minimum, mean, and maximum sweat rates, HWI resulted in 4.09 ± 1.52 x, 2.26 ± 0.39 x, and 1.61 ± 0.26 x the BM losses, respectively.

CONCLUSION: MMA training results in sweat losses similar to average values reported in other sports. Training session type seems to affect sweat rates, however, athletes increase fluid intake in response, resulting in similar BM changes across all session types. When athletes have adequate fluid access, they are at little risk of meaningful dehydration during training. Fluid intake may be suboptimal outside of training times based on waking USG, and this may compound across a training week. However, it is not understood if confounding dietary or physical activity factors impact USG readings (e.g. proteinuria, haematuria, elevated creatinine). Finally, passive dehydration methods appear a more effective method of acute weight loss, based on the greater hourly sweat rate, and the absence of muscular fatigue induced. The caveat is that significant passive dehydration should only be implemented when athletes are provided the time to adequately recover post weigh-in, and athletes, coaches, and support staff are mindful of the heat stress associated with such techniques.

THE ATHLETE-IQ: EVALUATING IRON KNOWLEDGE OF FEMALE ATHLETES AND STAFF; WITH INSIGHTS INTO PRACTICES AMONG DIETITIANS AND IRON EXPERTS.

PENGELLY, M., PUMPA, K., PYNE, D.B., ETXEBARRIA, N.

UNIVERSITY OF CANBERRA

INTRODUCTION: Iron deficiency (ID) is common in female athletes, with variable diagnostic criteria and supplementation protocols. Understanding iron rich food sources is fundamental to optimal nutritional intake. Our aim was to characterize the iron knowledge of female athletes and affiliated staff, and explore factors influencing ID practices among dietitians and iron experts.

METHODS: A cross-sectional design was employed using a web-based iron questionnaire. Part One consisted of 16 items (11 iron questions) and was completed by athletes and staff. Part Two consisted of 22 items (14 on ID practice) and was completed by dietitians and iron experts.

RESULTS: Sixty-two participants (athletes $n=42$; staff $n=20$) across 10 sports completed Part One. Iron knowledge scores ranged from 21% to 88% among athletes ($46\% \pm 13\%$) and staff ($60\% \pm 16\%$). Twenty-eight practitioners (sports dietitians: $n=14$; other professions: $n=14$) across 28 sports completed Part Two. Between 10% and 56% of practitioners applied established criteria for diagnosing ID. Supplementation protocols varied between 20 to 100 mg/d or bi-daily of elemental iron for earlier stages of ID increasing to 60 to 200 mg/d or bi-daily for anaemic athletes.

CONCLUSION: Iron knowledge is highly variable in female athletes and club staff. Teams and organisations should promote valid nutritional resources when access to a sports dietitian is not feasible. Practitioners may adopt heightened criteria to categorise ID but should adjust individual thresholds based on factors underpinning fluctuations in iron status.

INTERSEASONAL HYDRATION AND BODY COMPOSITION DYNAMICS IN YOUTH TEAM HANDBALL: INSIGHTS FROM BIOELECTRICAL IMPEDANCE ANALYSIS

SERAFINI, S., PAPALE, O., DI CREDICO, A., MASCHERINI, G., PRESTANTI, I., MONTENEGRO, S., FUSCO, A., IZZICUPO, P.
GABRIELE DANNUNZIO UNIVERSITY OF CHIETI AND PESCARA

INTRODUCTION: Team Handball is a high-intensity sport that places significant demands on both the cardiovascular and neuromuscular systems. Monitoring body composition and hydration is crucial for optimizing training and player selection among young athletes. Given the rapid physical development in this population, analyzing bioelectrical impedance variations over time can provide valuable insights into training adaptations and recovery. This study aimed to evaluate longitudinal changes in hydration status and body composition in elite under 17 (U17) male handball players using Bioelectrical Impedance Analysis (BIA).

METHODS: The body composition of 15 athletes (age: 16.44 ± 0.60 years) from the Italian U17 national handball team was assessed at four time points: the end of the competitive season (T0), the pre-season (T1), the start of the new season (T2), and before the winter break (T3). BIA measurements included stature-adjusted resistance (R_z/H) and reactance (X_c/H), phase angle (PhA), total body water (TBW), and the extracellular-to-total body water ratio (ECW:TBW). Changes in fat mass percentage (FM%) and fat-free mass percentage (FFM%) were also analyzed. Statistical analyses involved repeated measures of mixed models, with significance set at $p < .05$.

RESULTS: R_z/H significantly decreased at T2 ($262.9 \text{ Ohm/m} \pm 26.1$) compared to T1 ($275.6 \text{ Ohm/m} \pm 27.8$) and at T3 ($249.7 \text{ Ohm/m} \pm 21.4$) compared to T0 ($269.7 \text{ Ohm/m} \pm 27.9$), T1, and T2; X_c/H significantly increased at T1 ($39.0 \text{ Ohm/m} \pm 3.7$) compared to T0 ($35.3 \text{ Ohm/m} \pm 3.6$), then decreased at T2 ($36.2 \text{ Ohm/m} \pm 3.2$) and T3 ($35.7 \text{ Ohm/m} \pm 3.4$) compared to T1; TBW increased progressively from T0 to T4 ($59.9\% \pm 3.6$ to $61.1\% \pm 3.7$, $p < .001$), while ECW:TBW decreased ($41.1\% \pm 3.6$ to $37.5\% \pm 1.9$, $p < .001$); PhA, a marker of cellular health and membrane integrity, rose from $7.4^\circ \pm 0.5$ to $8.1^\circ \pm 0.5$ at T1, thus decreased to $7.8^\circ \pm 0.7$ at T2 and finally increased to $8.1^\circ \pm 0.6$ at T3 ($p < .001$); FM% showed a significant reduction from T0 to T3 ($18 \pm 4.5\%$ to $16 \pm 5.1\%$, $p = .006$) while FFM% exhibited the opposite trend, increasing significantly from $82 \pm 4.5\%$ at T0 to $84 \pm 5.1\%$ at T3 ($p = .006$).

CONCLUSION: Temporary dehydration patterns were observed during T1, likely due to environmental and training stressors, but these were mitigated as the competitive season progressed. Reductions in FM% and extracellular water, coupled with increases in PhA, FFM% and intracellular water, further supported improved hydration status and body composition. Changes in bioelectrical parameters reflect training stress, adaptations and recovery processes. BIA is a practical method for monitoring variations in body composition and hydration status in U17 handball players.

THE RELATIONSHIP BETWEEN VEGETABLE INTAKE AND COOKING SKILLS IN FEMALE PHYSICAL EDUCATION COLLEGE STUDENTS

INOKUCHI, K., KOIZUMI, K.

JAPAN WOMEN'S COLLEGE OF PHYSICAL EDUCATION GRADUATE SCHOOL

INTRODUCTION: The National Health and Nutrition Survey (2019) revealed that young women do not consume enough vegetables. Sasamaki et al. (2023) suggested that individuals with advanced cooking skills consume vegetables. This study aimed to clarify the relationship between vegetable intake and cooking skills in female university students majoring in physical education.

METHODS: Vegetable intake was measured in 435 participants using a vegetable check kit (Kagome Co. Ltd.) and a survey was conducted using Google Forms. The survey items included a food diversity score consisting of 10 foods (Kumagai et al. 2003) and vegetable preferences. Differences were observed in the frequency, technique, preference, and possession of cooking utensils were used for cooking. Cooking skills were according to Kasahara et al. (2023), with five points for each item and a 10-point scale for cooking skill scores. The group was divided into groups with high ($n = 210$) and low ($n = 225$) levels. High levels were classified as having an average vegetable intake level of 5.3 ± 0.9 . To clarify the differences in vegetable intake levels, differences in food diversity and cooking technique scores were examined using a t-test. Differences in other items were cross-tabulated and examined using the chi-square test. The probability was $< 5\%$.

RESULTS: Green and yellow vegetable scores (0.43 ± 0.50) in the high-level group were significantly higher than that in the low-level group ($p=0.041$); however, the food diversity score was $2.2\text{--}2.4$ out of 10 ($p=0.159$) with no significant difference between the two groups. Vegetable preference differed significantly between the two groups, with 90% liking vegetables in the high-level group ($p<0.001$). Tomatoes, bell peppers, spinach, okra, paprika, asparagus, komatsuna, rapeseed flowers, lettuce, cabbage, and eggplant were significantly more disliked in the low-level group than in the high-level group. Half of participants in both groups liked cooking ($p=0.307$). In addition, cooking frequency did not differ significantly

between the two groups, and approximately 20% of the respondents cooked at least once a day ($p=0.267$). In contrast, measuring spoons, cutting boards, bowls, and induction stoves as cooking utensils were significantly more common in the high-level group than the low-level group. Cooking skill scores were significantly higher in the high-level group for "being able to make vegetable salads" ($p<0.001$), "being able to make spinach ohitashi" ($p=0.033$), and "overall score" ($p=0.019$).

CONCLUSION: Individuals with a low vegetable intake tended to dislike green and yellow vegetables. Providing cooking experiences with disliked green and yellow vegetables is necessary to increase the vegetable intake of female physical education university students along with developing cooking techniques to easily eat these vegetables.

IS THE COMBINATION OF SODIUM BICARBONATE AND GLYCEROL BETTER THAN SODIUM BICARBONATE FOR HYPERHYDRATION?

FREIRE, R., SIEGLER, J.

ARIZONA STATE UNIVERSITY

INTRODUCTION: It is well established in the literature that dehydration can impair exercise performance. Hyperhydration is a strategy commonly used in sports before competing in the heat in order to increase the amount of fluids in the body before exercise, thereby delaying the onset of dehydration evoked by exercise. Glycerol (GLY) and sodium bicarbonate (BIC) have been investigated in isolation as hyperhydration agents to increase fluid retention and plasma volume expansion. However, no study has investigated the combined effect of both agents. Thus, this study aimed to compare the combined (GLY+BIC) and single (BIC) effects to a control (CON) condition on hyperhydration parameters.

METHODS: Ten healthy adults (3 females) were recruited for this randomized, single-blind study. The experimental trials consisted of three different conditions: Control (CON), sodium bicarbonate alone (BIC), and sodium bicarbonate and glycerol combined (BIC+GLY). Upon arrival at the laboratory, the subjects provided a urine sample (repeated every 20 min), a blood sample (repeated every 60 min), body mass (repeated every 20 min), and a gastrointestinal (GI) questionnaire (repeated every 20 min). For the intervention trials, the total dose of BIC (0.3g/kg) and, BIC+GLY (1.2g/kg), and 25mL/kg of body mass of water were administered in four equal aliquots every 20 minutes from baseline. The same procedures were followed in the CON condition using artificially sweetened water. A two-way repeated measures ANOVA with effect size calculations was used to identify differences between conditions across time. The Bonferroni post hoc test was used when a significant main effect was found. A two-tailed statistical significance was set at $p<0.05$.

RESULTS: No differences were observed across conditions for urine production ($F = 0.54$, $p = 0.59$, $\eta^2 = 0.04$) and body mass ($F = 0.10$, $p = 0.88$, $\eta^2 = 0.01$). Despite not being significant, the mean difference between conditions was substantial at 180 min (SB vs CON: 446 mL and SB+GLY vs CON: 409 mL). There was an interaction effect for urine specific gravity (USG) ($F = 5.1$, $p < 0.001$, $\eta^2 = 0.34$), in which BIC+GLY presented higher values than CON after 80 min. Plasma volume was greater in SB+GLY only at 60 min (Condition: $F = 8.54$, $p = 0.002$, $\eta^2 = 0.47$) ($5.5 \pm 8.6\%$) than in CON ($-4.0 \pm 4.7\%$) and SB ($-3.2 \pm 4.4\%$). Not surprisingly, SB ($F = 22.0$, $p < 0.001$, $\eta^2 = 0.67$) and SB+GLY ($F = 26.9$, $p < 0.001$, $\eta^2 = 0.71$) conditions reduced acidosis (pH) and improved buffering capacity (HCO_3) during the protocol compared to CON. Mild GI discomfort was perceived during the protocol, with no effect of either condition or time (Interaction: $F = 0.81$, $p = 0.56$, $\eta^2 = 0.10$).

CONCLUSION: Although SB or SB+GLY did not improve fluid retention, plasma volume was improved acutely in the SB+GLY condition, most likely induced by the glycerol. SB and SB+GLY induced significant alkalosis and improved buffering capacity compared to CON.

AN EXPLORATORY STUDY OF SKIN CAROTENOID STATUS AS A MARKER OF FRUIT AND VEGETABLE INTAKE IN ELITE FEMALE MATCH OFFICIALS

BROWN, L., TARNOWSKI, C., RANDELL, R., PIMLOTT, E., HELSEN, W., QAQAYA, N., ROLLO, I.

PEPSICO

INTRODUCTION: Fruit and vegetable consumption is recommended to contribute to the macro- and micronutrients required for a well-balanced diet, which serves as the foundation for effective sports nutrition strategies. Traditional methods to quantify fruit and vegetable consumption in athletes, such as dietary analysis, are time intensive and prone to error. Analysis of blood plasma carotenoid concentration is the gold-standard biomarker of fruit and vegetable consumption, however, this method is invasive. The Veggie Meter® is an optical device that provides rapid, non-invasive measurements of skin carotenoid status^{1,2}. This study aimed to evaluate skin carotenoid status in elite female match officials using the Veggie Meter®.

METHODS: Skin carotenoid concentration was measured in three groups of elite female match officials: Football Referees (FOOT-R; $n=27$), Football Assistant Referees (FOOT-AR; $n=34$) and Futsal Referees (FUT-R; $n=18$). Match officials placed the index finger of their non-dominant hand onto the Veggie Meter® lens under a spring-loaded cover. The finger remained under topical pressure for ~10 seconds before removing and re-inserting twice to obtain an arbitrary score using reflective spectroscopy. Veggie Meter® scores were categorised based on fruit and vegetable intake as previously described³, anchored at 0-239 (severe shortage); 240-310 (shortage); 311-395 (average intake); 396-506 (good intake); >507 (excellent intake). Data were analysed using independent samples t-tests and reported as mean $\pm$ SD, with statistical significance set at $p < 0.05$.

RESULTS: Average Veggie Meter® score was 414 ± 92 , with 1% of match officials categorized as having a 'severe shortage' of fruit and vegetable intake, 6% were categorized as 'shortage', 38% 'average', 37% 'good' and 18% 'excellent'. No differences were observed between FOOT-R, FOOT-AR and FUT-R (427 ± 92 , 405 ± 78 and 410 ± 109 , respectively, $p > 0.05$). Overall, 4% of FOOT-R were categorized as 'severe shortage', 7% 'shortage', 26% 'average', 44% 'good' and 19% 'excellent'. Results for FOOT-AR were 0%, 9%, 38%, 32% and 21%, and FUT-R were 0%, 0%, 56%, 33% and 11%, respectively.

CONCLUSION: This is the first time that skin carotenoid concentration has been assessed using the Veggie Meter® to assess fruit and vegetable intake in elite female match officials. Whilst ~50% of match officials had 'good'/'excellent' intakes, ~50% were below the recommended classification ('good'). In addition, a greater percentage of FOOT-R were classified as 'good'/'excellent' in comparison to FOOT-AR/FUT-R. Future research is required to understand health and performance implications of low skin carotenoid scores in match officials and wider athletic populations.

CP-PN23 Thermoregulation Tools and Mechanisms

EXPLORING A NOVEL PASSIVE HEAT ACCLIMATION METHOD USING CO₂ WATER BATHS.

IWATA, R., NAKAMURA, M., TAMAI, S., KODESHO, T., TAKAHASHI, S., SASADAI, J., SHIMIZU, R., SHOJI, R., FUKAMI, K., NAKAJIMA, K.

JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Heat acclimation training enhances thermoregulatory adaptation; however, it can be time-consuming and physically demanding for athletes. As an alternative, passive methods such as hot water immersion have gained increasing attention (1). In particular, CO₂ hot water bathing imposes greater thermal stress than tap hot water bathing (our unpublished data), leading us to hypothesize that it may be effective for heat acclimation. Therefore, this study explores the feasibility of CO₂ water bathing as a novel heat acclimation method.

METHODS: Participants were 10 male college athletes. The acclimation trial consisted of whole-body CO₂ hot water bathing (40°C, 1000 ppm) for 10 min and resting for 5 min $\times$ 3 sessions $\times$ 3 days. During the trial, rectal temperature (Tre), skin temperature (Tsk), subjective indicators (thermal sensation (TS), and thermal comfort (TC)), heart rate, whole-body sweat loss (WBSL) and sweating sodium concentrations (Na) were measured. To assess heat acclimation, a heat stress test was conducted before and after the acclimation trial, in which participants cycled at 50% VO₂max until their rectal temperature reached 38.5°C. Heat acclimation effects were evaluated based on the time required to reach 38.5°C.

RESULTS: Mean exercise duration increased slightly but not significantly (Pre 38.7 ± 6.1 min, Post 39.6 ± 7.7 min, $p = 0.70$). WBSL and Na also showed slight improvements, but the changes were not significant (WBSL, Pre 1369.5 ± 387 g, Post 1394.5 ± 483.5 g, $p = 0.80$; Na, Pre 1619.0 ± 538.6 mmol/L, Post 1379.4 ± 454.8 mmol/L, $p = 0.099$). There was also no interaction effect for Tre; however, Tsk was significantly lower in the Post condition during exercise ($p < 0.05$). TS and TC were also significantly lower in the Post condition ($p < 0.05$).

CONCLUSION: A short, three-day acclimation bath reduced Tsk, TS and TC during exercise. Since a decrease in Tsk is associated with a lower TS (2), this short acclimation with CO₂ baths may have contributed to a reduced subjective indicator during exercise in hot environment. These improvements in subjective indicators are important for athletes competing in sports (3).

HEAD, FACE AND NECK COOLING FOR PERFORMANCE: A SYSTEMATIC REVIEW AND META-ANALYSIS

STEVENS, C., BORG, D., BRADE, C., CARTER, S., FILINGERI, D., LEE, J., LIM, L., MUNDEL, T., TAYLOR, L., TYLER, C.

SOUTHERN CROSS UNIVERSITY

INTRODUCTION: Cooling the head, face and neck can have strong perceptual effects that contribute to improved performance. The aims of this systematic review were to; i) determine the effect of cooling strategies targeting the head, face and neck on physical and cognitive performance; ii) determine any associated physiological and perceptual responses; iii) synthesize any reported adverse events following the use of these strategies; and iv) provide practical applications for the use of these strategies to improve performance.

METHODS: We conducted a systematic review and multi-level meta-analysis, adhering to the PRISMA guidelines. Studies that investigated the effect of cooling strategies targeting the head, face, or neck on a physical or cognitive task using a controlled trial design were included.

RESULTS: Sixty-three studies were identified, involving 618 participants (86.6% male). Cooling strategies included water-perfused devices (18.7%); phase change neck collars (17.3%); fanning/cold air (14.7%); phase change headwear (13.3%); ice/gel packs (13.3%); cold towels (5.3%); menthol application (4.0%); water spraying/dousing (4.0%); or a combination of strategies (9.3%). The effect of cooling on both self-paced and fixed-intensity exercise tasks was inconclusive; the 95%CI of the pooled effect was compatible with no effect and medium beneficial effects, but not harmful effects. We were unable to pool cognitive data. Cooling reduced the skin temperature at the target site and improved thermal sensation and thermal comfort. Effects on heart rate, and core and mean skin temperatures were negligible. Adverse events were rare, and no intervention subgroup was superior.

CONCLUSION: The effect of cooling the head, face and neck on self-paced and fixed-intensity exercise tests was inconclusive, with both no and medium beneficial effects possible. We found no evidence of harmful performance effects. Cooling the head, face and neck reduced the skin temperature at the target site and improved thermal sensation and thermal comfort. There was no effect on heart rate, and effects on core temperature and mean skin temperature were so small they were considered physiologically negligible. Adverse events associated with the interventions were rare, and there was no report of any cooling strategy making a participant feel cooler and then pushing beyond their thermal limits, causing exertional heat illness. No intervention subgroup was superior, and hence, athletes are recommended to experiment with a range of rule-compatible and available head, face and neck cooling strategies, including different doses and timings, to determine the optimal strategy for their individual and sport context.

EFFECT OF MUSCLE TEMPERATURE-INDUCED CHANGES IN BLOOD FLOW AND STIFFNESS ON MAXIMAL STRENGTH

KITANO, A., MATSUURA, Y., SUZAKI, Y., KAGAMI, T., KUMAZAWA, S., YAMAZAKI, A., OKAMOTO, Y., FUJIMOTO, T.
NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: Athletes strive to achieve optimal performance in competitions, with warm-up or passive warming being commonly employed to enhance muscle function. Previous studies indicate that elevated muscle temperature can increase maximal muscle strength (1). This effect is hypothesized to result from increased blood flow to active muscles through vasodilation and enhanced contractility due to reduced muscle viscosity (2). Although this suggests that blood flow and muscle stiffness are related to maximal muscle strength, the direct relationship between muscle temperature-induced changes in blood supply, muscle stiffness, and performance enhancement remains unclear. Therefore, this study aimed to examine whether variations in maximal muscle strength following muscle temperature modulation through cold water immersion (CWI), hot water immersion (HWI), and neutral-warm water immersion (NWI) are attributable to changes in muscle blood flow and muscle elastic modulus.

METHODS: 12 healthy males participated in three conditions: CWI (10°C), HWI (40°C), and NWI (34°C). Lateral vastus muscle temperature, muscle shear wave velocity, and femoral artery blood flow were measured pre- and post-immersion. In addition, isokinetic maximal knee extension muscle strength was also measured post-immersion. Repeated-measures correlation analysis was conducted to assess intra-individual relationships between muscle temperature, blood flow, shear wave velocity, and maximal muscle strength in paired measurements collected multiple times across individuals.

RESULTS: The muscle temperature and femoral artery blood flow decreased in the CWI and NWI conditions, and increased in the HWI condition (all $P < 0.05$). The shear wave velocity showed no differences between conditions, as well as no main effects of time or interactions ($P > 0.05$). The maximal knee extension muscle strength was lower in the CWI condition than in the HWI and NWI conditions ($P < 0.05$). Additionally, repeated-measures correlation analysis revealed positive associations between muscle temperature and blood flow ($r = 0.66$, $P < 0.05$), muscle temperature and muscle strength ($r = 0.76$, $P < 0.05$), and blood flow and muscle strength ($r = 0.59$, $P < 0.05$), while there was no relation between muscle strength and shear wave velocity ($P > 0.05$).

CONCLUSION: These results suggest that the increase in maximal knee extension muscle strength induced by muscle warming may be attributed to enhanced blood supply to active muscles. In contrast, muscle stiffness remained unchanged with muscle warming and was not associated with maximal knee extension strength.

THE EFFECT OF A HIGHER AIR VELOCITY IN REDUCING THERMAL STRESS DURING EXERCISE IN HIGHER ABSOLUTE HUMIDITY CONDITION.

SHI, J., AHMAD YUSOF, H., CHE MUHAMED, A.M.
ADVANCED MEDICAL AND DENTAL INSTITUTE, UNIVERSITI SAINS MALAYSIA

INTRODUCTION: Given that previous research has demonstrated that higher air velocity can reduce thermal stress during exercise in hot, dry conditions, it raises the question of whether this observation would hold true in more humid environ-

ments, where the evaporative capacity of the environment (E_{max}) is reduced due to higher absolute humidity, potentially limiting the cooling benefits of increased. The purpose of this study was to examine the effect of a higher air velocity in mitigating thermoregulatory stress under varying vapor pressure conditions.

METHODS: Twelve trained heat-acclimated males cyclists performed a 60 min of fixed-intensity cycling at 65% $\dot{V}O_{2peak}$ across a high (HVP: 3.37 kPa) and moderate (2.69 kPa) vapor pressure conditions. The HVP environment was set at 31°C and 75% RH. While the MVP was made up of two different conditions of MVP1: 31°C and 60% RH, and MVP2: 25°C and 85% RH. In each of these three conditions, participants performed trials at two air velocity settings: high velocity (HV: 4.5 m·s⁻¹) and low velocity (LV: 2.8 m·s⁻¹). Thermoregulatory and perceptual responses were recorded during exercise.

RESULTS: T_{re} was significantly lower in the HV compared to LV trial within each environmental conditions (HVP: 38.6±0.2 vs 38.4±0.2; $P=0.004$; MVP1: 38.5±0.2 vs 38.3±0.3; $P=0.002$; MVP2: 38.5±0.2 vs 38.4±0.2; $P=0.007$). Comparison between HVP and MVP1 also demonstrated the ability to lower T_{re} in HV trials ($P=0.010$). T_{sk} was significantly lower in the HV as compared with the LV trial in the MVP1 (33.54±0.53 vs 33.95±0.56; $P=0.008$) and MVP2 (30.78±0.80 vs 31.69±0.39; $P=0.006$) conditions. However, there was no significant difference in T_{sk} between HV and LV within the HVP condition (34.10±0.42 vs 34.39±0.52; $P=0.061$). Forehead sweat rate was significantly lower at HV compared to LV in the MVP1 condition ($P=0.046$). However, in HVP conditions, no significant differences were observed in forehead sweat rates between HV and LV ($P=0.131$). HR was significantly lower in the HV trial compared to LV in both MVP1 and MVP2 conditions ($P=0.010$ and $P=0.021$, respectively). Contrary, HR was not significantly ($P=0.970$) different between HV and LV trials within the HVP conditions. Air velocity had no effect on perceptual responses of thermal sensation and thermal comfort during the fixed-intensity cycling (both $P \geq 0.057$).

CONCLUSION: This study highlighted that a higher air velocity was less effective in reducing thermoregulatory and circulatory strain in the higher vapor pressure. It was evident that higher air velocity significantly reduced thermal and cardiovascular strain in both MVP1 and MVP2 conditions. These observations are consistent with the earlier report by Saunders et al. (2005). This supports the notion that high humidity presents a formidable barrier to effective heat dissipation.

A DIGITAL TWIN AND DECISION SUPPORT TOOL FOR EXERTIONAL HEAT-RELATED ILLNESS

RAVANELLI, N., LAU, R., TAN, S., REMUS, A., ZHENG, Y., ANG, W.H., LAW, L., LEE, J.

NATIONAL UNIVERSITY OF SINGAPORE

INTRODUCTION: Exertional heat-related illnesses (HRI) such as heat stroke (EHS) continue to be a public health concern for recreational, athletic, and occupational sectors, with increasing incidence expected due to global warming. While the combination of high metabolic heat production and hot environments exacerbates the risk of HRI, potentially fatal EHS can still occur in cooler climates. Rapid recognition and management of individuals experiencing EHS is pivotal for improving patient outcomes. However, the multi-organ dysfunction and overlapping symptoms with other comorbidities makes early diagnosis of potentially fatal HRI challenging. The objective of this systematic review was to investigate the signs and symptoms associated with exertional HRI from published cases to inform the development of a decision support tool for HRI diagnosis and treatment.

METHODS: In accordance with the 2020 Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) and registering the review a priori (PROSPERO; CRD42024560456), a systematic search of relevant databases returned a total of 212 publications describing 463 cases of HRI occurring between 1932 and 2023 (EHS: $n=333$).

RESULTS: 70% of the reported EHS occurred during occupational tasks, with the majority during military training (50%). Wet bulb globe temperature ranged from 2.0 – 36.0°C (22.5±7.1°C). Sex was not reported in 7% of the cases and most EHS cases were male (male: 87%, female: 7%). Signs and symptoms ($n=397$) were identified among nine organ systems: cardiovascular (27%), nervous (24%), digestive (13%), respiratory (10%), urinary (10%), muscular (6%), integumentary (5%), endocrine (3%), and lymphatic (2%). Core temperature was reported in 93% of diagnosed EHS cases and exceeded 40°C in most (71%). Irrespective of core temperature, the most reported signs and symptoms were altered conscious state or unconsciousness (59%), tachycardia (55%), elevated levels of aspartate transaminase (44%), rhabdomyolysis (31%), hypotension (27%), sweating (25%), seizures/convulsions (23%), metabolic acidosis (22%), and tachypnea (20%).

CONCLUSION: Overall, heterogeneity of signs and symptoms between cases was observed. To address this, an interactive tool was developed to dynamically generate a HRI “digital twin” highlighting the most common signs and symptoms present based on user defined case characteristics (age, environment, activity, intensity, etc.). The digital twin HRI phenotype also provides a ‘signs and symptom’ map layer illustrating their co-presences and associations. This innovative decision support tool has the potential for ameliorating EHS recognition and reporting, to hasten the implementation of appropriate treatment strategies, and improve patient health outcomes.

EFFECTS OF MID-COOLING VIA SINGLE ARM IMMERSION IN CARBONATED COLD WATER ON INTERMITTENT EXERCISE PERFORMANCE IN THE HEAT

CHOO, H.C., CHOO, D.H.W., YANG, B.H., CHEONG, R., IHSAN, M., XU, C.Z.

SINGAPORE SPORT INSTITUTE

INTRODUCTION: Intermittent sport athletes have been shown to experience hyperthermia (38.5°C to $\geq 39.5^\circ\text{C}$) during competitions (1), which may adversely impact muscle force output (2) and complex motor-cognitive function (3). Arm immersion in cold water is a practical mid-cooling intervention for intermittent sports. Adding CO₂ to 25°C water induces

vasodilation, potentially increasing heat loss and hence the robustness of this cooling modality (4). We investigated the effect of half-time cooling via single arm immersion in cold CO₂ water during intermittent exercise in the heat.

METHODS: In a repeated measures design, 8 men and 1 woman (maximal oxygen uptake: 46.4 ± 9.4 mL/min/kg) completed 3 trials of 2×39 min sprint cycling in the climate chamber (35°C , 54% relative humidity [RH]), interspersed by a 13-min single arm cooling outside the chamber (22°C , 65%RH): (1) cold water immersion (CWI, $9.6 \pm 0.6^{\circ}\text{C}$); (2) cold CO₂ water (CO₂, $9.4 \pm 0.5^{\circ}\text{C}$); and (3) control condition (CON). Rectal (Tre) and skin temperature (T_{skin}), heart rate (HR), working memory (serial 7), mean (MPO) and peak power output (PPO), thermal sensation (TS), thermal comfort (TC), rating of perceived exertion (RPE) and whole-body sweat loss (WBS) were assessed. Analyses were performed using linear mixed models with restricted maximum likelihood. Multiple pairwise comparisons following significant effects ($p \leq 0.05$) were performed using Tukey method.

RESULTS: During half-time, reductions in Tre were greater in CWI ($-0.67 \pm 0.34^{\circ}\text{C}$) versus CON ($-0.52 \pm 0.30^{\circ}\text{C}$, $p = 0.005$), but similar between CO₂ ($-0.63 \pm 0.37^{\circ}\text{C}$) and CON ($p = 0.379$). Reductions in T_{skin} were greater in CO₂ ($-3.98 \pm 1.02^{\circ}\text{C}$) than in CON ($-2.95 \pm 0.80^{\circ}\text{C}$, $p = 0.192$), but similar between CWI ($-3.62 \pm 1.07^{\circ}\text{C}$) and CON ($p = 0.080$). Decreases in MPO (CO₂: $-6.1 \pm 4.5\%$; CON: $-6.4 \pm 3.8\%$; CWI: $-2.7 \pm 3.1\%$, $p = 0.112$) and PPO (CO₂: $5.4 \pm 6.8\%$; CON: $-4.4 \pm 6\%$; CWI: $-1.7 \pm 4.8\%$, $p = 0.280$) during the second-half were similar between conditions. WBS were similar between conditions (CO₂: 2299 ± 692 mL; CON: 2341 ± 842 mL; CWI: 2347 ± 773 mL, $p = 0.777$). Whilst TS and TC were lower during half-time ($p < 0.001$), these were not based on condition ($p = 0.875$ to 0.936). The halftime cooling did not affect HR, working memory or RPE ($p > 0.05$).

CONCLUSION: Mid-cooling via CWI or CO₂ did not decrease T_{skin} (difference of 0.66 - 1.03°C) or Tre (difference of 0.1 - 0.14°C) appreciably more than CON. Hence, there was minimal influence on cognitive accuracy (i.e., working memory) and physical performance during high-intensity exercise in the heat. Mid-cooling should be reconsidered when half-time are undertaken in cooler environments.

FATIGUE INDUCED BY WORKING IN HOT CONDITIONS: A SCOPING REVIEW

AIT ALI BRAHAM, M., PAMART, N., DESHAYES, T.A., PAGEAUX, B., ARVISAIS, D., GAGNON, D., GENDRON, P.
UNIVERSITÉ DU QUÉBEC À TROIS-RIVIÈRES

INTRODUCTION: Fatigue is a common symptom in occupations with high physical and/or cognitive demands. It not only reduces work productivity but also heightens the risk of workplace injuries. Environmental factors such as temperature and humidity can contribute to the development of fatigue or its exacerbation. The combination of increasingly hotter temperatures that expose workers to heat strain and the relation between heat stress, fatigue, and occupational injuries provide a strong rationale for a thorough and timely review aiming to map existing knowledge on how fatigue induced by working is influenced by hot condition.

METHODS: A search was conducted in 10 databases to identify relevant studies on fatigue during work in the heat. Included studies focused on fatigue in an occupational context under hot environments ($\geq 25^{\circ}\text{C}$), with fatigue triggered by a fatiguing task and a subsequent impact on an occupational-specific/related performance outcome. Data about the (i) study, (ii) participants, (iii) fatiguing task, (iv) environmental conditions, and (v) performance task characteristics were extracted.

RESULTS: A total of 29 experimental studies were included, with 24 studies conducted in laboratory settings and 5 in field conditions. Of these, 57% included a temperate control condition. Most studies (90%) were conducted in countries with a high development index and involved 406 participants (87% males, 13% females). Average age of participants was 31 ± 7 years old (range: 20-50) and only 6 studies included employed workers. Concerning the fatiguing tasks, 89% of studies used physical tasks, only 1 used a cognitive task, and 2 used subsequently cognitive then physical tasks. The average duration of tasks was 119 ± 215 minutes (range: 30-720), with an average ambient temperature of $34 \pm 4^{\circ}\text{C}$ (range: 26-46) and relative humidity of $42 \pm 10\%$ (range: 24-60). To attest of the presence of fatigue, most studies (85%) used subjective variables (e.g., increased perceived fatigue). Concerning the performance tasks, only 4 studies used occupational-specific tests (e.g., box lifting), while others employed non-specific tests. Approximately 33% of studies evaluated both cognitive and physical performance, 10% focused on cognitive performance only (e.g., Stroop test), and 57% assessed physical performance only (e.g., maximal force). Only 46% of all studies reported a significant decline in performance after fatiguing tasks, and 31% found a significantly greater decline in performance in hot conditions compared to temperate conditions.

CONCLUSION: This review highlights that relatively few studies have focused on fatigue induced in hot environment on performance outcome related to work. Most studies have been conducted in high development index countries within laboratory settings. The results identify a need to employ more occupationally-relevant simulations in laboratory settings or conduct additional field studies to further understand how hot environments might affect fatigue in occupational contexts.

THE COOL FOREARM – MECHANISMS OF SKELETAL MUSCLE HYPOPERFUSION DURING COLD STRESS.

MUGELE, H., CARR, J.M.J.R., HOWE, C.A., DENEKE, J., BRUCE, N.D., PERKINS, D.R., RIEMER, K., LAWLEY, J.S.

UNIVERSITY INNSBRUCK

INTRODUCTION: Cold exposure reduces blood flow to exercising skeletal muscle. However, whole-body cold stress induces hypometabolism and systemic hemoconcentration thereby increasing oxygen content. This study aimed to determine whether restoring oxygen content normalizes exercise blood flow to normothermic levels.

METHODS: In an environmental chamber (terraXcube, Italy), 12 healthy individuals were cold stressed (ambient temperature, 10°C; relative humidity, 55%) for a period of 24h. Physical activity, clothing, nutrition, and fluid intake were controlled. Participants performed rhythmic (1:2 work rest ratio) handgrip exercise at 25% of their maximal voluntary contraction for 3 minutes. At baseline and after 24 hours of cold stress, mean skin (8-site thermocouples) and core temperature (rectal thermistor) were measured. Thereafter, brachial blood flow (ultrasonography) in combination with antecubital venous blood samples were measured at rest and during handgrip to calculate forearm blood flow, oxygen delivery, A-VO₂diff and oxygen consumption. Blood pressure (finometer, electrophygmomanometer) was measured at rest and during exercise to calculate forearm vascular resistance. In a subset (n=6), muscle temperature (hypodermic needle thermocouple) was assessed and targeted hemodilution (PV; Sterofundin®) was performed to reverse the expected cold induced hemoconcentration and normalize oxygen content.

RESULTS: 24h at 10°C reduced mean skin (Δ -4.6°C; $p<0.001$; n=12), rectal temperature (Δ -0.8°C; $p<0.001$; n=12), forearm skin (Δ -4.13°C; $p=0.002$; n=12) and muscle temperature (Δ -4.61°C; $p=0.027$; n=6). Moreover, hemoglobin and thus arterial oxygen content increased ($p<0.001$; n=10). 24h at 10°C reduced forearm oxygen consumption during exercise ($p=0.033$, n=7). Surprisingly, 24h at 10°C had a variable effect on exercising muscle blood flow ($p=0.16$; n=11), albeit it was statistically reduced in the subsample ($p=0.04$; n=5) as was a trend in oxygen delivery ($p=0.06$; n=5) whereas A-VO₂diff ($p=0.40$; n=5) remained at thermal neutral values. Hemodilution effectively restored hemoglobin concentration to normothermic values (BL, 14.9 ± 1.4 ; Cold, 16.2 ± 1.1 ; hemodilution, 15 ± 0.7 , $p<0.001$; n=5), yet had almost no impact on forearm blood flow (211 ± 106 vs. 205 ± 88 mL/min, $p=0.71$; n=5).

CONCLUSION: During prolong periods of whole-body cold stress, muscle temperature is reduced and the reduction in muscle blood flow during exercise seems primarily due to cold induced hypometabolism and not the systemic hemoconcentration.

SELF-PACED PHYSICAL WORK IN THE HEAT: THE HIGHS AND LOWS OF CORE BODY TEMPERATURE INDICES

SKINNER, B., PHILPOT, G.1, SCHLADER, Z.2, LUCAS, R.1

1 UNIVERSITY OF BIRMINGHAM; 2 INDIANA UNIVERSITY, IN USA

INTRODUCTION: Measurement and monitoring of core body temperature (TCore) in field-based settings is fundamental to understanding the magnitude and consequences of excessive heat exposure. Rectal temperature (TR) and gastrointestinal temperature (TGI) are accurate and well-correlated indices of TCore in laboratory-based studies yet are either incompatible (TR) or have logistical and interpretive challenges (TGI) with use in the field. Subsequently, estimating TCore from continuous heart rate measures (TECT) is an attractive alternative. However, it is unclear how typical in situ responses to heat stress such as self-pacing, fluid intake and rest influence TGI and TECT measures. Therefore, this study aims to examine the influence of a rest and hydration intervention on TGI, TR, and TECT indices of TCore during self-paced work in the heat.

METHODS: In a pseudo-randomised crossover order, 8 participants (23 ± 2 yrs; 5 male; VO₂max: 45.7 ± 7.7 mL/kg/min) completed two 2-h cycling time trials in hot conditions (38°C, 30% relative humidity), one with a mandatory rest (REST; 10-min seated rest after 1-h, access to cool water [$\sim 8^\circ\text{C}$]) and one without (NO-REST; no mandatory rest, access to room temperature water [$\sim 33^\circ\text{C}$]). In both trials participants were asked to cycle as far as possible while maintaining an RPE of 12-14 and could rest at any time with water available by dismounting the bike. TCore indices were continuously measured via rectal, gastrointestinal (pill ingestion ~ 54 min prior by design) and estimated from continuous heart rate measures. Paired t-tests (REST vs. NO-REST) and two-way RM ANOVAs (trial [REST vs. NO-REST] x core [TR vs. TGI vs. TECT]) were performed.

RESULTS: Distance covered was greater in NO-REST compared to REST (41.7 ± 6.1 km vs. 39.1 ± 5.0 km; $p<0.01$), although mean power output when cycling was similar (NO-REST: 101 ± 37 W, REST: 99 ± 34 W; $p=.20$). Maximum TCore differed between TCore indices (core: $p<0.01$), irrespective of trial (trial: $p=.10$; core x trial: $p=.98$). Maximum TECT was higher than TGI ($+0.58 \pm 0.44$ °C; $p<0.01$) and TR ($+0.39 \pm 0.40$ °C; $p=.02$), but was similar between TGI and TR ($p=.40$). Average TCore differed between TCore indices (core: $p<0.01$), irrespective of trial (trial: $p=.10$; core x trial: $p=.29$). Average TGI was lower than TR (-0.38 ± 0.37 °C; $p=.05$) and TECT (-0.69 ± 0.55 °C; $p<0.01$), with no difference between TR and TECT ($p=.12$). Following drinking, TGI nadir was similar between trials ($p=.13$), decreasing below resting TGI by -0.7 ± 1.0 °C and -1.3 ± 1.2 °C during NO-REST and REST, respectively.

CONCLUSION: Despite fluid consumption strongly influencing measures, maximal TCore appeared to be reliably captured via TGI. Conversely, while TECT overestimated maximal TCore, average TECT matched TR during exercise in the heat. This introduces interpretive considerations when conducting field-based heat strain assessments, as the assessment's aim (i.e., cumulative strain vs. exertional heat stress risks) may determine the most appropriate measurement method.

CP-SH10 Mentoring / Coaching II - Elite Athletes

UNDERSTANDING RELATIONSHIP QUALITY IN SPORT PSYCHOLOGICAL COUNSELING: A LONGITUDINAL STUDY ON THE ROLE OF RELATIONSHIP-INFLUENCING ATTRIBUTES IN ADOLESCENT ELITE SPORTS

BECKMANN, J., KLEINERT, J., BELZ, J.

GERMAN SPORT UNIVERSITY COLOGNE; INSTITUTE OF PSYCHOLOGY

INTRODUCTION: The relationship quality between an athlete and a sport psychology practitioner is regarded as a critical factor for successful sport psychological counseling (e.g., perceived improvement of performance or well-being) [1][2]. However, there is limited understanding of specific mechanisms underlying it. In the psychotherapy setting, certain relationship-influencing attributes of the practitioner—such as perceived trustworthiness, expertness, and attractiveness—have been shown to influence relationship quality [3]. Thus, this study aims to examine the extent of perceived relationship quality and relationship-influencing attributes in sport psychological counseling (i.e., athletes' perception of trustworthiness, expertness, and attractiveness) and their stability over time.

METHOD: As part of a longitudinal study, 14 adolescent elite athletes from German state teams (15.14±1.29 years; 57.1% female, 42.9% male) participated in a survey following their first and fifth counseling sessions. The sample is expected to reach N = 60 by the time of the conference. Relationship quality was assessed using the QS17 scale [4], measured on a 4-point Likert scale while relationship-influencing attributes were evaluated using the CRF scale [3] on a 6-point Likert scale with a maximum score of 24. Paired-sample t-tests analyzed changes over time.

RESULT6

Following the first session, the mean relationship quality was 3.76±0.25, and 3.84±0.21 after the fifth session. Mean CRF scores after the first session were 23.36±1.01 for trustworthiness, 22.79±1.25 for expertness, and 22.93±1.64 for attractiveness. After the fifth session, mean scores were 22.71±1.90, 22.57±1.70, and 22.71±2.02, respectively. Paired-sample t-tests showed no significant changes over time in either relationship quality ($p=.37$) or relationship-influencing attributes, including trustworthiness ($p=.24$), expertness ($p=.68$), and attractiveness ($p=.65$).

DISCUSSION: Preliminary findings ($n = 14$) suggest that relationship quality and relationship-influencing attributes may remain stable over time in sport psychological counseling in adolescent elite sports. This stability could indicate that initial impressions form early and persist, aligning with psychotherapy research [5]. This study is the first to longitudinally examine relationship quality and relationship-influencing attributes; however, additional data (expanding from $n = 14$ to $N = 60$) is required to further support these initial findings. Understanding the mechanisms behind the initial impression is essential for optimizing sport psychological counseling, particularly by strengthening the initial practitioner-athlete interaction in terms of trustworthiness, expertness, and attractiveness.

DEVELOPING A METHOD TO SUPPORT COACHES' PRACTICAL KNOWLEDGE ACQUISITION: A CASE STUDY OF YOUTH TENNIS COACHING

HIOKI, K., TOKAIRIN, Y.

KEIO UNIVERSITY

INTRODUCTION: The knowledge required of coaches includes professional knowledge, interpersonal knowledge, and intrapersonal knowledge [1]. Professional knowledge has long been the subject of coach education, and an environment has been developed to support its acquisition [2]. In contrast, interpersonal knowledge and intrapersonal knowledge are characterized as practical knowledge, and the development of an environment to support the acquisition of this knowledge is insufficient [3]. Therefore, the purpose of this study was to develop a method to help sports coaches acquire practical knowledge.

METHODS: This study focuses on pattern language, a methodology for systematizing and describing the practical knowledge of experts in an accessible format. In recent years, it has been increasingly applied in fields such as education, welfare, and management [4]. This study marks its first application in sports.

In this study, interviews were conducted with seven Japanese expert youth tennis coaches to explore their practical knowledge in helping players achieve their goals. The findings were systematized and documented in the form of a pattern language.

Building on this, an accompanying support program was designed and implemented with four Japanese youth tennis coaches, utilizing the developed pattern language. Specifically, one-on-one sessions were conducted approximately once a week for a total of four sessions, utilizing the pattern language. A qualitative inductive analysis was conducted on the verbal data from the sessions and follow-up interviews to examine the program's impact on the coaches.

RESULTS: The practical knowledge of expert youth tennis coaches was documented as 36 patterns. These patterns were then categorized into three categories: "Fostering a Foundational Relationship," "Leading to High Performance," and "Developing Autonomy Together."

Within the accompanying support program utilizing pattern language, changes were observed in both coaching practices and perceptions. Specifically, through the program, coaches engaged in "Practices Beyond the Limits of Individual Ideas" and "Practices That Are Important but Previously Untried." Furthermore, "Willingness to Continue Practicing" was confirmed, indicating that these practices were sustained beyond the program's completion. Moreover, changes in perceptions were observed in "Deeper Self-Understanding" and "Revision of Personal Coaching Theories."

CONCLUSION: Utilizing the pattern language developed from the practical knowledge of expert coaches was suggested as a potential trigger for coaches to acquire practical knowledge. By continuing to engage in practice after completing the program, participants are expected to further develop their practical knowledge.

EFFECTS OF MUSIC LISTENING ON ANAEROBIC PERFORMANCE AND MOTIVATION IN HEALTHY YOUNG ADULTS

MANENTE, A., CAVAGGIONI, L., FORMENTI, D., OUERGUI, I., PERPETUINI, D., CASTIGLIONI, P., BERENGAN, A., TRECROCI, A., ARDIGÒ, L.P., DE DONATO, S., MERATI, G.

UNIVERSITY OF INSUBRIA

INTRODUCTION: Music has long been incorporated into training sessions for both competitive and non-competitive athletes. Numerous studies confirmed its ability to enhance strength, sprint, and endurance performance, by affecting three key dimensions of human nature: psychological, physiological, and psychophysiological (1). However, conflicting evidence exists regarding the effectiveness of music, which may be influenced by differences in music selection, individual preference, and gender (2). This study aimed to investigate, from both physiological and psychological perspectives, whether motivational music influences anaerobic performance (3) in the Running-Based Anaerobic Sprint Test (RAST).

METHODS: Eighteen athletes (male = 12, female = 6) competing at a sub-elite level in track and field and football (age: 22.2 ± 2.1 (m $\pm$ SD) years; height: 175.3 ± 8.0 cm; mass: 66.4 ± 10.6 kg; BMI: 21.5 ± 2.2 kg/m²) were voluntarily recruited. The RAST procedure was conducted while participants listened to either preferred music or no music through headphones. Measurements included maximum power (Pmax), average power (Pmean), minimum power (Pmin), rating of perceived exertion (RPE), and motivational level assessed using a Visual Analogue Scale (VAS). The "music" and "no-music" conditions were compared by paired Student's t-test or by Wilcoxon signed rank test, where appropriate. Effect size (ES) was quantified using Cohen's d index for paired data.

RESULTS: No significant differences were observed between the "music" and "no-music" conditions for Pmax ($p = 0.50$, ES = 0.04, very small), Pmean ($p = 0.25$, ES = 0.28, small), and Pmin ($p = 0.053$, ES = 0.52, medium). The difference between conditions was also not statistically significant for RPE ($p = 0.71$, ES = 0.08, very small). However, VAS was significantly higher in the music condition compared to the no-music condition ($p < 0.001$, ES = 1.31, very large).

CONCLUSION: Motivational music can enhance motivation during high-intensity, repeated exercise without directly improving anaerobic performance, as supported by previous studies (3). Athletes can use music as a natural and cost-effective tool to boost motivation and strive toward higher goals while ameliorating their current performance level. Furthermore, as high-intensity exercise enhances overall well-being in the general population, incorporating music into exercise routines may play a role in improving training adherence and motivation, even in non-competitive settings.

EXPLORING ATHLETES' PREFERENCES FOR STRENGTH AND CONDITIONING COACHES' LEADERSHIP BEHAVIOURS IN COACHING: A MIXED-METHODS STUDY AT A BRITISH UNIVERSITY

TIBERI, S., COOPER, S.M., JENNINGS, G., ESFORMES, J.I., MOODY, J.A.

CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: Understanding athletes' preferences for strength and conditioning coaches' leadership behaviours in coaching contributes to coaching effectiveness. While research in this area has increased in recent years, no mixed-methods (MM) research exists. Therefore, we explored athletes' preferences for strength and conditioning coaches' leadership behaviours in coaching.

Method: Informed by pragmatism, we integrated quantitative and qualitative data to evaluate a confirmation or divergence of results. A survey using the 5-point Likert Revised Leadership Scale for Strength and Conditioning (RLSSC) was completed by 49 British university athletes (male = 25, female = 24), with 13 (male = 5, female = 8) agreeing to participate in the follow-up interviews. Data analyses included summary statistics, template thematic analysis, and MM integration through primary data analysis. Cronbachs alpha coefficients, existing content, construct validity of the RLSSC, audit trail, parallel questions, and database triangulation were used to confirm reliability and validity.

RESULTS: Training and instruction, situational consideration and positive feedback behaviours ranked the highest (median = 4.0), social support and democratic behaviours ranked moderately (median = 3.5 and 3.0, respectively) and autocratic

behaviours ranked lowest (median = 2.5). Qualitative results confirm and expand quantitative findings by providing contexts in which behaviours are mostly preferred. Integrated MM analysis highlights how behaviours cannot be evaluated independently from context and that strength and conditioning coaches should exhibit adaptability and a genuine interest in developing personal connections.

Discussion: Athletes appreciate a balanced coaching style where autocratic and democratic behaviours are used selectively, recognising the value of authority but prioritising collaboration, especially in goal-setting. Positive feedback and instructions grounded upon strength and conditioning knowledge are highly valued when genuine and contextually appropriate and are provided during significant efforts, heavy lifting or learning new techniques. Additionally, athletes prefer coaches who show empathy and strong social interaction skills while maintaining professional boundaries and the ability to consider situational factors to set achievable goals. Coaches can use this knowledge to inform and adapt their practice, engage in self-reflection, and consider key behaviours contributing to their personal and professional development. Ultimately, these findings encourage coaches to approach their development and practice with curiosity, humility, and a desire for lifelong learning.

INTUITION OR REFLECTION? COGNITIVE PROCESSING AND PERFORMANCE IN ESPORTS

STAEDTER, C.

BRANDENBURG UNIVERSITY OF TECHNOLOGY COTTBUS-SENFTENBERG

Introduction: Esports (electronic sports) have evolved into a hyper-competitive, professionalized, and organized setting. They share similarities with other professional sports where individuals and teams strive to optimize their performance. Although cognition is essential in esports, research on the topic and its link to performance remains scarce [1]. The purpose of this paper is to examine whether cognitive processing predicts performance of professional esports athletes. In doing so, this study applies the dual-process theory framework, describing two qualitatively different modes of cognitive processing—Type 1 (intuition) and Type 2 (reflection) [2]. To the best of our knowledge, this study is the first to examine how esports athletes employ Type 1 and Type 2 cognitive processing and their relationship to performance.

Research question: Does Type 1 and Type 2 cognitive processing predict performance in esports athletes?

Methodology: The study adopts a quantitative approach by analyzing digital trace data of esports athletes during performance episodes. In doing so, videos and transcribed audio data from the esports title Teamfight Tactics will be leveraged. After coding and categorization based on criteria of cognitive processing types from the dual-process theory literature, data will be analyzed.

Results: Within the full paper, statistical analysis will be carried out to investigate the relationship between Type 1 and Type 2 cognitive processing and performance. Specifically, variables used are: frequency, strategic planning, self-reflection, and situational analysis, as well as the dependent variable game performance. In addition, the influence of variables (e.g., player experience, game state, and rank) will be investigated. Lastly, the association between game states and cognitive processing types will be analyzed.

Discussion: Key findings will be discussed in relation to existing literature. Furthermore, practical implications for practitioners will be highlighted. Furthermore, the study will suggest guidance for future research in esports and cognition, especially the potential of employing digital trace data from gaming in both fields.

INJURIES, INJURY TIME AND EMOTIONAL DIRECTION IN GYMNASTS AND OTHER HIGH-PERFORMANCE ATHLETES

BARRIOS, M.

UNIVERSIDAD DE ALCALA

Emotions play a crucial role in sports performance, being key to success at high levels. Depending on the sport practiced, coping resources vary in the face of injury. At a young age, preventing injuries is a priority, as they affect negative emotions and anxiety. As the age and level of performance increases, the severity of injuries increases, especially in artistic gymnastics, the second discipline with the highest incidence of injury.

METHODS: Participants 307 athletes aged between 8 and 18 years ($M=15.11$; $SD= \pm 2.44$ in individual and collective disciplines; $M=12.29$; $SD= \pm 2.48$ in artistic gymnasts), equivalent in competitive experience ($M=6.27$; $SD= \pm 2.43$ years) and performance level (national-international).

Instruments. Differential Emotion Scale (mDES), $\alpha=0.82$, spanish version adapted to sports population.

RESULTS: In individual and team sports, the distribution of injured and non-injured is similar ($\phi=-0.17$; $p=0.010$). In artistic gymnastics, the injured (62) significantly outnumber the non-injured (30) ($z=3.34$; $p<0.001$). In individual and team sports, Short and Long-term injuries predominate ($\phi=-0.27$; $p=0.014$), while in artistic gymnastics Short-term injuries are significantly more frequent ($z=2.98$; $p=0.003$) than Medium and Long-term injuries ($z=5.58$; $p<0.001$). Positive and moderate

correlations were found between Number of Injuries and Negative Emotions (0.27 ; $p=0.041$). In addition, there were significant differences in Negative Emotions ($F(2/204)=4.99$; $p=0.008$; $\eta^2=0.05$), with a tendency to increase with Time of injury. No significant relationships were found between Sex and Time of injury ($\phi=-0.13$; $p=0.190$), Sex and Number of injuries ($\phi=-0.09$; $p=0.113$), nor Field of competition ($\phi=-0.05$; $p=0.409$), indicating similar distribution between men and women, as well as between competitive levels.

Discussion: The high incidence of injuries in artistic gymnastics coincides with previous studies, being attributed to the risks inherent to the discipline and high demand from a very early age.

However, it disagrees with research that associates a higher level of performance with longer injury time. In individual sports, injuries due to overuse and mechanical stress predominate, explaining their short duration, while in team sports, acute injuries due to contact stand out. Regarding emotions, the results are consistent with previous studies that found that individual athletes maintain stable levels of positive emotions in the face of injury, which could be an adaptive strategy in sports with greater emotional independence. On gender, the findings differ from the ones that reports higher rates of certain injuries in women due to anatomical and biomechanical differences, while in men, injuries are linked to direct contact. The results are consistent with previous studies regarding the insignificance between injury time and sex.

Further studies on high performance injuries are needed to reduce their occurrence and promoting longer and more successful sports careers

INTEGRATING PSYCHOLOGICAL SKILLS WITH SWIFT-SMART MOTION PATTERN TRAINING ON YOUNG BADMINTON PLAYERS FOOTWORK AGILITY PERFORMANCE

NG, C., LIM, B.

SEGI UNIVERSITY

Badminton is the fastest and most demanding racket sports globally, requiring athletes to excel in physical, technical, and psychological domains to achieve peak performance. Footwork agility is a critical physical attribute in badminton performance as it forms the foundation for executing quality technical skills. The Swift-Smart Motion Pattern (SSMP) training program was developed with a combination of shadow drills powered by the Onigoe device, a technology specifically built for badminton footwork agility. These drills are designed for badminton that encompasses the entire court, including the front, mid (side), and rear court zones. Within each zone, it addresses the two key corner positions encountered during gameplay with data-driven feedback. Although Psychological Skills Training (PST) has been established as a technique to enhance mental skills and improve sports performance, the interaction between PST and badminton footwork agility has received little attention. To address these research gaps, this study examines the effectiveness of a comprehensive PST program integrating goal-setting, self-talk, and their combination with SSMP training on badminton footwork agility. The study involves three intervention groups—SSMP with goal-setting (GS), SSMP with self-talk (ST), and SSMP with combined goal-setting and self-talk (GS + ST) and a control group (SSMP only) to establish a baseline for comparison. This study aimed to examine the effectiveness of the SSMP training program combined with psychological skills on badminton footwork agility. Eighty ($N=80$) participants aged 12-16 years from Duo Sparks Badminton Academy, Malaysia were randomly divided into four groups: Goal-Setting + SSMP ($n=20$), Self-Talk + SSMP ($n=20$), Combined Goal-Setting and Self-Talk + SSMP ($n=20$), and a Control Group that only followed the SSMP training program ($n=20$). There was a statistically significant difference in front court of badminton footwork agility within pre test and post test [$F(1,3) = 22.51$, $p < 0.05$] and between groups [$F(1,3) = 2484.5$, $p < 0.05$], mid-court of badminton footwork agility within pre test and post test [$F(1,3) = 20.15$, $p < 0.05$] and between groups [$F(1,3) = 3020.7$, $p < 0.05$] and in rear- court of badminton footwork agility within pre test and post test [$F(1,3) = 20.14$, $p < 0.05$] and between groups [$F(1,3) = 3020.7$, $p < 0.05$]. The Self-Talk group showed significantly higher performance in the front court ($M = 2.3$, $SD = 0.59$), mid-court ($M = 1.88$, $SD = 0.35$), and rear-court ($M = 2.29$, $SD = 0.51$); $p < .05$. The findings suggest that the Self-Talk intervention is the most effective psychological skills intervention in enhancing training efficacy for badminton footwork agility performance. In conclusion, this study provides valuable insights of swift-smart motion pattern (SSMP) training program with psychological skills training in enhancing badminton footwork agility.

Conventional Print Poster Presentations

TSST-VR AND STRESS REACTIVITY: A MULTISYSTEM ANALYSIS OF ENDOCRINE, METABOLIC, CARDIOVASCULAR, AND PSYCHOLOGICAL RESPONSES

FELLINGER, E., BRANDT, T., SCHITTENHELM, A., QUARG, E., PRÖLL, M., SCHMIDT, A.

UNIVERSITY OF THE BUNDESWEHR

Background: The Trier Social Stress Test (TSST) is a widely used tool for inducing and measuring stress responses in a controlled environment. In this study, we aimed to explore the effectiveness of a virtual TSST (TSST-VR) in eliciting stress responses across multiple physiological and psychological markers.

Methods: A sample of 24 participants underwent the TSST-VR, during which salivary cortisol, alpha-amylase (AA), blood glucose levels, heart rate (HR), root mean square of successive differences (RMSSD) as a measure of heart rate variability (HRV), and subjective stress ratings (NRS) were collected at multiple time points.

Results: In a baseline-to-peak analysis, significant increases were observed in HR (MDiff = 13.04, 95%-CI [8.19 – 17.90], $p < .001$), RMSSD (MDiff = 17.75, 95%-CI [3.28 – 32.22], $p < .001$), AA ($p < .001$, $r = 1.07$), and NRS ($p < .001$, $r = 1.31$) measures following the TSST-VR. While no significant changes in cortisol levels were found in the baseline-to-peak analysis across all participants, a secondary cluster analysis identified distinct cortisol responders (baseline-to-peak rise > 1.5 mmol/l). Within this group, high cortisol responders (HCR) showed significantly higher cortisol (Wald $\chi^2(7) = 118.03$, $p < .001$), HR (Wald $\chi^2(8) = 17.91$, $p = .022$), and AA levels (Wald $\chi^2(7) = 17.13$, $p = .017$) compared to low cortisol responders (LCR). Area-under-the-curve analysis further confirmed a more robust cortisol stress response in HCR.

Conclusion: These findings suggest that the TSST-VR can effectively induce measurable stress responses and may provide insights into individual differences in physiological and metabolic stress reactions. The study highlights the potential of virtual stress paradigms in stress research and underscores the advantages of a virtual setting in terms of standardization and economic considerations.

ADAPTIVE AND MALADAPTIVE FEATURES OF EXERCISE AS COPING WITH PERCEIVED STRESS - A SCOPING REVIEW OF THE UNDERPINNING RESEARCH

OMHOLT LOSSIUS, L., ANDERSSON, K., ANDREASSON, J.
LINNAEUS UNIVERSITY

Introduction: Exercise has been suggested as relevant coping to attenuate detrimental health effects connected to perceived stress. However, research addressing exercise as coping in a healthy population is scarce. Moreover, the adaptive features of exercise as coping is usually exclusively highlighted. Few papers have addressed exercise as maladaptive coping in a healthy population, e.g. connected to the risk of exercise addiction. Thus, the literature base might be limited and polarized, with scarce literature addressing both adaptive and maladaptive features. **Aim:** The purpose of this study was to review the literature underpinning exercise as coping in a healthy population, including current knowledge gaps. We aimed to highlight key features and themes in the research underpinning exercise as adaptive or maladaptive coping – or both. **Design and methods:** In this scoping review, we conducted a systematic search in the databases Web of Science, PubMed, PsycInfo, Scopus, and SPORTDiscus. We used a combination of exercise terms (general, strength training, endurance exercise and yoga) and perceived stress terms, together with coping terms, targeting papers addressing exercise as coping with perceived stress in a healthy population. The data-base search was followed by a reference-list search in 30% of the included articles. Both quantitative and qualitative papers were included. Key information about population, design and methods, and exercise mode was collated. To further exhaust the material, an in-depth analysis was applied, generating codes and overreaching themes in the research. **Results:** The literature search resulted in 483 papers, of which 80 were retrieved in full text. The reference list search contributed with three additional papers. 47 papers were included in the analysis. We found that cross-sectional studies applying quantitative methods dominated the research. The papers mainly reported from mixed gender populations, addressing general physical exercise. For the specified articles, students were the most studied population and yoga the most addressed exercise mode. Overall, few papers were oriented at maladaptive features of exercise, with one paper addressing these exclusively. The rest of the research emphasized adaptive features of coping or were neutrally oriented. We identified four overreaching themes in the research: establishing exercise as adaptive coping, explaining exercise as adaptive coping, complicating exercise as coping and questioning exercise as coping. **Conclusion:** Our findings suggest that research addressing exercise as coping in a healthy population portray mainly adaptive features. Qualitative findings about exercise as coping, that can provide in-depth knowledge about the nuances, underlining both adaptive and maladaptive features, is lacking. Understanding exercise as coping is important in preventing negative outcomes related to perceived stress in a healthy population.

PSYCHOBIOLOGICAL STATES IN ARTISTIC GYMNASTICS: DIFFERENCES BY TYPE OF APPARATUS

DI FRONSO, S., DI PINTO, G., CURZI, D.
ECAMPUS UNIVERSITY

Artistic gymnastics (AG) is one of the main closed-skill sports where athletes perform as planned and within a stable environment. Specifically, in this discipline of gymnastics, athletes usually perform short routines on different types of apparatus that can be distinguished in floor exercises and equipment ones (i.e., balance beam, vault, uneven bars, pommel vault, high bar, etc.). Despite the stable environment, the aerial actions in AG challenge and motivate the athletes, elevate and enrich the routines, yet they can intimidate athletes (Duarte et al., 2015) sometimes discouraging them from competing in (major) tournaments. Precisely, this study aimed to unveil the differences between floor and equipment exercises in functional and dysfunctional psychobiosocial states (PBS-S) experienced by AG athletes in Italy. Ninety-eight athletes with a mean age of 29 years ($SD = 8.03$) were recruited. They were asked to think about their routines on the floor and the equipment and reply twice to PBS-S scale (Robazza et al., 2016). A within-subjects multivariate analysis of variance was performed using the type of apparatus (floor vs equipment) as a factor. Statistical analysis yielded significant differences in PBS-S usually experienced during floor and equipment exercises ($\lambda = 0.885$, $F(2, 96) = 6.240$, $p = 0.003$, $\eta^2 = 0.115$, Power = 0.886). Moreover, univariate analysis of variance showed significant differences both for functional_F ($F(1, 97) = 5.604$, $p = 0.020$, $\eta^2 = 0.055$, Power = 0.649) and dysfunctional_F ($F(1, 97) = 12.589$, $p = 0.001$, $\eta^2 = 0.115$, Power = 0.940).

PBS-S. In particular, AG athletes experienced higher levels of functional PBS-S during floor routines compared to equipment, while dysfunctional PBS-S seem to mainly characterize routines on the equipment. These results could be ascribed to the fact that, in the case of the floor, the gymnasts own body is "free" to perform evolutions and figures. Moreover, injuries are more frequent during the final part of the exercise—particularly during the so-called "exits" or in the jumps and landings of aerial acrobatics—because these moments tend to be unpredictable, especially when performed on gymnastics equipment. This unpredictability, as well as the use of an external apparatus, which implies an increased challenge, can contribute to dysfunctional emotions. A better understanding of functional/dysfunctional emotions, like the responses to their manifestation, can aid coaches in adopting strategies to prevent the interference of fear (for example) in the gymnast's performance.

PRELIMINARY VALIDATION OF AN ITALIAN VERSION OF THE ATHLETE BURNOUT QUESTIONNAIRE

VALDESALICI, A., GHISI, M.1, SPOTO, A.1, SMITH, A.L.2, BORELLA, E.1

1 UNIVERSITY OF PADOVA, PADOVA, ITALY; 2 UTAH STATE UNIVERSITY, LOGAN, UT, USA

INTRODUCTION: Burnout in athletes is a growing concern in sport environments. There is need for a psychometrically sound assessment tool to examine this phenomenon in Italian sport contexts. The purpose of the present study was to examine the psychometric properties of an Italian version of the Athlete Burnout Questionnaire (ABQ; Raedeke & Smith, 2001, 2009). The ABQ is a 15-item scale measuring the three dimensions of burnout: physical and emotional exhaustion (5 items), reduced sense of accomplishment (5 items) and sport devaluation (5 items).

METHODS: A sample of 177 high-level athletes, ranging from ages 18 to 37 years ($M=23.2$, $SD=3.8$; 44.1% women), of varied sports completed an Italian version of the ABQ along with measures assessing distress (Depression Anxiety Stress Scales-21, DASS-21) and resilience (Connor-Davidson Resilience Scale-10, CD-RISC-10). The Italian version of the ABQ was developed using a standard translation and back-translation procedure. The factor structure of the measure was inspected by comparing the fit of three confirmatory factor analysis models: (i) a first-order model with three correlated factors, (ii) a first-order model with one global factor, and (iii) a bi-factor model. Internal consistency reliability of scores on the questionnaire were inspected as was construct validity of scores.

Results

The confirmatory factor analysis showed that the first-order model with three correlated factors presented acceptable fit to the data ($\chi^2(87) = 219.42$, $p < .001$, $CFI=.97$, $TLI=.97$, $RMSEA=.09$, $SRMR=.09$) and a better fit compared to the alternative models. All standardized factor loadings were $>.40$. The results also showed scores on the respective burnout dimensions to have good internal consistency reliability, with all Cronbach's alphas $\geq .80$. Furthermore, the pattern of relationships of the ABQ subscales with the measures of distress and resilience supported the construct validity of the Italian version of the ABQ. As expected, the three dimensions of burnout were significantly positively correlated with distress ($r = .22$ to $.35$) and significantly negatively correlated (or non-correlated) with resilience ($r = -.04$ to $-.31$). These findings support the three-factor multidimensional model of burnout that is conceptualized by Raedeke and Smith (2001, 2009) and supported in previous research.

CONCLUSION: This study offers preliminary evidence for the reliability and validity of an Italian version of the ABQ. Future studies in the Italian athletic context should confirm and expand the findings of the present study with larger athlete samples and broadened nomological networks of constructs.

THE IMPACT OF HIGH-INTENSITY INTERVAL TRAINING ON ANXIETY, STRESS, AND TRAIT MINDFULNESS IN COLLEGE STUDENTS

HE, Z., LI, F.X.

PEKING UNIVERSITY

INTRODUCTION: High-Intensity Interval Training (HIIT) has demonstrated advantages in reducing anxiety and stress, as well as in enhancing trait mindfulness. This study aimed to investigate the impact of HIIT on college students' psychological well-being, with a specific focus on anxiety, stress, and trait mindfulness.

METHODS: With convenience sampling method, 68 students (Males: $n=21$; Age: $M=24.04$ years old) from an academically prestigious university voluntarily attended the study. The experimental group ($n=35$) took an eight-week HIIT program with one-hour session biweekly, whereas the control group ($n=33$) did not engage in exercise. Students responded to validated scales including the State-Trait Anxiety Inventory (Spielberger, 1983), the Perceived Stress Scale (Cohen et al., 1983), and

the Five Facet Mindfulness Questionnaire (Baer et al., 2006) to measure levels of anxiety, stress, and mindfulness respectively.

RESULTS: The experimental group showed significant decreases in state anxiety ($W=120.5$, $p<0.01$), trait anxiety ($W=112$, $p<0.01$) and stress ($T=-2.78$, $p<0.01$), as well as an increase in mindfulness ($T=3.44$, $p<0.05$). The control group reported increases in state anxiety ($T=2.66$, $p<0.01$), trait anxiety ($T=2.20$, $p<0.05$) and stress ($T=2.37$, $p<0.05$), as well as a decline in mindfulness ($T=-3.01$, $p<0.01$). While before the intervention no significant differences were observed in both groups, after the experiment the HIIT group demonstrated a significantly higher level of trait mindfulness ($T=3.54$, $p<0.01$) and lower levels of stress ($T=-3.26$, $p<0.01$), state anxiety ($W=331.5$, $p<0.01$), and trait anxiety ($W=324$, $p<0.01$) when compared to the control group.

CONCLUSION: This study supported the efficacy of HIIT in reducing anxiety and stress, which could be elevated for academic and social pressures. The enhancement of trait mindfulness indicated that HIIT could improve self-awareness and present-moment focus, which are crucial for cognitive development.

ENDURANCE RUNNING AND MENTAL HEALTH: LOWER DEPRESSION AND STRESS IN HALF AND FULL MARATHONERS, INDEPENDENT OF SEX AND TRAINING AGE

MELVIN, A., KOZLOFF, K., LEPLEY, A.

UNIVERSITY OF MICHIGAN

INTRODUCTION: Endurance running participation continues to grow, with increasing female representation and greater engagement across various age groups and distance categories. The psychological benefits of running extend beyond its physiological effects, yet the relationships between race distance (RD), training age (TA), and mental well-being remain underexplored. Understanding these associations is essential for elucidating the interplay between physical and mental health in the context of this widely practiced and adaptable form of exercise. The purpose of this study was to examine the relationships between RD history and TA with psychological characteristics, including depression, anxiety, perceived stress, autonomy, and motivation, while investigating potential sex interactions.

METHODS: Data from 210 participants (110M,100F; age:32±11yrs; TA:10±9yrs) were evaluated from a larger study of physically active individuals. Participants self-reported TA (years of regular running), sex, and RD history (longest RD completed) via electronic questionnaire. Standardized psychological assessments measured depression (PHQ-9), anxiety (GAD-7), perceived stress (PSS), autonomy (BREQ-3), and motivation (GOEM). Scores were categorized by established severity classifications for each outcome. Depending on the scale of the variable, linear or ordinal regression models or Chi-squared analyses, adjusted for sex, were used to analyze the relationships between RD history (

RESULTS: Marathoners reported lower stress (PSS:Mdn=9,IQR=5-14; beta=-.717; $p=.04$), and half marathoners exhibited lower depression (PHQ-9:Mdn=1,IQR=0-3; beta=-.806; $p=.04$) compared to those running

CONCLUSION: Regularly physically active individuals report low stress and minimal depression outcomes. History of completion of half and full marathons is associated with significantly lower stress and depression risk, irrespective of sex or TA, when compared to individuals who have only completed races

Funding: This study received funding from Samsung Electronics Co, LTD.

EXAMINATION OF THE HUNGARIAN NATIONAL ADULT SWIMMERS' COMPETITIVE ANXIETY AND RESILIENCE IN A CONNECTION TO THEIR FAMILY OF ORIGIN'S RESILIENCE

ESZTER, R., SZÁJER, P., TÓTH, L.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

Psychological resilience is the ability of a system (e.g., a family) to successfully adapt despite strong, frequent, or sudden external stressors (Masten, 1990; Garmezy, 1993). It is closely related to and has an impact on personal and intrafamilial coping, adaptive capacity, and the attainment of optimal outcomes in challenging life situations (Werner & Smith, 1982). Family resilience refers to the collective cohesion and shared coping efforts influenced by both internal and external factors within and outside the family (Walsh, 2003). Individuals characterised by resilience also typically exhibit traits such as internal control, empathy, optimism, positive self-image, positive coping with change, and self-efficacious behaviour (Masten, 1990).

In Meggs (2016) study, it was found that resilience levels in swimmers significantly predicted their performance. Based on the results, it can be hypothesised that resilience may directly or indirectly influence athletic performance through the reappraisal of stressors (i.e., by interpreting the stressor as facilitating rather than threatening).

The aim of our study was to investigate and gain deeper insight into the family background, resilience, and dynamics of Hungarian national swimmers to help them better manage anxiety and competitive-related stress through a holistic approach.

In our research, we examined 12 adult swimmers who are part of the national swimming team, along with their family of origin—parents and siblings. The average age of the participating swimmers was approximately 25.18 years, with a standard deviation of 3.21 years. The average age of the 14 participating family members was approximately 45.07 years, with a standard deviation of 10.33 years.

To measure family resilience, we used the 10-item Connor-Davidson Resilience Scale for both families and swimmers. Swimmers also completed the Competitive State Anxiety Inventory-2 to assess their levels of competitive anxiety.

We examined the relationship between family resilience and swimmers personal resilience, cognitive anxiety, somatic anxiety, and self-confidence.

After analysing the data using SPSS, we found that family resilience was significantly associated with athletes' self-confidence and personal resilience levels. However, no significant relationship was found between family resilience and either cognitive or somatic anxiety.

PERCEPTION OF STRESSORS AND RESOURCES IN YOUTH SPORT CLIMBING: PERSONAL AND TRAINING RELATED FACTORS

MITTERMEIER, R., TSCHERNTSCHITZ, S., RIML, S., RASCHNER, C.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: How we experience stress has an impact on our health and well-being. Recently dropping out from sport became related to social factors such as perceived autonomy and task climate [1]. Sustainable and long-term development, on an athletic as well as personal perspective, and motivation of athletes are linked to basic human needs [2,3]. Sport climbing is currently undergoing significant professionalisation, which is affecting young athletes. The aim of the study was to get a better understanding of perceived stressors and resources and to identify starting points to support health-promoting sport participation.

METHODS: Three active and six non-active climbers between the ages of 18 and 25 were interviewed using a semi-structured interview approach. The inclusion criterion was the qualification for the national team. After assessment of their competitive status a retrospective reflection on their career in terms of stressors and resources followed. A qualitative content analysis was conducted [4].

RESULTS: Among other topics, training environment and personal factors were addressed. Personal stressors were self-inflicted pressure and concerns about their development. In addition, health issues and the confrontation with body weight were identified as a burden. On a personal level, coping strategies and hobbies were named as resources. The experience of autonomy and maturity were positively emphasised. Beliefs sentences were reflected ambivalently. In terms of training, stressors mentioned were lack of individualisation, insufficient communication, favouritism and inadequate comparison. Respectful interaction and interest were named as resources. A professional relationship with coaches and fun during training were highlighted as positive factors. Aspects of motivation were discussed ambivalently, especially if there was a discrepancy between experienced and externally assessed motivation.

Discussion: The perceived stress experience, expressed in stressors and resources, reflects individual and fundamental needs [3]. The results might be considered not only in sport climbing, but in the support of athletes and in exercise research. Needs-orientated interaction with athletes could promote athletic and personal processes, resulting in more sustainable participation and a reduction in dropouts. Further athletes from climbing and other sports will be interviewed.

SMR NEUROFEEDBACK TRAINING ENHANCE ATTENTION-RELATED BRAIN REORGANIZATION IN BASKETBALL ATHLETES

CHANG, C., WU, Y., HUNG, T.

NATIONAL TAIWAN NORMAL UNIVERSITY

Neurofeedback training targeting sensorimotor rhythm (SMR) is a form of biofeedback that helps athletes improve their performance by reducing sensory motor interference and helping them to process their attention more efficiently. However, the changes in brain structure caused by neurofeedback training in athletes remain to be clarified by scientific evidence. Therefore, the purpose of this study was to investigate the changes in brain gray matter caused by SMR neurofeedback training to enhance basketball shooting performance, and to understand the effects of SMR neurofeedback training on the structure of attention-related brain regions. A total of 20 mens university basketball players were recruited for this study, and the participants were randomly assigned to the experimental group and the control group. The experimental group was required to undergo two weeks of 6 sessions of SMR neurofeedback training, in which the participants learned to enhance the SMR amplitude prior to executing the shooting action by using an auditory feedback method. The control group was given the same training without neurofeedback. All the participants were tested before and after the experiment, and the brain structures were scanned by 3T fMRI scanning. The results of the study showed that the experimental group not only showed a significant improvement in shooting performance, but also a significant increase in gray

matter volume in attention-related brain regions, including the right middle frontal gyrus, right supplementary motor area, and right inferior parietal lobule, but the control group did not show any significant changes in shooting performance and brain structure. This result provides scientific evidence that SMR neurofeedback training leads to structural plasticity in attention-related brain regions, and that this structural change may also be strongly associated with optimal sport performance.

A STUDY ON THE PRACTICAL PATH OF COLLABORATIVE GOVERNANCE BY MULTIPLE STAKEHOLDERS IN COMMUNITY SPORTS FOR THE ELDERLY: A TRIPARTITE COLLABORATION MODEL INVOLVING COMMUNITY GOVERNMENTS, COMMUNITY HOSPITALS, AND COMMUNITY HOSPITALS

WANG, J., DONG, X.

HARBIN SPORT UNIVERSITY

INTRODUCTION: With the intensification of population aging, community sports governance for the elderly has become an important approach to address the degradation of physical function and health issues among the elderly population. However, current community sports governance for the elderly generally faces problems such as uneven resource allocation, insufficient service provision, and the lack of a supervision mechanism. These issues severely affect the participation rate of the elderly in sports and the level of health management, and constrain the sustainable development of community social services. Therefore, exploring the practical path of collaborative governance by multiple stakeholders in community sports for the elderly has significant practical and academic value. This study is based on structural functionalism theory and collaborative governance theory, with community governments, community hospitals, and community sports organizations as the research subjects. A collaborative model involving the

THE IMPACT OF SPIRITUALITY/RELIGION ON ATHLETES MENTAL TOUGHNESS, SPORT MOTIVATION, AND PERCEIVED COMPETENCE.

PAIC, R., MARTON, G., KARSAI, I.

UNIVERSITY OF PÉCS FACULTY OF SCIENCES

INTRODUCTION: In contemporary sport psychology, the role of religious behavior and psychological functioning is receiving increasing attention. Religious beliefs and practices can promote athletes emotional and psychological well-being. They can also play a significant role in enhancing sports performance and have positive effects, such as managing stress and anxiety. Our goal was to assess the impact of spirituality/religion on various psychological factors like mental toughness, sport motivation, and perceived competence. Additionally, we sought to find correlations between the strength of faith and other components.

METHODS: We conducted a survey with 182 active athletes using various questionnaires. The average age of the participants was 19.34 years ($SD=5.58$). We measured the strength of religious faith using the Santa Clara Strength of Religious Faith Questionnaire (SCSRF). Athletes mental toughness was assessed with the Mental Toughness in Sport Questionnaire (SMTQ), sport motivation with the H-SMS questionnaire, and perceived competence with Lintunen's Perceived Physical Competence Scale (PPCS). Additionally, we administered the Spiritual Health and Life-Orientation Scale (SHALOM). For statistical analyses, we used normality tests, the Mann-Whitney U test, and Spearmans correlation analysis.

RESULTS: Religious athletes strength of faith ($M=27.72$, $SD=10.61$) is significantly higher ($p<.01$), and the transcendent importance and realization are also significantly higher ($p<.01$). Religious athletes have higher scores in perceived competence, mental toughness, intrinsic motivation, identified and integrated regulation, and lower scores in amotivation and external regulation compared to other groups, although this difference is not significant. Religious female athletes achieved significantly higher values in intrinsic motivation ($p<.05$) and cognitive intrinsic motivation ($p<.05$) compared to non-believing female athletes. The power of faith is significantly higher among professional athletes ($p<.05$) compared to semi-professional and amateur athletes. The power of faith positively correlates with cognitive intrinsic motivation ($p<.05$) and identified regulation ($p<.01$). Additionally, among believers, perceived competence positively correlates with intrinsic and autonomous extrinsic (integrated and identified regulation) motivation.

Discussion: Clearly, the strength of faith, importance, and realization of transcendence is higher among religious respondents. Since this group has higher values of self-confidence and control, believing can help enhance sports performance on the field. Believers, especially female athletes, have higher intrinsic motivation towards their sport compared to non-believers, thus intrinsic motivation can be linked to faith. Additionally, believers have higher perceived competence, meaning that faith, or its presence, positively impacts self-confidence and intrinsic motivation needed for achieving good sports performance.

EXAMINING THE IMPACT OF SELF-TALK AND MENTAL TOUGHNESS ON SELF-EFFICACY WITH THE MEDIATION OF LEARNING AGILITY

MAROUFI, S., KASHEF, S.M., BEHNAM, M.

DEPARTMENT OF MOTOR BEHAVIOUR AND SPORTS MANAGEMENT, FACULTY OF SPORTS SCIENCES, URMIA UNIVERSITY, URMIA, IRAN

Introduction: In today's world, psychological and cognitive factors play a critical role in enhancing individual and organizational performance. Among these, self-talk and psychological resilience are key components that significantly influence

individuals self-efficacy. This study investigates the effects of these factors on self-efficacy and examines the mediating role of learning agility.

Method: This descriptive-correlational study targeted a statistical population of 698 employees from the Sports and Youth Departments in the northwest regions of Iran (West Azerbaijan, East Azerbaijan, and Ardabil). Using stratified random sampling, 248 participants were selected. Data were collected using standardized questionnaires on learning agility, self-talk, mental toughness, and self-efficacy. Statistical analysis was conducted using multiple regression and structural equation modelling with SPSS-26 and Amos-24 software.

Findings: The results indicated that the proposed research model had a good fit, with self-talk and mental toughness influencing self-efficacy both directly and indirectly through the mediating role of learning agility ($\chi^2/df = 1.56$, GFI = 0.94, AGFI = 0.92, CFI = 0.98, RMSEA = 0.05, SRMR = 0.04).

Conclusion: The findings highlight the importance of strengthening self-talk and mental toughness to enhance self-efficacy while underscoring the critical role of learning agility as a mediator in this process.

STATUS QUO ANALYSIS OF SPORT AND LEISURE SECTOR IN EUROPE

VÄÄNÄNEN, I., MYNTTINEN, M.

LAB UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: The sports and leisure (S&L) sector has a considerable role in regional development and promoting physical activity. Analysing the S&L sector improves understanding of its influence on social, economic, and cultural aspects across various geographical contexts. Although sports activities, sports and recreation education, and the manufacturing of sports goods represent 0.2 % (€60 billion) of EU total turnover, status quo analyses are lacking on a larger scale in Europe. This paper offers a status quo analysis of the S&L sector in five European provinces.

METHODS: The data consists of regional status quo reports from Castilla-La Mancha in Spain, Dalarna in Sweden, North Brabant in the Netherlands, Päijät-Häme in Finland, and Vratsa in Bulgaria. Reports were formed using a questionnaire focused on the current state of the S&L sector. In addition, the regional SWOT analysis and good practices were collected. All data was analysed by a content analysis method.

RESULTS: The reports were classified into five categories: strategies and plans, clusters and other organisations, activities, economics, and innovations. The regions emphasised sustainability initiatives, well-being, and digitalization in the S&L sector. Research, development, and innovation activities focused on projects and internationalisation. The regions leveraged strategic planning to create growth opportunities, new businesses, job possibilities and promote tourism. Despite some regions lacking specific S&L strategies, sustainable economic growth was seen as possible by supporting technology adoption and targeted upskilling programmes. In addition, national programmes enhanced the potential for regional development and prosperity. Clusters and organisations fostered innovation and cross-sector collaboration among companies, authorities, academia, and civil society. From the economic growth view, sports from recreational events to major annual competitions, generated millions in direct and indirect turnover. Innovations were driven by investing in recent technologies and green practices. Differences were found in specific activities and economic impacts. Some regions emphasised more major sports events, while others focused on outdoor recreational activities and local sports infrastructure.

CONCLUSION: The S&L industry needs to adapt to the structural and behavioural challenges that a sedentary lifestyle poses for health. By providing holistic support and connecting regional S&L small and medium-sized enterprises (SMEs) to market changes and societal challenges, it is possible to strengthen S&L innovation ecosystems. Facilitating digital and green upskilling supports the S&L enterprises' competitiveness and adaptability. It can enhance significant opportunities for growth, new businesses, and job possibilities, contributing to the overall vitality and prosperity of EU regions. The S&L sector could be encouraged to use regional ecosystem services more intensively.

EXPLORING THE INFLUENCE OF EXPLORATORY ACQUISITION OF PRODUCTS AND EXPLORATORY INFORMATION SEEKING ON EWOM AND IMPULSIVE BUYING BEHAVIOR

WU, Y.T.

SOOCHOW UNIVERSITY

INTRODUCTION: Involvement in sports not only contributes to physical well-being but also promotes interaction socially, impacting individual psychological health. The popularity of modern-day technology has contributed tremendously to how individuals interact with one another, the electronic word-of-mouth (eWOM) has transformed consumer purchasing decisions, particularly in the context of sport brands. Previous studies have found individuals would seek information online before acquiring a product. This study examines the relationships between exploratory acquisition of products (EAP), exploratory information seeking (EIS) on eWOM and impulsive buying behavior, and the mediating role of eWOM toward impulsive buying behavior of sport brands.

Method: This research is grounded in the framework of exploratory behavior-based tendencies (EBBT), this research highlights the dual pathways of EAP and EIS as key precursors to eWOM and their subsequent impact on impulsive buying behavior of brand. A questionnaire was conducted among 359 individuals, after invalid response a total of 299 valid response was recorded, and the data were analyzed using Partial Least Squares Structural Equation Modeling (PLS-SEM).

Result

The results indicated a positive relationship on EAP significantly influencing eWOM; demonstrating how consumers exploratory tendencies drive their engagement and reliance on electronic word-of-mouth and toward impulsive buying behavior while EIS showed no significance with eWOM. However, eWOM showed a positive relationship toward impulsive buying behavior. Furthermore, eWOM exerts a strong positive effect on impulsive buying behavior, emphasizing its critical role in shaping consumer decisions.

Discussion: The findings delivered valuable understandings into the interaction between consumer exploratory tendencies and eWOM, contributing strategic implications for sport brand marketers aiming to foster customers engagement and drive impulsive buying through effective eWOM strategies. EIS showed no significance may focus predominantly on understanding factual or objective information about products rather than sharing or engaging in discussions about them. Consumers determined by EIS might prioritize individual information acquisition over contributing to eWOM. This study contributes to the existing literature by interpreting the pathways linking exploratory tendencies to impulsive buying behavior in the context of sport brands and highlights the significance of leveraging eWOM in modern marketing practices.

ATHLETIC CAREER DEVELOPMENT STRATEGIES AND TRANSITION APPROACHES FROM ELITE YOUTH FOOTBALL TO ELITE FOOTBALL: COACHES BELIEVES

KOVALOV, A., FERNATE, A.

RIGA STRADINS UNIVERSITY

INTRODUCTION: The development process of successful athletes has always been non-linear, multifactorial, dynamic, and with multiple possible outcomes, suggesting that the process is multidimensional and needs to be assessed in a complex manner. In the scientific literature, the transition from youth sport to adult sport is associated with a young person (up to and including 18 years of age) starting a career in adult sport. The onset and duration of this transition period may vary depending on the sport.

The aim of the research is to find out coaches beliefs about athletic career development strategies and transition approaches from elite youth football to elite football.

METHODS: 25 football coaches took part in semi-structured face-to-face interviews online. The interview was developed to evaluate the coaches beliefs about athletic career development strategies and transition approaches from elite youth football to elite football. Open coding was used for data analysis.

RESULTS: There were main themes to find out about athletic career development strategies: talent development, support system, and motivation development. There were main themes about the transition approaches from elite youth football to elite football: challenges during transition in football and in life, strategies for overcoming transition challenges.

Discussion

The transition in a football player's career is a holistic process that involves not only skill, tactical and physical development, but also motivation, social influences, and structured strategies such as goal setting and education. Athletes undergoing transitions experience changes in both their sporting and non-sporting lives. A successful transition in a football career requires a structured, multidimensional approach that includes different skill development, motivation, social influences, and long-term career planning. By integrating individualized training, strong support systems, and mental health resources, athletes can navigate transitions effectively and achieve sustained success in and outside of sports.

THE PROCESS OF RESOLVING COACHING DILEMMAS AND ITS RELATIONSHIP TO PLAYERS LIFE SKILLS

YUKO, T.

KEIO UNIVERSITY

Background: A training environment in which players can speak freely enhances their communication skills and builds team strength (Tokairin, 2024). However, when coaches are focused solely with winning and enforce the exercise of their own coaching authority, they create an environment in which players have difficulty expressing their own opinions. This results in a decline in life skills. Communication that enables athletes to play with a common understanding is especially important in ball games, but inexperienced coaches struggle to find the right balance and are faced with a dilemma.

Purpose: In this study, we conducted a life skills coaching intervention for coaches to create a training environment that takes into account life skills, which have a complementary relationship to athletic performance (Bedir et al., 2023). The purpose of this study was to clarify how coaches change their own coaching authority and how the resulting dilemma impacts players life skills.

Methods: The subjects of the study were a university mens handball coach (27 years old, 4 years coaching experience) and 18 players (age range 18-22) on the team. The life skills coaching interventionist was a researcher (the author) with 11 years of coaching experience who specializes in life skills coaching. The study period was from September, 2024 to February, 2025. Life skills coaching was conducted through e-mail and direct dialogue based on the players current life skills scores. To validate the coaching, a life skills questionnaire (Cronin, L. D., and Allen, J., 2017) was administered to the players before and after the intervention. Semi-structured interviews were also conducted with coaches to investigate psychological changes toward life skills coaching.

Results: One-way analysis of variance analysis of life skills questionnaires before and after the intervention revealed no significant change in any of the scales, including Emotional Skills ($F(1,34)=2.344$, $P=.136$, n.s.) and Teamwork Skills ($F(1,34)=.333$, $P=.568$, n.s.). The results of the interviews with the coaches revealed: 1) Given their past successes, coaches

were very conflicted about being asked to change their coaching. 2) Coaches' mindsets changed from "The most important thing for a college coach is winning," to "While targeting winning competitions, it is also important to help athletes develop as people in order to build a team that is respected by other institutions and supported. In order for that to happen, communication must come from the coach."

Conclusion: Although it can come with conflict, it is important for coaches to be introspective and to evolve in their coaching methodology in order to achieve desirable coaching practices. By incorporating a life skills perspective, the scope of coaching may be broadened and improve both players' empathy and competitive abilities.

THE MOMENTUM OF SOCCER MATCHES

CHAO, Q., HIROYUKI, H.

WASEDA UNIVERSITY

The purpose of this study was to investigate perceptions of soccer players experiences of psychological momentum (PM). In our study aimed to provide insights into how individual PM states and local elements of skill execution influence game momentum. Semi-structured interviews were conducted with five soccer players (three males, two females, average age: 19.8 ± 2.0 years). Interview transcripts were analyzed using an inductive qualitative approach to identify psychological and behavioral patterns associated with different PM conditions.

Findings revealed distinct characteristics across momentum states. Scoring goals, making successful passes, and executing key saves were the most frequently reported triggers of positive PM. In these moments, players experienced heightened confidence, improved concentration, and entry into the zone, leading to enhanced team coordination and decision-making. Neutral PM was associated with maintaining stability, controlling physical and psychological conditions, and preparing for potential momentum shifts. Negative PM, on the other hand, was characterized by increased anxiety, technical errors (e.g., misplaced passes, poor ball control, misjudgments), reduced communication, and a more passive playing style. Players in negative PM states often prioritized safe but less effective actions, limiting their ability to regain momentum.

Additionally, differences in playing styles and positions influenced how players experienced and responded to PM shifts. In positive PM states, the players in different position became more clearly defined, optimizing team functionality. In neutral states, players aimed to sustain consistency while anticipating momentum changes. In negative states, increased pressure often led to hesitation, disorganization, and mistakes.

Overall, findings suggest that PM is a dynamic process influenced by both technical execution and psychological factors. By understanding players experiences and perceptions of PM, coaches may develop targeted interventions to maximize positive PM, mitigate negative PM, and implement strategies to optimize PM during competition.

SPORTS POLICIES AND MANAGEMENT: BETWEEN GROWTH AND SUSTAINABILITY

GIRGINOV, V.

BRUNEL UNIVERSITY LONDON

Growth is a constitutive word in the strategies of sport organisations as they aspire to grow participation, medals and revenue. The quest for growth occurs in parallel with a raising awareness about sustainability and many sport organisations have developed dedicated strategies. The UN Sustainable Development Goals (2015) named sport as an important enabler of the aims of 2030 Agenda. The simultaneous drive for growth and sustainability of sport poses a host of management challenges. Despite new literature on sustainability and sport (Lindsey & Chapman, 2017; McCullough, et al, 2020; Tangen, 2021), debates about sustainable policies and management are still lacking. This study examines the conceptual and practical challenges facing management in making sport sustainable.

The study followed Faber, et al's (2005) conceptualisation of sustainability based on three key properties including (i) what is to be sustained; (ii) the goal orientation of sustainability (i.e., absolute vs relative perspective); (iii) relational implying that something (i.e., sport) is related to its supporting environment. Two case studies of an international (World Athletics) and one national governing body (Paddle UK) with sustainability strategies were conducted (Stewart, 2012). The results suggest that both organisations interpret sustainability differently: WA focused on the environmental dimensions while Paddle UK on the institutional one. Neither organisation offered a clear answer to the question of what they wish to sustain in sport. Visions varied from growing the number of competitions, participants and medals to protecting the environment. WA and Paddle UK showed a relative goal orientation to sustainability by committing to become carbon neutral (i.e., absolute goal) but allowed for other aspects of sport only to become better. Regarding the relationship between sports and their supporting environment, apart from general statements of the positive impact of sport on people and communities, management did not offer ideas of what and how is going to change to become sustainable. Management deals with a composite problem concerning the tensions between the unfettered growth of sport and the need for its sustainable development. The focus of management needs to be on understanding and shaping the interactions between complex adaptive natural systems and sport organisations as socio-economic entities. Sport management ought to prioritize all types of participants as citizens as opposed to treating them as consumers.

Faber, N., Jorna, R., & Van Engelen, J. O. (2005). The sustainability of "sustainability"—A study into the conceptual foundations of the notion of "sustainability". *Journal of Environmental Assessment Policy and Management*, 7(01), 1-33.

IS-PN07 When Ageing Muscles Lose Their Nerve: The Neuroprotective Effects of Exercise

FROM NERVE TO MUSCLE AND VICE VERSA: EXPLORING HOW EXERCISE SHAPES THE MOTOR UNIT

BARALDO, M.

UNIVERSITY OF BASEL

Ageing is associated with ongoing cycles of muscle denervation and reinnervation, resulting in a decline in muscle contractility. Exercise has been shown to mitigate age-related defects at the neuromuscular junction (NMJ), enhancing collateral reinnervation and improving neuromuscular transmission. Nevertheless, elderly and sarcopenic individuals often experience mobility limitations. Consequently, understanding motor unit plasticity and the molecular mechanisms driving these exercise benefits is essential. In this presentation, Dr. Martina Baraldo will share published and unpublished findings on molecular pathways that support neuromuscular stability, particularly focusing on how changes in mechanistic target of rapamycin complex 1 (mTORC1) activity are linked to NMJ maintenance in adult and aged mice. Additionally, the presentation will examine the effects of endurance exercise on the motor unit across untrained and trained states. This research sheds light on acute and chronic responses of motor units to exercise, suggesting potential therapeutic targets for enhancing neuromuscular function in individuals with mobility impairments. These findings open avenues for innovative interventions aimed at improving the quality of life in advanced age.

FLEXING MUSCLES AND STIMULATING NERVES – THE EFFECTS OF HEAVY RESISTANCE EXERCISE ON MUSCLE INNERVATION

SOENDENBROE, C.

INSTITUTE OF SPORTS MEDICINE COPENHAGEN

Heavy resistance exercise effectively increases muscle mass and strength at all ages. However, there remains limited understanding of how, and to what extent, resistance exercise provides neuroprotective benefits, particularly in preventing or slowing the loss of muscle innervation. This presentation will cover what is known about resistance exercise-induced changes in muscle innervation in both healthy and diseased populations. Various biomarkers related to muscle innervation, assessed in either muscle tissue or blood, will be introduced and critically discussed. Special attention will be given to outlining the frontiers of current knowledge in this area, with recent studies leveraging in vitro experiments to offer insights into the cellular mechanisms by which muscle contraction can stimulate a nerve. Dr. Soendenbroe is an equal 5th-place recipient of the ECSS Young Investigator Award, with research interests in muscle innervation, adaptation to exercise and disuse, and cellular crosstalk.

THE NEEDLE IN THE HAYSTACK: INTRAMUSCULAR ELECTROMYOGRAPHY TO UNCOVER CHANGES IN NEUROMUSCULAR FUNCTION WITH AGEING AND EXERCISE

SARTO, F.

UNIVERSITY OF PADOVA

The plasticity of human motor units (MUs) has been widely assessed through in vivo evaluation of their electrophysiological properties. In this presentation, Dr. Fabio Sarto, an ECSS Young Investigator Award Winner (equal 5th) in 2022, will explore the use of intramuscular electromyography (iEMG) to reveal changes in neuromuscular function with ageing and exercise. He will provide an overview of key findings from the literature, highlighting that alterations in MU properties—including reduced firing rate, increased MU potential complexity, and neuromuscular junction (NMJ) transmission impairment—are prominent features of human neuromuscular ageing. Furthermore, several studies employing the motor unit number estimate (MUNE) technique have observed age-related MUs loss. The presentation will also examine the role of sex differences on MU properties. Finally, Dr. Sarto will discuss the controversial evidence regarding the effects of chronic aerobic training on MUNE in humans, as well as the impact of (re)training with resistance exercise on NMJ transmission and MU properties. Overall, this presentation will contribute to a deeper understanding of how neuromuscular function adapts to ageing and exercise, providing insights that complement the cellular and molecular perspectives covered by the other speakers.

Invited Symposium

IS-AP06 Breathing monitoring in sport and exercise: mechanisms, applications and technological solutions

CAN MEASURING BREATHING DURING TRAINING IMPROVE THE TRAINING MONITORING PROCESS?

SEILER, S.

UNIVERSITY OF AGDER

Athletes and coaches intuitively understand that breathing is a truth teller. They use expressions like “catching my second wind”, and “I felt him breathing down my neck” that reflect the sensitivity of athletes to both their own breathing during exercise and the breathing of their opponents as vital information revealing the state of the athlete and their intensity of effort. Breathing, along with heart rate (HR) are indeed vital signs. Historically, exercise ventilation measurements have been reserved for the laboratory, while heart rate has moved into the field as a standard physiological intensity proxy in training monitoring. But do heart rate and breathing frequency provide the same information about intensity, exertion, and effort, with the same adjustment scope and sensitivity? New wearable technologies that make valid and reliable ventilation measurement in general, and breathing frequency in particular, highly accessible in the field are providing unique insight into this fundamental question. Importantly, under field conditions, using wearables that allow normal ventilation, unconstrained by changes associated with the measurement process, data collected during training among professional cyclists demonstrate that: 1) the scope for ventilatory adjustment during high-intensity efforts exceeds the scope for HR adjustment, 2) breathing frequency continues to climb during high-intensity intermittent exercise at times when HR responses become quasi-stable and 3) maximum functional breathing frequency shows substantial individual variation and reproducible peak responses, in a manner similar to maximum heart rate. We argue that breathing frequency monitoring has been successfully translated to practical use in the field, providing unique information about the acute status of an athlete during exercise that is not captured by heart rate. Currently, systematic studies are ongoing with the goal of adding ventilation and breathing frequency to heart rate, blood lactate, and rating of perceived exertion to form a more complete and complementary assessment toolbox in daily training monitoring.

A NEW MODEL OF BREATHING CONTROL DURING EXERCISE

NICOLÒ, A.

UNIVERSITY OF ROME

The correct interpretation of breathing data collected in the field requires an understanding of the different mechanisms involved in modulating breathing depth and frequency. Unlike tidal volume (VT), respiratory frequency (fR) is closely associated with perceived exertion and is sensitive to changes in exercise capacity in different protocols, experimental interventions, and populations. These observations stimulated our interest in investigating the mechanisms controlling breathing during exercise, ultimately culminating in the development of a simple yet effective model that explains how fR and VT are regulated. The main feature of this model is the differential control of fR and VT; fR is substantially modulated by central command (especially during high-intensity exercise) and muscle afferent feedback (especially during moderate exercise) whereas VT is mainly modulated by metabolic inputs. Furthermore, VT is fine-tuned based on fR levels to match alveolar ventilation with metabolic requirements in different exercise-intensity domains. This model has the potential to address mechanistic and practical issues that exercise scientists and practitioners commonly deal with. For instance, it suggests that the extra increase in ventilation observed during high-intensity incremental exercise may not be primarily driven by the progressive development of metabolic acidosis. Indeed, that increase in ventilation is mainly due to the non-linear increase in fR that can only to a minor extent be attributed to metabolic acidosis. Conversely, the magnitude of central command appears to contribute substantially to the fR response observed during incremental exercise. This example shows how our breathing control model can enhance the interpretation of breathing data collected during testing, training, and competitions. Hence, the target audience of this lecture is broad, encompassing: i) researchers interested in the mechanisms underlying ventilatory control and exercise tolerance; ii) scientists and practitioners seeking insight into the physiological rationale for monitoring breathing during exercise; and iii) any researcher or company focused on enhancing the interpretation of breathing data collected in the field.

WEARABLE SENSORS FOR BREATHING MONITORING IN THE FIELD: CHALLENGES AND SOLUTIONS

ROMANO, C.

UNIVERSITÀ CAMPUS BIO-MEDICO DI ROMA

The ever-growing demand for measuring breathing variables during a variety of applications has favoured the development of different wearable sensors that can be effectively used during sporting activities and exercise. From a technological perspective, this is a fruitful area for research and development because there is an abundance of solutions that can be used for this purpose, especially for monitoring breathing frequency. Among these, two contact-based methods are attracting particular attention, i.e. the measurement of breathing-induced torso movements and the extraction of breathing frequency from cardiac signals such as electrocardiogram and photoplethysmogram. Different sensors are suitable for measuring torso movements, including strain sensors that can be integrated into clothes used for training and competition. On the other hand, the extraction of breathing frequency from cardiac signals does not require the use of additional

sensors beyond those already used for heart rate monitoring. However, the suitability of the latter solution may be challenged by motion artefacts, that are sport specific. This talk will provide a state-of-the-art overview of the commercial wearable sensors that can be used in the field for monitoring breathing in different sports disciplines, with a specific focus on soccer and cycling. It will be outlined that it is essential to develop wearable sensors and related algorithms that face the specific challenges offered by different sports settings. The lecture will show how the currently available technological solutions are ready to meet the demands of the field of sport and exercise. The target audience of this lecture includes: i) researchers and practitioners interested in using available techniques to monitor breathing during sport and exercise; and ii) any researcher or company interested in developing or testing wearables specifically designed for sporting activities.

Oral Presentations

OP-BM10 Neuromuscular Function across the Menstrual Cycle

VASTUS MEDIALIS AND VASTUS LATERALIS ACTIVATION AND KNEE EXTENSOR NEUROMUSCULAR FUNCTION ACROSS THE MENSTRUAL CYCLE

NÉDÉLEC, E., O'HANLON, M.2, INNS, T.2, ANSDELL, P.1, HUNTER, A.2, PIASECKI, M.3, PIASECKI, J.2

NORTHUMBRIA UNIVERSITY, UK <1>, NOTTINGHAM TRENT UNIVERSITY, UK <2>, UNIVERSITY OF NOTTINGHAM, UK <3>

INTRODUCTION: Oestrogen and progesterone, the primary female reproductive hormones, have neuroactive properties, with oestrogen eliciting excitatory and progesterone inhibitory influences [1]. However, their effects on neuromuscular function across the menstrual cycle (MC) remain unclear [2]. Muscle force production is mediated by motor unit (MU) recruitment and discharge rate, the effective regulation of which is key for movement control and injury prevention. Female athletes have a higher risk of non-contact anterior cruciate ligament (ACL) injuries compared to male counterparts, which may be a result of impaired neuromuscular function [3]. Despite evidence suggesting hormonal fluctuations may influence this, no study has examined motor control and MU activation in the vastus medialis (VM) and vastus lateralis (VL) across the MC.

METHODS: Ten recreationally active, eumenorrheic females (age: 30 ± 8 years; BMI: 24 ± 2.8 kg/m²) tracked their MCs across a minimum of two consecutive cycles (mean length: 28 ± 3 days), with luteinising hormone surges detected after 14 ± 2 days. Blood samples were collected at the early follicular (EF), pre-ovulatory (Ov), and mid-luteal (ML) phases to measure 17 β -oestradiol and progesterone levels. Knee extensor maximum voluntary contraction (MVC) was recorded, motor control was assessed via isometric trapezoid contractions at 40% and 75% MVC, and via a sine wave task at 25% MVC with real-time visual feedback. A 64-channel high-density surface electromyography (HDsEMG) electrode recorded VM and VL activity at 40% MVC, with root mean square (RMS) EMG calculated as peak amplitude within a 50ms window, expressed as a percentage of max RMS EMG. One-way ANOVA and mixed-effects models were used ($p < 0.05$).

RESULTS: 17 β -oestradiol and progesterone varied significantly across the MC (17 β -oestradiol: EF, 159 pg/ml; Ov, 200 pg/ml; ML, 208 pg/ml; $p = 0.028$; progesterone: EF, 11.96 ng/ml; Ov, 12.11 ng/ml; ML, 39.27 ng/ml; $p = 0.036$). However, no significant differences were found in knee extensor maximal strength (EF, 408 N; Ov, 395 N; ML, 419 N; $p = 0.393$) or normalised VM and VL RMS EMG (VM: EF, 58%; Ov, 49%; ML, 55%, $p = 0.324$; VL: EF, 54%; Ov, 60%; ML, 50%, $p = 0.775$). Neuromuscular control remained stable across MC phases, with no differences in force steadiness at 40% ($p = 0.756$) and 75% MVC ($p = 0.895$) or motor control during the sine wave task (correlation coefficient, $p = 0.199$; normalised AUC, $p = 0.116$).

CONCLUSION: These findings suggest hormonal fluctuations across the MC have minimal influence on VM and VL activation, knee extensor neuromuscular function, and motor control. However, further research is needed to assess individual MU behaviour across different contraction intensities and dynamic tasks to better understand sex-related differences in non-contact ACL injury risk.

THE MAGNITUDE OF THE REPEATED BOUT EFFECT IN FEMALES FOLLOWING MAXIMAL UNACCUSTOMED ECCENTRIC EXERCISE OF THE ELBOW FLEXORS.

RILLING, A., POWER, G.A.

UNIVERSITY OF GUELPH

INTRODUCTION: Neuromuscular function is impaired following an unaccustomed bout of eccentric exercise, however, through the repeated bout effect (RBE) the muscle is protected from damage following a subsequent bout of eccentric exercise. As a result of unaccustomed eccentric contractions, structural muscle damage occurs in both sexes, meanwhile, the inflammatory response may be mitigated in females due to protective effects of estradiol, thereby attenuating the secondary effects of muscle damage and potentially limiting the magnitude of the RBE. We investigated the relationship

between menstrual cycle phase and oral contraceptive use on neuromuscular impairments following the first bout of exercise, and the magnitude of the RBE.

METHODS: Fifteen female participants performed two bouts of 150 maximal eccentric voluntary contractions of the elbow flexors four weeks apart. Normally menstruating females participated during the late follicular phase (day 10-14) of their menstrual cycle, as determined through cycle tracking, when estradiol is near peak, and progesterone is lower. Oral contraceptive users were tested on their placebo pill days (lower estradiol). Neuromuscular function was assessed for Bout 1 before the eccentric protocol and then again 48 hours following, and this was repeated 4 weeks later for Bout 2. The magnitude of the RBE is calculated as the difference between maximal voluntary contractions in bout 1 48hr post-eccentric protocol and bout 2 48hr post-eccentric protocol.

RESULTS: Eccentric exercise-induced muscle weakness and soreness did not differ between groups following Bout 1 ($p > 0.05$), and the magnitude of the RBE ($p < 0.05$) was similar between groups ($p > 0.05$).

CONCLUSION: Females in the late follicular phase (classified as high estradiol) and females on combined oral contraceptives (low estradiol) had similar impairments in neuromuscular function following the first bout of eccentric exercise, and a similar RBE.

IMPACT OF HORMONAL STATUS ON POSTURAL CONTROL AND VIBRATION EXPOSURE IN EXPERT RIDERS

OLIVIER, A., BONNIGAL, J., PROVOST, T., CASTAGNIER, C., COLLOMP, K., TEULIER, C.

INSTITUT FRANÇAIS DU CHEVAL ET DE LEQUITATION

INTRODUCTION: Equestrian sports are dominantly by women and require a highly specific posture. Performance in horse riding result from dynamic interactions between the rider and the horse, which may contribute to musculoskeletal injuries (MSIs), particularly in the spine. Vibrational forces play a key role in both performance and health, potentially exacerbating MSIs. Throughout the menstrual cycle, fluctuations in sex hormone levels primarily estradiol and progesterone are known to influence postural control. However, their specific impact on expert riders, particularly in relation to vibration exposure, has never been investigated.

METHODS: Eight female riders (22 ± 3 years) with regular menstrual cycles were tested on an equestrian simulator during two phases of their menstrual cycle: the early follicular phase (CHF) and the luteal phase (CPG). Five Inertial Measurement Units (IMUs; Shimmers) were placed along the riders spine (7th cervical, 10th thoracic, 3rd lumbar), on the head, and on the simulator. Four variables were computed to assess postural control, including trunk orientation and angular variance. Vibration exposure was analyzed using the root mean square (RMS) of accelerations at the head and along the spine, as well as the total vibration dose at the lumbar level (ISO 2631). Wilcoxon tests were performed to compare the variables between the two menstrual phases.

RESULTS: No significant differences in postural control were observed between menstrual cycle phases ($p = \text{NS}$). However, vibration exposure analysis revealed that the total lumbar vibration dose and the root mean square (RMS) acceleration at the cervical level were significantly lower in the CHF phase compared to the CPG phase ($p < 0.05$).

CONCLUSION: This study suggests that hormonal status influences lumbar and cervical vibrations in expert riders during horseback riding, while postural control remains unaffected. Specifically, vibration attenuation was observed during the luteal phase, when progesterone levels are high. Although further research is needed to clarify the underlying mechanisms, these findings provide valuable insights into both performance optimization and rider health.

HORMONE THERAPY ATTENUATES MENOPAUSE-RELATED IMPAIRMENTS IN CORTICAL NEUROPLASTICITY

ANSDELL, P., SPILLANE, P., OHANLON, M., NÉDÉLEC, E., INNS, T., HAUSMANN, M., PIASECKI, M., GOODALL, S., VINCENT, K., STAGG, C., PIASECKI, J.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: Previous research has demonstrated the neuroactive effects of ovarian hormones across the menstrual cycle [1]; however, it remains less clear how the cessation of hormone production across the menopause influences motor cortical properties. Furthermore, it is currently unknown how nervous system adaptation (neuroplasticity) is mediated by endogenous and exogenous hormones across the human lifespan. Paired associative stimulation (PAS) provides a method of quantifying an individual's capacity for neuroplasticity and offers insight into the pathology of several neurological disorders [2].

METHODS: The menopausal status of 33 participants was classified according to NICE guidelines on the diagnosis and management of menopause, with 12 pre-menopausal females (age: 29 ± 7 years), 7 peri-menopausal females (50 ± 4 years), 7 post-menopausal females (59 ± 10 years), and 7 females using hormone therapy (HT, 53 ± 3 years) taking part in the study. Participants underwent a resting baseline neurophysiological assessment in the first dorsal interosseous muscle, including electrical stimulation of the ulnar nerve and transcranial magnetic stimulation (TMS) of the motor cortex to assess corticospinal excitability, intracortical inhibition (SICI), and facilitation (ICF), as well as the maximum compound muscle action potential (Mmax). Subsequently, a PAS protocol was performed with electrical stimulation at 300% perceptual threshold delivered 25 ms prior to TMS at 120% motor threshold; 200 paired stimuli were delivered at 0.2 Hz, followed by repeated neurophysiological assessments immediately, then 10, 20, and 30 minutes after PAS.

RESULTS: No differences between groups were observed at baseline for corticospinal excitability ($\sim 10\%$ Mmax, $p = 0.941$), SICI ($\sim 40\%$ unconditioned MEP, $p = 0.829$) or ICF ($\sim 150\%$ unconditioned MEP, $p = 0.204$). In response to the PAS protocol,

the one-way ANOVA revealed a main effect of group ($p = 0.024$), whereby pre-menopausal females ($+69 \pm 67\%$, $p < 0.001$) and HRT users ($+48 \pm 32\%$, $p = 0.020$) experienced an increase in corticospinal excitability. In comparison, peri- ($+13 \pm 19\%$, $p = 0.228$) and post-menopausal ($+1 \pm 30\%$, $p = 0.401$) females exhibited no change from baseline.

CONCLUSION: The menopause appears to blunt motor cortical neuroplasticity, with peri- and post-menopausal females experiencing no facilitation of the corticospinal tract following a PAS protocol, compared to their pre-menopausal counterparts. Hormone therapy appears to mitigate this menopause-induced decline, which has implications for a range of populations in health and disease where cortical neuroplasticity is essential for the (re)learning of motor skills in midlife and beyond.

OP-AP45 Coaching III - Endurance Sports

LONG-TERM, LARGE-SCALE OBJECTIVE TRAINING LOAD DATA IN TRIATHLON REVEALS DIFFERENCES BETWEEN TRAINING PHASES AND RACE DISTANCE PREFERENCES BUT NOT SEX OR AGE

WELLS, L., BRUCE, L., HOFFMANN, S.M., KREMER, P., DWYER, D.B.

DEAKIN UNIVERSITY

INTRODUCTION: Typical training load data for age-group triathletes has not been established based on long-term, objective data captured by technology. Establishing the typical TL of age-group athletes from this data may provide opportunities to improve the health and performance outcomes of athletes. Training load quantified through metrics like duration, distance, heart rate (HR), and Training Stress Score (TSS) – a load metric based on Banister's Training Impulse (TRIMP) [2], must be managed effectively to ensure performance optimisation and injury prevention [3]. Existing studies on TL are limited by reliance on subjective recall data [4], small sample sizes [5], or lack of comparison across factors like sex, age, race distance preference, and training phases. These comparisons are important to determine whether coaches may need to adjust the prescribed load across athlete categories.

METHODS: This retrospective cohort study analysed six months of objective training data exported by 95 age-group triathletes (18 female, 77 male) from the TrainingPeaks® training management system. Load metrics included weekly duration, distance, HR, and TSS. Data from 34,731 training sessions were coded for sex, age group, race distance preference, and training phase (General, Specific, Taper/Race/Post, Off-Season). A Generalised Linear Model (GLM) determined whether sex, age, race distance preference, and training phase affected load metrics.

RESULTS: Race distance preference and training phase showed significant differences between TL metrics ($p = < 0.05$), while sex and age did not. Long-course athletes had higher mean weekly TL (574 TSS, 10.25 hrs, 171 km) compared to short-course athletes (452 TSS, 8.45 hrs, 118 km). TL for all phases were significantly different ($p < 0.05$). The Specific phase showed the highest mean TL (620 TSS, 9.27 hrs, 166 km), while the Off-Season was the lowest (364 TSS, 5.67 hrs, 84 km).

CONCLUSION: Male and female athletes had similar TLs, as did athletes of different ages. Long-course athletes and those in the Specific training phase had the highest TL. Coaches and athletes can use these typical age-group loads to compare and adjust absolute TL according to the magnitude of change between training phases and race distance preference. Further research is needed to examine how variations in TL impact performance and injury risk, helping to refine TL guidelines. This study provides the first large-scale, objective TL dataset indicating typical load for age-group triathletes, offering actionable insights for training personalisation.

ROAD TO PARIS: TRAINING CHARACTERISTICS OF A WORLD CLASS MALE TRIATHLETES IN THE YEAR PRIOR OLYMPICS. A QUALITATIVE MULTIPLE CASE STUDY

BUDEL, L., BUTTURINI, J., ZENTI, L., MAGGIO, A., RASTELLI, F., SCHENA, F., TARPERI, C.

UNIVERSITY OF VERONA

INTRODUCTION: The objective of these four case studies is to describe the individual training characteristics of world-class male triathletes in the year leading up to the Olympics. Specifically, the aim is to determine whether periodization and intensity distribution follow common patterns or vary significantly based on individual needs and physiological characteristics.

METHODS: Training & physiological data from four world-class male triathletes (27 ± 4 years, $\text{VO}_{2\text{max}}$: 75 ± 2 $\text{ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$) were analyzed. Two exhibited predominantly glycolytic characteristics, with a lower $\%\text{VO}_{2\text{max}}$ at the anaerobic threshold ($83.7 \pm 0.3\%$), while the other two displayed predominantly oxidative characteristics, with a higher $\%\text{VO}_{2\text{max}}$ ($86.1 \pm 0.2\%$). Day-to-day power meter, GPS, and chronometer data from a 35-week macrocycle were retrospectively analyzed. Training volume, intensity distribution, altitude training, hypoxic exposure, competition schedule, and tapering strategies were considered. Training data were divided into two periods (General and Specific), and the three disciplines (swimming, cycling, running) were analyzed by total time spent in three physiological zones (Z1, Z2, Z3).

RESULTS: Athletes trained 676 ± 22 hours across 610 ± 34 sessions in the final macrocycle before the Olympics, with 87.0% of training below the first lactate threshold (Z1). Intensity distribution shifted from 86.7%, 8.3%, and 4.9% in the general period to 87.3%, 6.9%, and 5.8% in the specific period for Z1, Z2, and Z3, respectively. The polarized index increased from 1.72 to 1.82, indicating a greater polarization closer to the event. More glycolytic athletes exhibited a higher polarized index than oxidative athletes in both periods (1.79 ± 0.42 vs. 1.65 ± 0.00 ; 1.92 ± 0.11 vs. 1.81 ± 0.09). All four athletes trained at altitude for 28, 42, 23, and 25 days; two used a hypoxic tent for 21 and 25 days. Despite different pre-taper strategies, all athletes reduced training volume by $23.3 \pm 8.4\%$ in the week before Olympics without altering frequency or intensity. $\text{VO}_{2\text{max}}$ increased by 2.3% from the general to the specific period, while the second lactate threshold improved by 1.4% (swimming), 5.2% (cycling), and 2.7% (running). Notably, two athletes reached the Olympic podium. Moreover, those who competed in fewer races during the Olympic year performed better at the Games.

CONCLUSION: This study aligns with best practices in the literature regarding training volume and intensity distribution in Olympic-level triathletes. Achieving Olympic qualification and peak performance requires high training volumes, predominantly at low intensity, regardless of physiological characteristics. The most common strategy involves increasing intensity from the general to the specific period, followed by a short taper before competition. However, these best practices must be adapted to individual athlete characteristics. Furthermore, fewer races in the Olympic year appear associated with better Olympic performance.

FOOT STRIKE PATTERN AND SPATIOTEMPORAL VARIABLES ANALYSIS OF ELITE ATHLETES IN THE VALENCIA MARATHON 2021

GÁMEZ-PAYÁ, J., GALLEGU-DE MARCOS, D., ALARCON-JIMENEZ, J., VILLARÓN-CASALES, C., PEREZ-MALETZKI, J.
UNIVERSIDAD EUROPEA DE VALENCIA

INTRODUCTION: The Valencia Marathon is a race with the platinum distinction from World Athletics (WA), with a record of 2:01:48 as the best marathon in Spain according to the Royal Spanish Athletics Federation (RFEA).

There are various biomechanical variables that play a very important role in both running economy and athletic performance of the runners. Among these variables are the foot strike angle (FSA), duty factor (DF), ground contact time, flight time, and running cadence (1). Knowing these variables in the context of an official competition allows us to understand the reality of the athletes performance (2).

The objective of this study is to analyse the foot strike pattern and spatiotemporal variables that describe the running technique of elite marathon runners in a real competition context

METHODS: A biomechanical study of running in the sagittal plane (240Hz) was conducted on the top 48 athletes of the 2021 Valencia Marathon, with times ranging from 2:05:12 to 2:15:59. The sample was divided into two groups: from the 1st to the 24th place (G1) and from the 25th to the 48th place (G2). Two independent observers analysed variables such as: FSA (3), DF (4), running cadence, flexion time, and impulse time. To determine the differences between groups, the Students t-test for independent samples was used for parametric variables, and the Mann-Whitney U test was used for non-parametric variables ($p < 0.05$).

RESULTS: Regarding the FSA, it was observed that 61.5% of the analysed athletes run with a midfoot strike (MFS), 33.3% with a rearfoot strike pattern (RFS), and only 5.2% with a forefoot strike pattern (FFS). No differences were found between groups in terms of foot strike pattern ($p > 0.05$). On the other hand, differences were observed between groups in variables such as contact time (G1: $174\text{ms} \pm 7$, G2: $183\text{ms} \pm 12$, $P > 0.001$), flexion time (G1: $78\text{ms} \pm 6$, G2: $81\text{ms} \pm 7$, $P > 0.05$), impulse time (G1: $96\text{ms} \pm 8$, G2: $103\text{ms} \pm 8$, $P > 0.05$), cadence (G1: $186 \text{spm} \pm 6$, G2: $181 \text{spm} \pm 7$, $P > 0.05$). However, no differences were found in DF (G1: $37\% \pm 3$, G2: $38\% \pm 2$, $P > 0.05$).

CONCLUSION: This study has allowed us to characterize the running technique of elite marathon runners in a real context. Regarding the foot strike technique, it was found that most runners were MFS, results similar to those obtained in other recent studies (2) and contrary to previous studies (5). On the other hand, in a very homogeneous sample of runners, differences were observed in various spatiotemporal variables such as cadence or ground contact time. This contrasts with the equality observed in DF. These results can help coaches understand how their athletes perform relative to their peers and make informed decisions for training planning.

HEART RATE VS. RACE PACE-BASED PRESCRIPTION TRAINING: WHICH TRAINING METHOD LEADS TO INTENDED EXECUTION IN RECREATIONAL DISTANCE RUNNERS?

RANIERI, L., DEL COSO, J., JIMÉNEZ, A., GARCÍA-ORTIZ, C., SOLANO, V., CASADO, A.
UNIVERSIDAD REY JUAN CARLOS - CAMPUS DE FUENLABRADA

INTRODUCTION: Various training prescription methods are employed to optimize endurance performance. Conventional methods are based on physiological responses, such as heart rate (HR) associated with ventilatory thresholds (VT1 and VT2). On the other hand, the race pace-based (RP) method offers a practical alternative by considering training zones relative to percentage ranges of maximum performance pace in specific events (1).

Therefore, the aim of the present study was to compare the time spent in prescribed intensity zones (i.e., adherence) between HR- and RP-based training prescription methods during both low-intensity continuous and high-intensity interval training (HIIT) sessions in recreational distance runners.

METHODS: Thirty-seven recreational endurance runners (20 males, 41 ± 8 years; 17 females, 37 ± 10 years) underwent an incremental test to determine VT1 and VT2, and maximal oxygen uptake ($\text{VO}_{2\text{max}}$). $\text{VO}_{2\text{max}}$ was $56 \pm 7 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ for males and $51 \pm 5 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ for females. Additionally, time in a 5-km time trial (TT) performed at an athletics track was measured.

Runners completed two types of training sessions using both HR- and RP-based methods in a randomized controlled crossover order: a 45-min continuous low-intensity session and an 8x500m HIIT session with 90 sec of rest between repetitions. Intensity in the low-intensity training session was prescribed up to the HR associated with VT1 through the HR-based method and up to 80% of TT average pace through the RP-based method. For the HIIT session, intensity was prescribed at 95-100% of the maximum HR achieved during the $\text{VO}_{2\text{max}}$ test through the HR-based method, and at 105-110% of the TT average pace through the RP-based method. Paired t-tests and Wilcoxon tests were used to compare both prescription methods, and Cohens d was employed to analyse the effect size. The level of significance was set at $p < 0.05$.

RESULTS: HR-based training prescription of the 45-min low-intensity session yielded significantly greater adherence ($p = 0.002$, $d = 0.7$, $85\% \pm 23$ of session time) than RP-based method ($69\% \pm 21$). Similarly, for the 5x800m session, adherence was significantly higher ($p < 0.001$, $d = 0.7$) through HR- ($41.4\% \pm 19$) than RP-based prescription ($27\% \pm 14$).

CONCLUSION: The training prescription method influences time spent in prescribed intensity zones, potentially altering the training stimulus from what was intended. The HR-based approach results in greater time spent in the prescribed intensity zones for both low-intensity continuous and HIIT sessions. In contrast, RP-based training, despite its relative simplicity in prescription, leads to a short time spent in the target intensity zones, particularly during HIIT sessions.

SUCCESS AND FAILURE, OUR GAIN-RESEARCH ON THE KEY FACTORS OF IMPROVING HIGH PERFORMANCE OF ROWING TRAINING

ZI, W., LUO, C., ZHANG, X.Y.
CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Chinese rowing has only won two gold medals from Womens Quadruple Sculls in Olympic Games since 1980s. The same crew, who won gold medal in Tokyo, just got sixth place in Paris, which indicates weekpoints Chinese Rowing Coaches have not found key factors of performance enhancement in training. To finding out the key factors, this research reviews training plans between Tokyo and Paris Olmpyc Games of Chinese Women's Quadruple Sculls, analyzing training load, key physical ability and W4x performance during both cycle.

METHODS: Using tracking method, this research focus on the training of Chinese Women's Quadruple Sculls for two Olympic cycle. The related rowers(age: 29.1 ± 1.4 y, height: 183.3 ± 3.0 cm, bodyweight: 78.0 ± 4.5 kg) are all Olympic gold medalists. Training load data of 7 years (2018-2024) are recorded including rowing and rowing ergometer mileage, total training time of all kinds of training, training intensity distribution divided by low-, moderate- and high-intensity based on first and second lactate point. Key physical abilities such as maximum strength, aerobic threshold(P2) and anaerobic threshold(P4), rowing ergometer 2km performance(Erg2k) and W4x performance(W4x-2k) during both cycle are recorded too.

RESULTS: The last year of both Olympic cycle had the same length and are divided into two macro-cycles and five meso-cycles. Compared to the Tokyo cycle, 1) there were average 17.7km/week more rowing training and 1.13h/week more weightlift training while 10.8km/week less rowing ergometer training and 0.89h/week less core&functional training for a year in Pairs cycle; 2) training intensity distribution of a year both showed pyramid mode, while comparing each meso-cycle between both indicated unclear goals in Pairs; 3) maximum strength of lower and upper body were increased by 7kg (a rate of 6.07%) and 5.75kg (a rate of 6.76%) respectively, meanwhile aerobic threshold(P2) and anaerobic threshold(P4) both decreases by 22.6W (a rate of 9.27%) and 12.2W (a rate of 4.38%) respectively from Tokyo to Pairs; 4) the performance of rowing ergometer of 2km decreased by 0.8s (a rate of 0.2%) while the performance of W4x performance of 2km decreased by about 14s from Tokyo to Pairs.

CONCLUSION: 1) Rowing training volume is important but not the more the better. Rowing ergometer training should be paid more attention to develop or maintain fitness. 2) Maximal strength should not be developed continuously through the

whole year, because forces on blades have optimal range rather than bigger. Core&functional training is essential for strengthening the trunk and body posture, which can be the support for good rowing technique and applying the force on blades. 3) Problems of training intensity arrangement are hard to inspect from perspective of macro-cycle, but more easy to detect from at least meso-cycle, which means training intensity monitor should be more detailed. 4) Aerobic capacity is the most important factor of rowing performance, especially the power around first lactate point.

Invited Symposium

IS-PN09 Energy intake limitations in athletes: from Caloric Restriction to Time Restricted Eating

THE EFFECT OF LOW ENERGY AVAILABILITY ON SKELETAL MUSCLE: POSSIBLY NOT WHAT YOU THINK

ARETA, J.

LIVERPOOL JOHN MOORES UNIVERSITY

Low energy availability is typically vilified in the contemporary mainstream scientific literature as a factor negatively affecting sports performance. However, there is a lack of well-controlled, unbiased studies showing positive or negative effects of acute or chronic low energy availability on performance. Importantly, beyond the potential decrease of skeletal muscle glycogen in diets with low energy availability, there is nearly no mechanistic evidence providing explanations on how low energy availability may affect skeletal muscle, a key tissue for physical performance. To provide some insights in this under-explored area, this talk will provide an overview of the effects of low energy availability on skeletal muscle and show findings of our research on skeletal muscle proteomics of healthy exercising men exposed to pronounced low energy availability. We show that a short (5-day) exposure to energy availability of 10 kcal/kg FFM/day produces a significant shift in skeletal muscle proteome, resulting in a coordinated increase of mitochondrial proteins and key metabolic proteins, while reducing the expression of key proteins of the extracellular matrix and cytoskeleton. Is this positive or negative? Difficult to tell, though the findings are aligned with positive effects of energy restriction in maintenance of function in life-long caloric in a number of animal models, showing improved healthspan and lifespan.

ENERGY COMPENSATION: WHERE DOES THE ENERGY GO?

DOLAN, E.

UNIVERSITY OF SAO PAULO

Athletes sometimes consciously plan to induce an energy deficit in an attempt to attain a desired body mass or composition. This could involve increasing exercise energy expenditure by increasing the training load, reducing energy intake via caloric restriction, or a combination of the two. Total energy expenditure comprises the sum of various process, including resting metabolic rate, the thermic effect of food and activity energy expenditure, which includes both exercise expenditure and non-exercise activity thermogenesis (NEAT). Increasing training load in an attempt to increase total energy expenditure assumes that caloric expenditure between these processes is additive, however this assumption has been challenged, and the Constrained Model of Total Energy Expenditure posits that across the long-term, increasing activity energy expenditure may not necessarily lead to a commensurate increase in total energy expenditure, but instead, may trigger compensatory energetic savings in other processes. But could this really be true for elite athletes, whose estimated training energy expenditure may exceed all other processes combined? Within this talk, I will describe concepts related to energy constraint and compensation, from the point of view of elite athletes. Key questions to be addressed include whether total energy expenditure is additive or constrained, the mechanisms and nature of energy compensation, and the specific processes from which compensatory energy savings might arise to offset increases in exercise energy expenditure. I will also discuss the practical implications of energy constraint and compensation for athletes who purposefully increase training load in an attempt to induce an energy deficit and lose weight, along with the potential health and performance related consequences of energy compensation for athletes.

TRAIN, EAT, FAST: TIME RESTRICTED EATING FOR ATHLETES

PAOLI, A.

UNIVERSITY OF PADOVA

Time-restricted eating (TRE), a dietary strategy that confines food intake to specific time windows, has gained recognition as a potential approach for optimizing athletic performance and recovery. TRE has been shown to influence key physiological processes critical for athletes, including metabolic flexibility, hormonal regulation, and inflammation modulation. Thus, this time-related energy intake limitation may represent a hormetic stimuli for human organisms. This presentation reviews the latest evidence on TRE in athletic populations, focusing on its effects on performance, body composition, and recovery. Key findings include enhanced fat oxidation, preservation of lean muscle mass, and improvements in metabolic health markers, particularly when TRE is integrated into structured training regimens. Our findings indicate that, in resistance-trained athletes, long-term TRE improves inflammatory markers and increases muscle strength without significant changes in muscle mass. Additionally, preliminary evidence for our laboratory suggests that TRE may positively influence immune responses to training in endurance athletes. While TRE shows promise, its application in high-performance sports requires careful consideration of factors such as meal timing, energy intake, and training demands. This presenta-

tion also addresses a critical gap in the literature: although substantial evidence exists for the health benefits of TRE, there is limited research on its direct effects on athletic performance. To explore the rationale for using TRE in athletes, this talk will dissect the physiological and biological mechanisms—such as the repeated, moderate increase in ketone bodies during fasting periods—that may modulate the body's responses to the combined effects of fasting and exercise. Targeted at sports scientists, nutritionists, coaches, and athletes, this work contributes to the evolving field of nutritional periodization and highlights TRE's potential role in enhancing athletic performance and overall health.

VELOCITY-DEPENDENT NEUROMUSCULAR EXCITATION OF HIP EXTENSORS IN SPRINT-TRAINED ATHLETES

HEGYI, A., LÉBOUF, F., PÉTER, A., SARCHER, A., NORDEZ, A., RABITA, G., GUILHEM, G., LACOURPAILLE, L.

1HUNGARIAN UNIVERSITY OF SPORTS SCIENCE; 2LABOMIP NANTES; 3CHU NANTES; 4INSEP PARIS

INTRODUCTION: In running, hip extensors such as the gluteus maximus (Gmax) and the hamstrings contribute significantly to forward acceleration of the body, particularly at high running speeds (1). Among the hamstrings, hypertrophy after sprint-specific training is more pronounced in the semitendinosus (ST) and biceps femoris long head (BFlh), than in the semimembranosus (SM) (2). This can be partly explained by the different architecture of these muscles (3). However, the effect of non-uniform muscle hypertrophy on hip extensor torque has not been investigated. In addition, non-uniform distribution of muscle activation between the hip extensors may also contribute to the non-uniform adaptations to long-term training. In this study we hypothesized that the torque-angular velocity relationship would differ between power and strength-trained athletes. We also hypothesized that the excitation of Gmax, ST, and BFlh would increase with increasing hip extension angular velocity on a dynamometer, which was not expected in SM.

METHODS: Thirteen competitive track and field athletes from sprint-based disciplines and 14 matched strength-trained controls participated in this study. Hip extension torque and electromyography (EMG) activity of the Gmax, ST, BFlh, and SM were recorded during maximal intensity isometric (50 deg hip flexion) and concentric contractions at 60, 120, 180, and 240 deg/s angular velocity when the dynamometer range of motion was 70 deg to -20 deg (neutral position = 0 deg). The knee was fixed at 40 degrees of flexion. The hip joint angle was measured using 3-D motion analysis to match the hip range of motion between individuals. Torque and EMG activity for each muscle and their interactions were compared between groups and contraction velocities.

RESULTS: There was no difference in isometric torque between the groups, but concentric torque was higher in the sprinting group than in the strength-trained group, especially at high angular velocities ($p < 0.05$). In the strength-trained group, EMG activity did not increase in any of the muscles with increasing contraction velocity. In the sprinting group, EMG activity increased in all muscles with increasing contraction velocity ($p < 0.01$). However, there was a significant muscle*velocity interaction, with an increase in hamstring EMG activity being most pronounced in the BFlh and ST as compared to a smaller increase in the SM.

CONCLUSION: Our results suggest that the velocity-dependent neuromuscular excitation pattern of the hamstrings is unique to sprint-trained athletes, which may explain why ST and BFlh show preferential hypertrophy after sprint-specific training. It appears that the ability of hip extensors to produce torque at high running speeds is a combined result of superior muscle volume and superior muscle excitation of muscles with a relatively low pennation angle.

MUSCLE SHAPE COMPARISON OF THE PLANTAR FLEXOR MUSCLES BETWEEN HIGH-LEVEL SPRINT AND DISTANCE RUNNERS

KOVÁCS, B., PÉTER, A., TIHANYI, J., KÓBOR, I., GYEBNÁR, GY., HORTOBÁGYI, T., HEGYI, A.

HUNGARIAN UNIVERSITY OF SPORT SCIENCE

INTRODUCTION: Plantar flexor muscles exhibit inter-individual variations in muscle bulging patterns during muscle contraction (1). Muscle shape affects its force production capacity, and different shapes may benefit the specific requirements of the sport. Sprint running requires higher propulsive forces, while distance running requires efficient muscle function over prolonged durations. While plantar flexor muscle volume has already been compared between sprinters and distance runners, these measures lack sensitivity to regional shape differences. This study aimed to compare the shape of plantar flexor muscles between sprinters and distance runners.

METHODS: Fourteen sprinters (IAAF score: 983 ± 110 , 5 females) and fifteen distance runners (IAAF score: 953 ± 116 , 5 females) were recruited. The 3-D muscle volume of the plantar flexor muscles was reconstructed by scanning the right leg

using T1-weighted magnetic resonance imaging. Muscle segmentation was performed manually to establish muscle boundaries and to generate the 3-D mesh of the muscles. Statistical shape modeling (2) was used to compare the differences in the group average shape of the medial (MG) and lateral gastrocnemius (LG) and the four compartments of the soleus for male and female athletes.

RESULTS: MG muscle shape was similar in the male distance and sprint runners, but female sprint runners had significantly larger proximal and distal MG (36.44% of the total vertices) compared to female distance runners. LG was more expanded across the length of the muscle on both the dorsal and frontal sides, with 30% of the total vertices showing this expansion in male sprinters compared to male distance runners. Similarly, female sprint runners had larger LG at the proximal and distal ends of the muscle (14.36% of the total vertices). We observed statistical differences in the average shape of the four compartments of the soleus at a few minor locations in both male and female runners.

CONCLUSION: This study provides novel insights into the differences in the plantar flexor muscles' shape between elite sprint and distance runners. Future research should investigate the functional implications of these differences and their relationship to performance. We further encourage longitudinal studies to understand training-induced changes in muscle shape.

ACUTE EFFECTS OF PLYOMETRIC, BALLISTIC, AND MIXED WARM-UPS ON KINEMATICS AND KINETICS DURING SPRINT RUNNING

CHUANG, W., NAGAHARA, R., FUCHS, P.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Plyometric and ballistic exercises incorporated into warm-up protocols have been reported to enhance sprint performance [1,2]. However, previous research often used these terms interchangeably while implementing exercises that combined both concepts [1,3,4]. These two concepts stimulate distinct neuromuscular adaptation mechanisms such as stretch reflexes in plyometric versus motor unit recruitment in ballistic exercises. Given the debated implications of isolating these concepts (e.g., non-ballistic plyometric exercises) [5], understanding their individual effects and contributions to sprint performance is important. This study aimed to investigate the acute effects of distinct plyometric and ballistic warm-ups in sprinting.

METHODS: Fifteen collegiate sprinters (height: 1.74 ± 0.05 m, weight: 67.7 ± 4.03 kg, personal best back squat: 130.0 ± 21.7 kg) completed four sessions in randomized order, separated by 24 hours. Each session included 5 minutes of low-intensity jogging, followed by one of four protocols (traditional as control, plyometric, ballistic, or mixed plyometric-ballistic) and two preparatory sprints before a single 40-m sprint for data collection. Kinetic and spatiotemporal data as well as split times at 10, 20, 30, and 40 m were obtained via 54 force plates embedded in a tartan track. Repeated-measures one-way ANOVA examined effects of warm-ups, with a significance level of $\alpha = .05$.

RESULTS: Of the 13 tests conducted, only one revealed a significant effect of warm-ups: step length at 40 m ($p < .05$, $\eta^2 = .21$), where step length was greater in the plyometric (2.19 ± 0.14 m) than in the mixed protocol (2.11 ± 0.14 m) in Bonferroni-corrected pairwise comparison ($p < .05$). No effects were found for maximum horizontal force and power output ($p = .35 - .46$, $\eta^2 = .06 - .07$), contact and flight times at the start and 40 m, step length at the start ($p = .10 - .85$, $\eta^2 = .02 - .14$), and any split times ($p = .38 - .79$, $\eta^2 = .03 - .07$). Other pairwise comparisons also showed no significant differences ($p = .07 - 1$).

CONCLUSION: The findings suggest no clear superiority of plyometric and ballistic over traditional warm-ups. The sole statistically significant result (step length at 40 m) may reflect a type I error rather than practical relevance. Contrary to previous reports [1-4], these results question whether plyometric and ballistic warm-ups provide substantial benefits over traditional methods. The protocols employed in previous studies [1,3,4] suggest that previously observed advantages might be due to suboptimal control protocols that did not adhere to best practices. Further research is necessary to validate or refute the benefits of plyometric and ballistic warm-ups compared to well-designed traditional protocols.

LEG MUSCLE ACTIVATION UNDER FULL AND PARTIAL TOWING ASSISTANCE IN SPRINT RUNNING

KAMANDULIS, S., SKUJYTE, A.1, GENITRINI, M.1, SATKUNSKIENE, D.1, SILINSKAS, V.1, LUKONAITIENE, I.1, BRADAUSKIENE, K.1, SAMOZINO, P.2

1 LITHUANIAN SPORTS UNIVERSITY, 2 UNIVERSITY SAVOIE MONT BLANC, FRANCE

INTRODUCTION: Research on sprint adaptation has focused on optimizing performance through various training methods (Van Den Tillaar & Gamble, 2017). Among these, assisted sprinting has been studied for its potential to enhance speed via neuromuscular adaptations (Cecilia-Gallego et al., 2022). However, there is concern that muscle activation during supra-maximal sprinting may not be optimal due to passive contributions from external towing forces.

The present study compared fully assisted sprinting with partially assisted sprinting, where assistance was applied until approximately 0.5 m/s below the athletes supra-maximal speed, after which the impact of the towing force diminishes to zero, allowing the athlete to continue unassisted. This technique may require greater voluntary effort. It was hypothesized that partially assisted sprinting would increase propulsive muscles activation.

METHODS: Fourteen male students from different sports (age: 21.3 ± 1.3 years, body mass: 81.5 ± 8.3 kg, height: 1.86 ± 0.06 m) performed full-assisted, partial-assisted, and unassisted (free-run, control condition) 30-m sprints in a randomized order within a single session. A motorized device provided precise assistance load. Sprint times and EMG activity of the Rectus Femoris (RF), Vastus Lateralis (VL), Semitendinosus (ST), Biceps Femoris (BF), and Gluteus Maximus (GM) were compared across conditions. Additionally, stride length, stride frequency, contact time, and flight time were recorded for each condition using Optojump.

RESULTS: Running speed over the 30-m sprint was higher in both assisted conditions compared to the unassisted condition (unassisted vs. partly assisted: $p < 0.01$; unassisted vs. fully assisted: $p < 0.001$). This increase in speed resulted mainly from a significantly greater stride length in both assisted conditions compared to the unassisted condition ($p < 0.001$ for both comparisons).

In both partially and fully assisted condition, ST ($p < 0.01$) and BF ($p < 0.001$) showed greater activation before initial contact (late swing phase) compared to the unassisted condition. Additionally, VL activation was significantly higher in the fully assisted condition during early stance (knee flexion) compared to the unassisted condition ($p < 0.05$). However, no significant differences were found between the partly and fully assisted conditions.

CONCLUSION: The absence of significant muscle activation differences between the partly and fully assisted conditions suggests both techniques provide similar neural drive, sufficient to enhance sprinting performance, as evidenced by higher sprint speed and greater stride length compared to the unassisted condition. These findings highlight how assistance levels influence neuromuscular demands and can be applied in training.

LOADED JUMP SQUAT EFFICACY IN FEMALE SPRINTERS

POMPA, D., DI PINTO, G., ZUCCARINI, G., BEATO, M., BERTOLLO, M.

UNIVERSITY G. DANNUNZIO OF CHIETI-PESCARA

INTRODUCTION: Recently, an athlete's momentum, the product of change in velocity and the athlete's body mass, has gained attention in strength training literature, particularly in loaded jump squat(1) (LJS), sprinting, and agility(2). LJS can stimulates neuromuscular adaptations, while system momentum (SM), which also accounts for the lifted load, serves a useful metric for individualized training.

This study examines the relationship between position and load on the SM/Impulse ratio (jump efficacy) and system momentum (SM) in sprinters

METHODS: We recruited 10 highly trained(3) female sprinters with highly advanced resistance training status(4), and daily exposure to barbell LJS using the Smith machine. Each athlete performed three trials at individual 90-degree position with additional loads of 0.6- and 1.2- bodyweight (BW), followed by the same sequence at a parallel squat position. Positions were counterbalanced across participants, with athletes aiming to jump as fast and high as possible. A force platform synchronized with a linear encoder transducer, sampling at 1000 Hz, recorded force-time metrics and barbell velocity, respectively. The outcome measures collected were Impulse, SM, and the jump efficacy, which were processed using a customized MATLAB script. A linear mixed model (LMM) analysis was conducted using R version 4.4.2. Load and position were included as fixed effects for marginal estimates, while athletes were modeled as random effects to account for inter-individual variability

RESULTS: LMM results for jump efficacy show significant effects for both position ($t = -7.29$, $p < .001$, $d = -2.81$) and loads ($t = -8.39$, $p < .001$, $d = -3.23$) but not for the interaction ($p = .14$). Pairwise comparisons indicated that LJS90° with 0.6 BW load was the condition with the greatest efficacy ($p < .001$), whereas the LJSparallel with 1.2 BW demonstrated the lowest the least efficacy ($p < .001$). For SM, the analysis revealed a significant main effect of BW ($t = 3.30$, $p = .003$, $d = 1.27$), while neither positions nor the interaction effect reached significance. Subsequent pairwise comparisons showed that SM was significantly higher in the LJS90° 1.2BW condition compared to LJS90° 0.6 BW ($p = .016$). The marginal R^2 values indicate that load

and position explain 84.7% of the variance in jump efficacy and 12.3% in SM. The random effects contribute 5.0% to jump efficacy and 48.9% to SM, highlighting greater inter-individual variability in SM

CONCLUSION: Although the momentum equals the athlete's applied impulse, the impulse-momentum relationship seems inapplicable to LJS at different loads. Female sprinters struggle to convert ground impulse into bar velocity, even with a guided Smith machine, supporting the idea that jump efficacy reflects short-term coordination rather than direct impulse transfer. High inter-individual SM variability highlights the complexity of momentum generation in LJS and the need for individualized training

NEUROMUSCULAR FATIGUE IN RECREATIONALLY STRENGTH- AND ENDURANCE-TRAINED YOUNG MALES

WU, R., DE VITO, G.2, LUO, W.3, JIANG, J.3, SHAO, C.3, CHEN, X.3, WANG, D.3, LOWERY, M.M.1

1 UNIVERSITY COLLEGE DUBLIN, IRELAND; 2 UNIVERSITÀ DI PADOVA, ITALY; 3 SHANGHAI UNIVERSITY OF SPORT, CHINA

INTRODUCTION: Neuromuscular fatigue may be defined as an exercise-induced reduction in the force-generating capacity of muscle (1). It is a complex phenomenon involving a range of neural and muscular mechanisms. Previous research has suggested that there is a difference in the functional organization of the neuromuscular system between strength-trained (ST) and endurance-trained (ET) males (2), which may lead to different neuromuscular responses to fatigue. Research into the effects of fatigue in differentially trained individuals has mainly focused on dynamic exercise, whereas studies on sustained isometric fatiguing tasks remain limited. These can provide a paradigm in which the contribution of individual mechanisms may be more easily observed. The aim of this study was to assess the neuromuscular fatigue in recreationally ST males and ET runners during a sustained submaximal isometric knee extensor contraction.

METHODS: Eleven ST (21.5 ± 2.9 yr) and 11 ET (19.8 ± 2.4 yr) males volunteered for the study. Participants performed maximal voluntary isometric contractions (MVICs) of the knee extensors before and immediately after submaximal isometric knee extension at 30% MVIC until task-failure. High-density surface EMG was simultaneously recorded from the vastus lateralis muscle. EMG root mean square (RMS), median frequency (MDF) and muscle fibre conduction velocity (MFCV) were estimated. RMS and MDF post-fatigue were normalized with respect to their pre-fatigue MVIC values. RMS%, MDF% and MFCV were examined at intervals corresponding to 10% of the contraction time.

RESULTS: ST were 43% stronger ($p < 0.01$) than ET with a higher BMI (24.7 vs 21.1 kg/m²; $p < 0.001$). No differences were observed in post-fatigue MVIC (20.6 vs 22.5 %) or time-to-failure between groups. However, MDF% decreased by 8.7% in ST, while it remained unchanged in ET ($p < 0.05$) in post-fatigue MVIC. During the fatiguing task, MFCV was lower in ET compared to ST (4.4 vs 4.7 m/s, $p < 0.05$). Moreover, the linear mixed model revealed a decrease in MFCV ($p < 0.05$) and MDF% ($p < 0.001$) in ST, whereas they were unchanged in ET throughout the contraction. The increase in RMS% was similar between the two groups ($p < 0.001$).

CONCLUSION: In this study, both groups exhibited similar time-to-failure or reductions in MVIC%. However, ST showed a decrease in MDF% and MFCV during the fatiguing task, whereas ET remained unchanged. Additionally, MFCV was higher in ST compared to ET, suggesting that the muscle fibres with a larger cross-sectional area were recruited in ST. These findings indicate that while submaximal isometric fatiguing task induced comparable fatigue in both groups, the underlying neuromuscular fatigue mechanisms differ, likely due to a greater percentage of type II fibres and/or a greater relative area of type II fibres in ST.

SEX-DIFFERENCES IN THE ACUTE AND SHORT-TERM RESPONSES AFTER A RESISTANCE TRAINING SESSION IN BENCH PRESS

BACHERO MENA, B., SÁNCHEZ MORENO, M., RODILES-GUERRERO, L.

UNIVERSITY OF SEVILLE

INTRODUCTION: Sex differences in performance fatigability of limb muscles are specific to the task demands, and can vary according to the contraction type, speed and intensity or the involved muscle groups (1). In this line, research has consistently shown that women experience less fatigue than men during and in response to isometric and slow, dynamic-contraction tasks (performed at the same relative intensities) (2); however, less is clear about fast-dynamic contractions. In

addition, monitoring velocity loss (VL) throughout a set provides accurate information about the level of effort generated during the training session (3). This study aimed to compare the acute and short-term mechanical and metabolic responses in women and men with similar levels of strength performance (4) after a resistance training (RT) session in bench press (BP) exercise.

METHODS: Thirty-one participants (16 women and 15 men) performed a single RT bout in BP exercise: (load: 70% of one-repetition maximum (1RM), sets: 3, velocity loss VL: 50%, rest: 3 min). Before the performing protocol a previous session was carried out to obtain the 1RM and individualized load-velocity relationship. Measurement session involved recordings at different time points: pre-exercise (Pre), post-exercise (Post), 10-minute post (Post-10), and 24-hour post (Post-24), of different variables: mean propulsive velocity (MPV) of the load of 60% 1RM in the BP (Load-60) and lactate. In addition, the number of repetitions in each set and the total number of repetitions were registered and analyzed.

RESULTS: No significant "Sex $\times$ time" interaction was found for any variable. However, the lactate displayed a tendency toward a significant "Sex $\times$ time" interaction ($p=0.07$), with higher increments for men compared to women. A significant "Time effect" ($p<0.001$) was obtained for MPV Load-60, with a similar response in women and men in Post and Post-10 with respect to Pre ($p<0.001$), and both sexes were recovered at Post-24. A significant "Sex effect" was reported for total repetitions ($p=0.019$), women completed significantly more repetitions in set 2 (8.3 ± 2.0 vs. 6.9 ± 1.3 ; $p=0.03$), set 3 (7.6 ± 1.9 vs. 6.1 ± 1.0 ; $p=0.01$), and during all session (24.8 ± 5.1 vs. 21.1 ± 2.7 ; $p=0.019$).

CONCLUSION: Our results provide evidence about sex-differences in the acute and short-term fatigability after a BP training session when equalizing the strength performance level, the intensity, and volume through VL. Although no significant differences between sexes were found in the mechanical response at different time points, higher metabolic responses were observed for men compared to women, despite the higher number of repetitions performed by women.

COMPARING THE EFFECTS OF LOCOMOTOR MUSCLE FATIGUE AND MENTAL FATIGUE ON ENDURANCE PERFORMANCE IN CYCLISTS: A RANDOMIZED CROSS-OVER STUDY

SENATORE, T., ELIPANNI, L., MARCORA, S.
UNIVERSITY OF BOLOGNA

INTRODUCTION: This study compared the effects of mental fatigue and locomotor muscle fatigue on endurance performance, perception of effort and physiological responses in a group of well-trained and elite cyclists.

METHODS: Seven performance level 4 and three level 5 (21.8 ± 2.7 yrs, 8 Male 68.4 ± 2.5 VO₂Max and 438.8 ± 50.1 PPO, 2 Female 58.7 ± 5.4 VO₂Max and 335.0 ± 14.1 PPO) have been recruited for this study. During the first visit to the laboratory, all participants performed an incremental ramp test on a cycle ergometer to determine the respiratory compensation point (RCP), VO₂Max and Peak Power Output (PPO). In the subsequent three visits, participants performed TTE at the power corresponding to 95% RCP under three different conditions: 1) Mental fatigue (MF) induced by a 1-hour psychomotor vigilance task (PVT); 2) Locomotor muscle fatigue (LMF) induced by a 100-drop jumps protocol; 3) Watching documentaries was used as a control condition. The order of the three visits was randomly assigned. Physiological and psychological responses measured during the TTE test included heart rate (HR), VO₂, ventilation, blood lactate concentration (La) and rating of perceived exertion (RPE). Manipulation checks included maximal voluntary contraction (MVC) of the knee extensors, PVT performance and perceived physical and mental fatigability scales. One-way (condition) or two-way (condition $\times$ time) repeated measure ANOVAs were used to analyse the data. Significance was set at $p<0.05$. The individual isotime method 1 was used to analyse the responses to the TTE test.

RESULTS: Manipulation checks revealed mixed results, with only PVT performance influenced by MF ($p<0.001$) and only perceived physical fatiguability affected by LMF ($p<0.001$). No significant differences in TTE were found between conditions (Control 989 ± 122 s, MF 1019 ± 137 s, LMF 973 ± 145 s, $p=0.876$). The RPE and HR at individual isotime in the LMF condition tended to be higher compared to the control condition but these effects were not significant ($p=0.081$ and $p=0.090$). No significant effects were found for the other physiological responses.

CONCLUSION: The results of this study confirm previous investigations 2 suggesting that well-trained and elite cyclists are resistant to the negative effects of MF. The current study also suggests that well-trained and elite cyclists may also be resistant to the negative effects of LMF experimentally induced in the laboratory. Larger studies are required to confirm these findings and to investigate the "dose" of MF and LMF that may eventually reduce the performance of high-level cyclists.

EFFECTIVENESS OF THE METHODS FOR ASSESSING PHYSICAL READINESS IN PREDICTING AEROBIC EXERCISE PERFORMANCE

MICHELI, L., GROSSI, T.1, IMPERIO, M.1, BRINK, M.2,3, KROEZE, M.2,3, PERIN, E.1, FERRI MARINI, C.2,3, LUCERTINI, F.1
 1 UNIVERSITY OF URBINO CARLO BO; 2 UNIVERSITY OF GRONINGEN; 3 UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: Assessing and monitoring an individuals readiness to exercise is essential for optimizing training programs, as it provides valuable insights into fatigue and fitness levels, and helps prevent overtraining [1]. Although several tools are available to assess fatigue, readiness indicators are poorly defined, with most studies focusing on their association with previous training load, neglecting their ability to predict future performance [2]. This study aims to assess whether readiness tools may predict future aerobic performance.

METHODS: 9 healthy adults (6 females, 24.7 ± 2.7 yrs and 3 males, 28.7 ± 2.6 yrs [mean $\pm$ SD]) visited the lab 9 times (at least 48 hours between sessions). Day 1 consists of a personalized maximal incremental cycling test to determine peak power output (POpeak) and familiarize participants with readiness tools. Days 2-9 involved readiness assessments (using total quality of recovery [TQR] scale and short recovery stress scale [SRSS], counter-movement jump [CMJ], and 10-sec sprint cycling test), followed by a constant-load exercise to task failure at 70% of POpeak. The corresponding time to task-failure (TTF) was considered as the performance indicator. For each individual, Spearmans correlation coefficients (ρ) were calculated to assess the correlation between TTF and readiness indicators. One-sample t-tests (or Kolmogorov-Smirnov test for CMJ's jump height [JH], due to not normally distributed data) were used to assess if the individual ρ between readiness indicators and TTF were significantly different from 0. α was set at 5%.

RESULTS: CMJ (highest JH, peak power, modified reactive strength index) expressed as average and best of three jumps), 10-sec sprint test (5-sec peak and 10-sec average power), and TQR (0-10 and 6-20) were not associated with TTF (ρ not significantly different from 0), showing weak association (average $\rho < 0.3$). Likewise, most SRSS items (physical performance capability, emotional balance, overall recovery, muscular stress, lack of activation, overall stress) were not associated with TTF. However, mental performance capability ($\rho = 0.370 \pm 0.335$; $p = 0.027$) and the negative emotional state ($\rho = -0.409 \pm 0.297$; $p = 0.006$) were positively and negatively associated with TTF, respectively.

CONCLUSION: This study found that most readiness indicators are poorly associated with future aerobic performance. However, SRSS mental performance capability and negative emotional state seem to be able to predict future performance and may represent useful readiness indicators. Specifically, higher mental performance leads to a longer TTF, whereas a more negative emotional state results in a shorter TTF, which is clearly reasonable. In conclusion, specific self-report measures predict aerobic performance and offer insights into training predisposition and fatigue, whereas neuromuscular tests such as CMJ and sprints are less relevant for predicting aerobic capacity.

INTEGRATING HEART RATE VARIABILITY AND URINARY BIOMARKERS TO EVALUATE FATIGUE AND RECOVERY IN ADOLESCENT FEMALE ROWERS: DIFFERENTIAL EFFECTS OF HIIT AND MICT TRAINING COMBINATIONS

LU, Z., LI, S., LI, J., HE, Z., MI, J.
 BEIJING SPORT UNIVERSITY

INTRODUCTION: In practice, coaches typically structure training schedules by incorporating high-intensity interval training (HIIT) on the first day, followed by moderate-intensity continuous training (MICT) on the second day, or by implementing moderate-intensity training on two consecutive days. In some instances, to enhance athletic performance, coaches may opt for two consecutive days of high-intensity training (HIIT + HIIT). However, this intense training regimen can lead to fatigue accumulation in adolescent athletes, potentially compromising training effectiveness and increasing the risk of injury. Consequently, it is essential to monitor the fatigue levels of adolescent athletes using scientifically informed methods. This study aimed to assess the utility of integrating heart rate variability (HRV) metrics with urinary biochemical parameters to monitor physiological adaptations in adolescent female rowers, while evaluating the differential effects of combined high-intensity interval training (HIIT) and moderate-intensity continuous training (MICT) regimens on systemic physiological states and recovery dynamics.

METHODS: Twelve adolescent female rowers (age: 13.9 ± 1.3 years) participated in a crossover randomized self-controlled trial comprising three endurance training combinations: 1) HIIT + HIIT, 2) HIIT + MICT, and 3) MICT + MICT. HRV indices and ratings of perceived exertion (RPE) were recorded pre-training, during training, and during immediate post-exercise recovery (0–5 min). Morning pulse rate and urine samples were collected the following morning for urinary protein analysis. Temporal variations in heart rate (HR), heart rate variability (HRV), and associated physiological/biochemical parameters (RPE, morning pulse rate, urinary protein levels) across pre-training, intra-training, and post-training phases during three training combinations sessions were analyzed using two-factor repeated measures ANOVA.

RESULTS: Consecutive HIIT sessions resulted in significantly reduced RMSSD ($P = 0.025$), SDNN, HF ($P = 0.041$), LF/HF ratio ($P = 0.042$), and LF ($P = 0.044$) during the second-day recovery phase compared to initial HIIT exposure. In the HIIT+MICT group, post-MICT recovery on day two exhibited elevated RMSSD ($P = 0.005$), LF/HF ($P = 0.014$), and HF ($P = 0.001$) relative to day one HIIT. The MICT+MICT regimen showed no inter-day HRV or cardiac parameter differences ($P > 0.05$). Immedi-

ate post-exercise RPE, recovery-phase morning pulse rate, and urinary protein levels in the HIIT+HIIT group significantly exceeded those in the HIIT+MICT and MICT+MICT groups ($P < 0.01$).

CONCLUSION: Compared to routine hybrid training models, consecutive HIIT protocols elicited superior endurance training stimuli in adolescent female athletes, inducing measurable fatigue while maintaining sub-threshold proximity to over-training thresholds.

OP-AP46 Sensor Technology and Monitoring

PREDICTING GROUND REACTION FORCES FROM CHEST-MOUNTED IMU DATA USING DEEP LEARNING

WADHI, T., MOORE, N., PLEWS, D., NEVILLE, J., CRONIN, J.

AUCKLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Wearable sensors have emerged as a viable alternative to traditional laboratory equipment for assessing biomechanical parameters. This study investigated whether data from a 6-axis inertial measurement unit (IMU) mounted on a chest-strap, along with a deep learning model can replicate the ground reaction forces (GRF) measured by a force plate, potentially broadening access to performance and injury risk assessments in sports science.

METHODS: 124 valid jumps from 12 participants with 2 years of resistance or endurance training experience were used for training. Synchronized recordings from a chest-mounted IMU and a force plate were obtained, with force plate data processed to extract the acceleration component of the GRF—normalized for body mass and with the gravitational component removed. Two deep learning architectures were employed: a vanilla auto-encoder and a recurrent auto-encoder incorporating gated recurrent unit (GRU) cells. Both models were trained for 500 epochs using 80% of the dataset, with the remaining data reserved for testing. Performance was evaluated using Mean Squared Error (MSE) as the loss metric.

RESULTS: The base MSE loss on the test set was 0.3145. Vanilla auto-encoder achieved a training loss of 0.0021 and a test loss of 0.0717, while the GRU auto-encoder recorded a training loss of 0.0057 and a test loss of 0.0774. Both models effectively reconstructed the GRF-derived acceleration signal, with the vanilla architecture showing marginally better performance on unseen data, while also being faster for training and inference.

CONCLUSION: These findings indicate that chest-mounted IMU data, when processed through an auto-encoder framework, can reliably approximate the acceleration component derived from GRF measurements. The comparable performance of both auto-encoder models suggests that even simple architectures can effectively translate the noisy data collected from a wearable sensor to GRF. This approach has the potential to facilitate on-field assessments where traditional force plates are impractical. Future research should focus on validating these preliminary results across varied athletic populations and movement patterns, as well as optimizing model parameters for real-time applications. Furthermore, additional pre-processing of the IMU signal may also lead to improved performance on this task, and requires further enquiry.

ESTIMATING FORCES DURING PULL-UPS WITH WEARABLE SENSORS AND AI FOR FIELD-BASED SHOULDER LOAD MONITORING

SABIONI, M., DESTRO, A., WILLÉN, J., JACOBSSON, M., GUTIERREZ-FAREWIK, E.M.

KTH ROYAL INSTITUTE OF TECHNOLOGY

INTRODUCTION: The shoulder is the most injury-prone area in functional fitness, particularly during high-volume movements such as kipping pull-ups (KPU) and butterfly pull-ups (BPU) [1,2]. Overuse and overload have been associated with these injuries [1], making joint load monitoring a promising strategy for injury prevention. However, current methods rely on highly specialized equipment, and measuring interaction forces at the pull-up bar is challenging even in lab-based conditions, with limited practical applicability. Inspired by previous work in running [3], we propose using a minimal set of wearable sensors to estimate bar reaction forces during different pull-up techniques and we validate estimates against force plate measurements. This setup can contribute to field-based monitoring of shoulder joint loads across different pull-up techniques.

METHODS: Nine experienced recreational CrossFit athletes performed one set of multiple upper body functional movements (Func), followed by sets of strict pull-ups (SPUs), KPUs, and BPUs. A pull-up rack was instrumented with two 6-DOF force transducers to measure the forces and moments at the handles. Participants wore two IMUs—one on the chest and one on the humerus. A two-step machine learning pipeline was developed. Step 1 used a multi-class classifier to distinguish between SPUs, KPUs, BPUs and other movements (Func). Step 2 applied a regression model for each technique, using raw IMU data to estimate anterior-posterior (Fap) and superior-inferior (Fsi) forces (medio-lateral forces were negligible as the movements were largely symmetric). Multiple machine learning models – including feature-based, kernel-based, and neural networks – were tested using single-sensor (chest only) and dual-sensor configurations. Validation used a leave-one-subject-out approach to ensure generalizability.

RESULTS: For movement classification, the best-performing model, Rocket classifier, single sensor, achieved $98 \pm 2\%$ accuracy and F1 scores. In estimating forces normalized by body mass, the best model, LSTM, dual-sensor, yielded RMSE (Fsi,

Fap] in N/kg: KPU: [0.30, 0.15], BPU: [0.27, 0.11], and SPU: [0.13, 0.05]. Normalized by the full range of values, these are [Fsi, Fap]: KPU: [21%, 17%], BPU: [15%, 11%] and SPU: [16%, 22%]. Linear coefficients of determination were [Fsi, Fap]: KPU: [0.70, 0.75], BPU: [0.83, 0.90], and SPU [0.59, 0.33]. Differences between measured and predicted peak forces varied largely between trials and participants.

CONCLUSION: We present a data-driven method to estimate external forces during pull-ups using 1-2 wearable sensors with strong accuracy. This setup holds promise for field-based biomechanical assessments which can be used for shoulder load monitoring, preventing overload and overuse injuries. Future work will evaluate how accurate these estimated forces can be used to compute joint moments via musculoskeletal modeling and inverse dynamics.

AUTOMATED DETECTION OF VENTILATORY THRESHOLDS: DEVELOPMENT AND COMPARISON TO VISUAL DETERMINATION

STÜTZ, L., CIVELLI, N., HELFENSTEIN, P., SCHMIDT-TRUCKSÄSS, A., KNAIER, R., WAGNER, J.

UNIVERSITY OF BASEL

INTRODUCTION: Ventilatory thresholds (VTs) mark aerobic and anaerobic metabolic transitions in exercise physiology. Traditionally, detecting these thresholds during cardiopulmonary exercise testing (CPET) involves manual assessment of respiratory gas exchange data based on visual inspection, which is time-consuming and prone to subjectivity. To address these limitations, we developed an algorithm to automate the detection of VTs and conducted an initial analysis of its performance based on the Power at which VTs were reached.

METHODS: An algorithm was developed in Python (Version 3.13.1) to detect VT1 and VT2 from continuous CPET data based on established criteria. VT1 was detected using four parameters: (1) the ventilatory equivalent for oxygen starts rising, (2) end-tidal oxygen pressure starts rising, (3) the V-slope method, and (4) a rise in excess carbon dioxide. VT2 was detected using three criteria: (1) the ventilatory equivalent for carbon dioxide starts rising, (2) end-tidal carbon dioxide pressure starts decreasing, and (3) the V-slope method.

The algorithm was applied to respiratory gas exchange data from 210 participants under 50 years old in the COMplete-Health study [1]. VTs detected by the algorithm were compared to visually determined values, with performance assessed using Mean Absolute Percentage Error (MAPE) and Root Mean Square Error (RMSE) for Power at VT1 and VT2.

RESULTS: The algorithm successfully detected VT1 in 92.9% of participants and VT2 in 93.3%, respectively. Among participants with valid threshold detections, the MAPE for VT1 was 12.6%, with an RMSE of 14 Watt, while VT2 had a MAPE of 5.7% and an RMSE of 11 Watt.

CONCLUSION: The observed error rates indicate a reasonable agreement with visual determination for both VT1 and VT2, respectively. Considering that an automated detection of VTs is i) more objective, ii) better reproducible, and iii) more time and cost efficient than manual visual VT determination, this provides high potential.

PREDICTING SUCCESS IN OLYMPIC SPORTS: INTEGRATING SOMATOSENSORY PERCEPTION AND MACHINE LEARNING FOR TALENT IDENTIFICATION.

MACGABHANN, S.1,3, DOWSE, R.3, COBLEY, S.2, WITCHALLS, J.1, WADDINGTON, G.1, NEWMAN, P.1

1 UNIVERSITY OF CANBERRA RESEARCH INSTITUTE FOR SPORT AND EXERCISE, AUSTRALIA; 2 THE UNIVERSITY OF SYDNEY, AUSTRALIA; 3 NEW SOUTH WALES INSTITUTE OF SPORT, AUSTRALIA

INTRODUCTION: While talent identification (TID) requires robust assessment of multiple performance-related factors, current practices often rely on subjective or physiological indices. In diving and winter sports, somatosensory perception - encompassing proprioceptive acuity (joint position sense) and visual-vestibular integration - is critical for performance but remains underexplored. This study applied advanced somatosensory analysis and an ensemble machine learning approach to examine relationships with Olympic potential.

METHODS: Participants were N = 63 (m = 24; f = 39) Olympic and aspiring Olympic athletes (27 divers, 36 winter sports), categorized as either Podium (n=27) or Emerging (n=36). A two-step somatosensory perception assessment evaluated (1) Ankle proprioception via the Active Movement Extent Discrimination Assessment (AMEDA) (Han et al., 2016); and (2) visual-vestibular function was quantified via - pupil light reflex for autonomic function, cognitive response delay, and vestibular function, measured through visual tracking error, time-to-target, and time-on-target (m/s). Statistical analysis using effect sizes and ANOVAs identified distinguishing variables between Podium and Emerging athletes. An ensemble of machine learning models (logistic regression, KNN, AdaBoost, decision tree, random forest, and CN2 rule) was evaluated for accuracy and to inform classification.

RESULTS: Podium-level divers demonstrated superior ankle proprioceptive accuracy (Ameda Left: +5.85, p=0.0159; Right: +5.90, p=0.014). Tracking error significantly predicted performance (Cohen's d = 0.31, p=0.004). Logistic regression, validated using 10-fold cross-validation, achieved strong classification (AUC=0.94), identifying 92% of Podium and 87% of Emerging athletes. Within the logistic regression model, tracking error approached significance (p=0.057), while proprioceptive measures improved group classification despite non-significant individual results (p>0.13). Lift-curve analysis

showed the model was 2.2 times more effective than random selection in identifying podium-potential athletes across probability thresholds 0.63–0.80.

Winter Sports: Podium-level athletes showed longer response delays (12.93m/s longer, $p=0.007$), prioritizing decision accuracy. Tracking error significantly predicted performance (Cohen's $d = 0.24$, $p=0.003$). A random forest model also validated using 10-fold cross-validation, achieved high classification accuracy (AUC=0.879), correctly identifying 93% of Podium and 100% of Emerging athletes. Within the random forest model tracking error was significant ($p=0.0482$). Lift-curve analysis showed the model was 2.4 times more effective than random selection at identifying podium-potential athletes at a probability threshold of 0.65.

CONCLUSION: Findings highlight the value of integrating somatosensory metrics for data-driven TID in Olympic sports. Machine learning can help organizations refine selection, optimize resources, reduce talent wastage, and strengthen pathways to success.

A GENERALIZED DATA-DRIVEN APPROACH FOR QUANTITATIVE TECHNIQUE ANALYSIS IN SPORTS: BRIDGING SCIENCE AND PRACTICE

DEBERTIN, D., FEDEROLF, P.
UNIVERSITY OF INNSBRUCK

INTRODUCTION: Quantitative technique analysis is crucial for optimizing sports performance [1]. However, translating scientific findings into practical coaching remains a challenge. Traditional biomechanical analyses often fail to align with practitioners terminology and understanding, limiting their applicability in training environments. This study presents a data-driven approach that provides quantitative and visually accessible feedback on distinct technique elements within a performed movement, ensuring familiarity for athletes and coaches while maintaining scientific rigor. The objective is to investigate its potential of generalizability across various sports disciplines.

METHODS: The approach builds upon previous proof-of-concept studies [2,3]. The methodology involves: (i) Technique demonstrations and recordings: The 3D segment coordinates of highly skilled athletes are recorded while they perform purposefully overemphasized technical movement elements commonly analyzed in their sport. (ii) Extraction of technique elements as quantifiable movement components: A principal component analysis (PCA) of the recorded segment coordinates reveals principal component vectors [4], which represent different technique elements. (iii) Projection of any movement onto component vectors: Partial movements along these vectors isolate specific technique elements from the overall movement. They can be visualized and analyzed based on scores.

RESULTS: Beyond skiing [2,3], the procedure was newly tested in running ($n = 20$) and soccer ($n = 16$). In each case, the analysis yielded a set of quantifiable movement components that directly correspond to practical execution strategies, i.e., technique elements, as demonstrated and described by experts. The component vectors allowed for technique comparisons between groups (e.g., female runners exhibited less upper-body pendulum movement than males) and performance-based variations (e.g., soccer players maintained a more upright posture before ball contact when aiming for a lower goal in penalty kicks).

CONCLUSION: By structuring technique feedback around established practitioner knowledge while maintaining a robust quantitative foundation, this approach helps bridge the gap between scientific analysis and practical coaching. The new findings for running and soccer suggest that this method can be applied across various sports. Similar analyses can be conducted in other disciplines, provided that 3D kinematic data from technique demonstrations are available. Visualizing the technique elements may enhance intuitive understanding and could be integrated into modern app development for practical technique analysis.

OP-MH43 Interventions II

DOES SIX WEEKS OF LOW-VOLUME SPRINT INTERVAL TRAINING IMPROVE PEAK OXYGEN UPTAKE COMPARED TO A NON-EXERCISE CONTROL? A RANDOMIZED CONTROLLED TRIAL.

RENWICK, J., KUDSI, M., BINET, E., BONE, J., MULKEWICH, N., BABIR, J., CRUKLEY, J., GIBALA, M.
MCMASTER UNIVERSITY

INTRODUCTION: Low-volume sprint interval training (LVSIT) has been reported to increase peak oxygen uptake ($\dot{V}O_{2peak}$) when performed thrice weekly for six weeks. However, methodological and statistical concerns have been raised that limit previous study findings. We sought to critically reassess the $\dot{V}O_{2peak}$ response to a six week, thrice-weekly LVSIT

intervention using a randomized controlled trial design that was constructed to mitigate bias and augment reporting quality.

METHODS: The study protocol was formulated in accordance with CONSORT guidelines and registered prior to participant recruitment on the Open Science Framework (<https://osf.io/7mwcj>). Utilizing individual participant data from two previous studies conducted in our laboratory, we constructed a generative model of our primary outcome, VO₂peak, as a function of group (LVSIT and control), age, sex, height, and body mass. Using these previous data and the model, we then conducted simulation experiments to estimate a required sample size of $n=15$ per group to achieve 80% power to detect a difference of 1 metabolic equivalent (MET) with a credible interval of ≤ 1 MET. Forty insufficiently active young adults were initially recruited and randomized; three were lost to follow-up, leaving $n=37$ (13 males and 24 females; 22 ± 2 yrs) who were assigned to perform either six weeks of LVSIT ($n=17$) or a non-exercise control condition ($n=20$). The LVSIT protocol involved 3x20-s 'all out' sprints over a 10-min session that otherwise consisted of low-intensity cycling. VO₂peak testing was conducted by investigators blinded to participant group allocation and performed in the absence of temporal, verbal, or physiological feedback. VO₂peak was measured in duplicate at each time point and not averaged prior to modelling. Data were analyzed using a generative linear mixed-effects regression model that regressed post VO₂peak on baseline VO₂peak, group allocation, age, sex, height, and body mass with varying effects for participants. All data were analysed by an investigator blinded to group assignment.

RESULTS: Bayesian linear mixed-effects modelling and individual response analyses revealed that LVSIT significantly improved absolute ($+370 \pm 168$ mL/min) and relative VO₂peak ($+5.5 \pm 2.4$ mL/kg/min), but there were no significant changes in the control group. A clinically meaningful increase in VO₂peak of ≥ 1 -MET occurred in 71% of LVSIT participants, with 88% exceeding a 0.5-MET + typical error threshold.

CONCLUSION: This study unequivocally demonstrates that a six-week LVSIT protocol significantly improved VO₂peak in insufficiently active young adults compared to a non-exercise control group. By implementing a robust design that included pre-registration of the study protocol, concealed allocation assignment, statistical best practices and applied bayesian methods, and open data-sharing, this study addresses prior methodological critiques of similar previous work.

COMPARATIVE EFFECTS OF SHORT HIGH-INTENSITY AND LONGER LOW-INTENSITY EXERCISE ON EXERCISE-INDUCED HYPOALGESIA: A RANDOMIZED CONTROLLED CROSSOVER STUDY.

TOMSCHI, F., STEPHAN, H., ZWACK, L., HILBERG, T.

UNIVERSITY OF WUPPERTAL

INTRODUCTION: Acute physical activity leads to exercise-induced hypoalgesia (EIH). The primary aim of this study was to investigate the effects of two different exercise interventions (low intensity but longer and highly intensive but short) on EIH compared to those of a control session. The secondary aim was to evaluate potential differences in EIH regarding the used body landmarks (muscular and bony/articular).

METHODS: 20 male (age: 29.4 ± 3.5 yrs, VO₂max: 52.9 ± 6.3 ml/min/kg) participants successfully underwent two exercise sessions on a bicycle ergometer (low intensity: 30 minutes at 60% of the individual anaerobic threshold; highly intensive: 90 second isokinetic all-out) and a control session on separate days in a randomized crossover design. Before (T0), post 1' (T1), and post 40' exercise (T2) pain sensitivity was determined via pain pressure thresholds (PPT, N/cm²) unilaterally at the rectus femoris (RF), knee, tibialis anterior (TA), ankle, pectoralis major (PM), and sternum. Lactate, heart rate (HR), and rate of perceived exertion (RPE, 6-20) were documented.

RESULTS: Baseline (T0) PPT values were not different between the sessions at any landmark ($p > 0.104$) indicating no carryover effects. The three-way ANOVA resulted in a significant 'time' $\times$ 'landmark' $\times$ 'intervention' effect ($p = 0.007$, $\eta^2_{\text{partial}} = 0.095$). Post hoc analyses revealed that PPT values changed following the highly intensive exercise session with PPT_TA being significantly higher at T1 (88.4 ± 28.2) compared to T0 (78.4 ± 24.9 , $p = 0.023$) and T2 (71.8 ± 20.3 , $p = 0.001$). PPT_ankle were significantly higher at T1 (55.9 ± 26.5) compared to T2 (45.9 ± 25.4 , $p = 0.007$) but not to T0 (51.3 ± 23.1 , $p = 0.519$). PPT_RF were significantly higher at T1 (89.3 ± 25.4) compared to T0 (73.3 ± 20.6 , $p = 0.007$) and T2 (74.2 ± 21.8 , $p = 0.004$). PPT_knee were significantly higher at T1 (89.4 ± 31.9) compared to T0 (77.4 ± 27.3 , $p = 0.045$) and T2 (70.6 ± 30.1 , $p = 0.001$). PPT_sternum were not significantly different with values of 44.8 ± 19.1 at T1 compared to 39.3 ± 13.7 at T0 ($p = 0.065$) and 41.0 ± 17.1 at T2 ($p = 0.067$). PPT_PM were significantly higher at T1 (41.8 ± 18.2) compared to T0 (33.3 ± 13.8 , $p = 0.002$) and T2 (34.6 ± 15.3 , $p < 0.001$). PPT values were neither different after the low intensity nor after the control session at any landmark. Lactate (low intensity: 1.1 ± 0.2 ; highly intensive: 7.7 ± 2.6 mmol/L), HR (low intensity: 128.9 ± 13.0 ; highly intensive: 175.2 ± 13.4 bpm), and RPE (low intensity: 11.6 ± 1.9 ; highly intensive: 19.6 ± 0.8) were significantly higher following the all-out exercise ($p < 0.001$).

CONCLUSION: Results indicate that a 90" all-out exercise induces EIH, whereas a 30' low intensity exercise does not. This emphasizes the role of exercise intensity, rather than duration, as a key determinant of EIH, shedding light on potential dose-response relationships. EIH effects were observed across muscular and articular landmarks but consistently subsided within 40 minutes.

RUNNING IMPROVED SOME MEASURES OF INTERVERTEBRAL DISC HEALTH IN ADULTS WITH CHRONIC LOW BACK PAIN: THE ASTEROID RANDOMISED CONTROL TRIAL

SAMANNA, C., NEASON, C., TAGLIAFERRI, S., BELAVY, D., BOWE, S., CLARKSON, M., CRAIGE, E., GOLLAN, R., MILLER, C., MITCHELL, U., MUNDELL, N., SCOTT, D., TAIT, J., VINCENT, G., NEZ, H., OWEN, P.

MONASH UNIVERSITY

INTRODUCTION: Low back pain is the primary cause of global disability with up to 40% of cases attributed to intervertebral disc degeneration. (1) Cross-sectional studies (2,3) showed running was associated with better magnetic resonance imaging-derived intervertebral disc health, yet no randomised controlled trials have assessed the effect of running. Therefore, we examined the effects of running on intervertebral disc health in adults with chronic low back pain.

METHODS: This 12-week parallel (1:1) randomised control trial allocated 40 adults aged 18–45 years (mean [SD] age: 33 [6] years, female: 50%) with non-specific chronic low back pain to a running intervention or waitlist control. The running intervention involved a digitally delivered, progressive run-walk interval exercise intervention (3 days/week, 30 minutes/session). Progression was self-directed by participants and in consultation with an accredited exercise physiologist. Magnetic resonance imaging of spinal levels T11/T12 to L5/S1 was performed at baseline, 6 and 12 weeks. The primary outcome was T2 (ms), an objective assessment of intervertebral disc hydration. Secondary objective outcomes were intervertebral disc: height (mm), height-to-vertebral body ratio, volume (cm³) and nucleus-to-annulus signal intensity ratio. Higher objective values indicate better intervertebral disc health. Lastly, Pfirrmann grade (points) assessed intervertebral disc degeneration, a subjective assessment on a 5-point scale, with lower values indicating better intervertebral disc health.

RESULTS: There was no attrition or study-related serious adverse events. Mean (SD) intervention adherence was 70% (20%) and total run distance was 50 (32) km, ranging from 2–110 km over 12 weeks. The intervention improved average lumbar Pfirrmann grade (estimated marginal mean net difference [95%CI]: 0.15 [0.25, -0.05] points, $P=0.004$) and height-to-vertebral body ratio (0.01 [0.00, 0.02] mm, $P=0.039$), yet not T2 (-0.13 [-1.74, 1.48] ms, $P=0.873$), height (0.00 [-0.13, 0.13] mm, $P=0.991$), volume (-0.01 [0.24, 0.23] cm³, $P=0.966$), or nucleus-to-annulus signal intensity ratio (0.05 [-0.04, 0.13], $P=0.272$).

CONCLUSION: Running improved some outcomes of intervertebral disc health in adults with non-specific chronic low back pain. Importantly, no deleterious effects or adverse events were observed. To determine if these improvements are sustained, exploring the effect of a longer running intervention warrants investigation, with potential implications for treating intervertebral disc pathology and low back pain.

IMPACT OF 12-WEEK RESISTANCE TRAINING DIFFERING IN SET CONFIGURATION ON MUSCULAR PERFORMANCE, BODY COMPOSITION, AND POSTURAL BALANCE IN POSTMENOPAUSAL WOMEN.

NINE, I., RIAL-VÁZQUEZ, J., FARIÑAS, J., RÚA-ALONSO, M., REVUELTA-LERA, B., ENRÍQUEZ-GONZÁLEZ, M.G., VARELA-SANZ, A., IGLESIAS-SOLER, E.

UNIVERSITY OF A CORUNA / Q6550005J

INTRODUCTION: Resistance training is a key strategy to counteract the decline in muscle function, body composition, bone mineral density and balance control associated with postmenopause (1,2). This study aimed to evaluate the adaptations of two resistance training protocols differing in set configuration on muscular performance, body composition, balance, and bone mineral density.

METHODS: Physically active postmenopausal women ($n=16$) were randomly assigned to control (CON) or experimental groups: 9 sets of 4 repetitions with 45 seconds inter-set rest interval (4S), or 4 sets of 9 repetitions with 120s rest (9S), ensuring an equivalent work-to-rest ratio. This study was funded by the Spanish Ministry of Science, Innovation and University (PID2021-124277OB) and lasted 12 weeks, with participants training twice per week using 12 repetition maximum (12RM) load in leg press, bench press, leg curl and lat pull-down. Muscular performance was assessed with 12RM load and was also evaluated by the number of maximal repetitions performed with the initial 12RM load (PRE) after the intervention (POST). Body composition –lean mass (kg) and fat percentage (%)– was measured using a Bodystat Quadscan 4000. The mean velocity of the center of pressure displacement (CoP) with a Wii Balance Board under four different conditions: eyes open (EO) and eyes closed (EC) on firm surface; eyes open (EOF) and eyes closed (ECF) on unstable surface. Bone mineral density (BMD) at the calcaneus was assessed using ultrasound densitometry. A 3x2 ANOVA (3 groups and 2 time points) was used for the statistical analysis.

RESULTS: The analysis of muscular performance showed a main effect of moment ($p=0.018$) and group $\times$ moment interaction ($p=0.049$), with an improvement of the load lifted for all exercises only in the experimental groups. The improvement was consistently greater in 9S compared to 4S. The number of repetitions completed with the initial 12RM load increased in POST ($p=0.004$). Compared to PRE, fat-free mass increased (+0.92 kg; $p=0.035$) and body fat percentage showed a decreasing trend (-1.16%; $p=0.067$) in POST. In postural balance, a group main effect was found in EO with the 9S exhibited

higher mean COP velocities compared to 4S ($p=0.048$). A main effect of moment in ECF condition was found ($p=0.007$) with higher velocities in PRE compared to POST. No significant changes were found in BMD.

CONCLUSION: Twelve weeks of resistance training enhanced muscular performance and body composition in postmenopausal women. Long set configurations (i.e., 9S) had a greater impact on muscular performance compared to shorter ones (i.e., 4S). However, set configuration did not modulate balance adaptations, and no significant effects were observed in BMD.

These findings reinforce the importance of resistance training in postmenopausal women, with potential implications for functional performance and fall prevention strategies.

HOME-BASED, APP-MONITORED BODY-WEIGHT RESISTANCE TRAINING ENHANCES STRENGTH, BALANCE, AND COGNITION IN OLDER ADULTS WITH SARCOPENIA: PRELIMINARY FINDINGS FROM THE GYM STUDY

BONATO, M., MARMONDI, F., GALLI, L., CERIZZA, C., ANNICHIARICO, G., BAGLIVI, A., DELLA TORRE, R., VERCESI, R., CASTAGNA, A., SCIORATI, C., ZAGATO, L., SCONFIENZA, L.M., BANFI, G., CINQUE, P.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Sarcopenia is an age-related condition characterized by reduced muscle strength, mass, and function, leading to an increased risk of falls, fractures, physical disability, and mortality. Few controlled studies have assessed the efficacy of physical activity in treating sarcopenia. This study presents preliminary results from the Grow Your Muscle (GYM) randomized-controlled trial, a 48-week home-based, app-monitored body-weight resistance training program aimed at improving muscle function and mass in older adults with sarcopenia, both in the general population (GP) and in persons with HIV (PWH).

METHODS: Participants were sedentary adults diagnosed with sarcopenia based on low appendicular skeletal muscle mass index (ASMMI) by bioimpedentiometry (BIA) and/or reduced handgrip strength, aged >60 years (GP) and >50 years (PWH). Participants were randomized (1:1) within each group into: (1) an Exercise Group (EG) performing a home-based, app-monitored resistance training program; or (2) a Control Group (CG) receiving no exercise prescription. Assessments at baseline (BL) and week 48 (W48) included muscle function (handgrip strength, chair-stand test, maximal knee extensor strength, Mini-BESTest, 6MWT), body composition (DEXA), cognitive function (TMA, TMB, digit symbol test), and MRI evaluation of Intermuscular Adipose Tissue (IMAT) and muscle Cross-Sectional Area (CSA). Changes between BL and W48 were assessed using the Wilcoxon matched-pairs signed-rank test, while differences in BL values and percent change between groups were analyzed with the Mann-Whitney test.

RESULTS: A total of 196 participants were enrolled (98 GP, 98 PWH), and 87 [EG: $n=43$, 69% male, age 63 (59-69); CG: $n=44$, 70% male, 67 (61-73), median (IQR)] completed the 48-week assessment, while 34% ($n=45$) dropped out. At W48, significant improvements from BL were observed in EG for measures of muscle function (handgrip strength, $p=0.017$, chair-stand, $p<0.0001$, maximal knee extensor strength, right: $p=0.033$, left: $p=0.002$ and Mini-BESTest, $p=0.0001$); body composition (leg lean mass, $p=0.024$); and cognitive function (TMA: $p=0.009$; TMB: $p=0.045$; digit symbol: $p<0.0001$). Significant between-group differences were found in handgrip strength ($p=0.013$), chair-stand ($p=0.0003$), left knee extensor strength ($p=0.04$), and Mini-BESTest ($p=0.0001$). No significant differences were observed for MRI measurements and the other parameters.

CONCLUSION: These preliminary findings suggest that a 48-week home-based, app-monitored body-weight resistance training program can improve muscle strength, and mass, balance, and cognitive function.

HOW CAN WE HIT PRENATAL NORMOTENSION THROUGH HIIT? ANALYSIS OF EXERCISE-INDUCED CHANGES IN INSULIN, LEPTIN, RESISTIN AND IRISIN IN THE SECOND TRIMESTER OF PREGNANCY - A RANDOMIZED CONTROLLED TRIAL

SZUMILEWICZ, A., SUN, J., SANTOS-ROCHA, R., MIESZKOWSKI, J., KOCHANOWICZ, A.
GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: To avoid blood pressure (BP) disorders, pregnant women have been advised to engage in moderate to vigorous physical activity (MVPA). However, there is little data available on the cardiovascular effects of high-intensity interval training (HIIT) in the perinatal period. We aimed to determine how an 8-week HIIT programme affects insulin, leptin, resistin, and irisin levels and their role in BP regulation during pregnancy.

METHODS: The study involved 54 Caucasian participants identifying as women in uncomplicated, singleton pregnancies (age 32 ± 4 years, week of gestation 24 ± 4 , mean $\pm$ SD). Thirty-four were randomly allocated to the 8-week supervised HIIT programme (HIIT group). The comparative (EDU) group consisted of twenty pregnant women who completed an edu-

cational programme and were encouraged to perform MVPA on their own. Before and after the interventions, maternal blood pressure (BP), serum glucose, carbohydrate and lipid metabolism markers (including insulin, leptin, resistin, and irisin) from blood samples taken in fasting conditions were assessed.

RESULTS: All participants had normal glucose and lipid profile values throughout the study. At baseline, both HIIT and EDU groups presented similar systolic (111.76 ± 9.42 and 115.95 ± 11.77 mmHg) and diastolic BP (73.12 ± 6.63 and 72.95 ± 8.66 mmHg) at rest. Although all participants met the inclusion criteria (normotension, normoglycaemia, and normolipidaemia), further analyses showed statistically significant differences in baseline levels of blood insulin ($p = 0.001$), leptin ($p = 0.001$), and resistin ($p = 0.046$). The baseline irisin concentration did not differ between groups ($p = 0.266$). In the HIIT group, we observed a significant decrease in diastolic BP ($p = 0.031$), and in the EDU group, a significant decrease in systolic BP ($p = 0.005$), but all values were within the normotension range. HIIT training induced a statistically significant increase in insulin ($p = 0.005$) and resistin ($p < 0.001$) levels. Moreover, leptin production tended to increase but did not reach statistical significance ($p = 0.071$). The only significant change observed in the EDU group was the decrease in resistin ($p = 0.037$). Despite these differences between groups, we observed similar associations of selected biomarkers with BP after eight weeks of interventions. In both groups, higher diastolic BP was significantly correlated with higher insulin ($r = 0.51$ and $r = 0.45$; $p < 0.05$) and leptin ($r = 0.39$ and $r = 0.62$; $p < 0.05$). After both interventions, we observed no associations of resistin and irisin with systolic or diastolic BP.

CONCLUSION: Physical activity in pregnancy, regardless of intensity, optimises physiological and biochemical responses, maintaining normotension. HIIT, similarly to the commonly recommended MVPA, due to the interconnection of hormones regulating the cardiovascular and metabolic systems, can help avoid BP disorders without negatively affecting the course of pregnancy or neonatal outcomes.

POSTPARTUM SPRINT INTERVAL TRAINING IS SAFE AND RAPIDLY INCREASES FITNESS IN TRAINED FEMALES

RICHARD, N., KOEHLE, M., CLAYDON, V., COTÉ, A.

SIMON FRASER UNIVERSITY

INTRODUCTION: Female athletes, or those in arduous occupations, lack objective guidance on effective and safe rigorous training postpartum. Our investigation examined the effectiveness and safety of sprint interval training (SIT) undertaken soon postpartum (PP) in a cohort of healthy females ranging from recreationally active to international-level athletes.

METHODS: Nine new mothers completed laboratory testing pre-intervention (PPpre) and post-intervention (PPpost). We measured maximal oxygen consumption ($\dot{V}O_{2\max}$) with a metabolic cart, peak cardiac output (Q_{peak}) with inert gas rebreathing, and blood volume (BV), plasma volume (PV), and haemoglobin mass (Hbmass) with carbon monoxide rebreathing. Between laboratory visits, participants completed six weeks of home-based SIT at 130% of $\dot{V}O_{2\max}$ peak power output (PPO). Sessions were conducted thrice weekly and progressed from four to eight 30-second sprints. Freely chosen moderate-intensity aerobic exercise was performed on alternate days. The training was supervised remotely by an experienced exercise physiologist.

RESULTS: No adverse events occurred, and collectively, 155/162 sessions were completed. All participants breastfed with no difficulties throughout the study duration. Mean study entry was 8.0 ± 2.5 weeks PP and parity 1.6 ± 0.8 children. Absolute (2.44 ± 0.34 vs 2.79 ± 0.27 L/min $p < 0.0001$) and relative $\dot{V}O_{2\max}$ (36.1 ± 4.8 vs 42.0 ± 4.8 mL/kg/min $p < 0.0001$) both increased from PPpre to PPpost. Similarly, absolute (236 ± 25 vs 267 ± 21 watts $p < 0.0001$) and relative (3.5 ± 0.4 vs 4.0 ± 0.4 watts/kg $p < 0.0001$) PPO also increased from PPpre to PPpost. Q_{peak} remained stable from PPpre to PPpost (14.7 ± 2.0 vs 14.6 ± 2.1 L/min, 8.3 ± 1.2 vs 8.3 ± 1.1 L/min/m²). Values for Hbmass (617 ± 76 vs 631 ± 84 g, 9.2 ± 1.3 vs 9.6 ± 1.4 g/kg), BV (4737 ± 610 vs 4877 ± 611 mL, 71 ± 11 vs 74.12 mL/kg) and PV (2937 ± 428 vs 3014 ± 391 mL, 44 ± 7 vs 46 ± 8 mL/kg) tended to be increased at PPpost, although this did not reach statistical significance.

CONCLUSION: Lack of change in Q_{peak} despite an increased $\dot{V}O_{2\max}$ could be explained by a greater arterio-venous oxygen difference at PPpost. In addition, variability in study entry time, combined with cardio-haematological transitions, could account for the nonsignificant changes in haematological and Q_{peak} results. Breastfeeding may have influenced Q_{peak} and PV. In summary, six weeks of SIT rapidly improves cardiovascular fitness, as demonstrated by enhanced PPO, in previously trained women. Ergometer cycling SIT is safe, can be started as soon as five weeks postpartum, and does not impede breastfeeding. Our intervention was effective in recreationally active females to professional sportswomen.

EFFECT OF EXERCISE TRAINING IN PREGNANCY IN PEOPLE WITH OVERWEIGHT/OBESITY ON ADIPONECTIN AND LEPTIN CONCENTRATIONS IN MATERNAL AND CORD BLOOD

MOHOLDT, T., GARNÆS, K.K., DRAVENG, G., STAVNES, E., NYRNES, S.A., SALVESEN, K.Å., MØRKVED, S.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: High maternal body mass index (BMI) is associated with adverse pregnancy outcomes. The adipokines adiponectin and leptin are involved in metabolic regulation. Exercise training during pregnancy can potentially influence the concentrations of these adipokines, lower the risk of several adverse pregnancy outcomes, and improve the intrauterine environment for the fetus. We aimed to study the effects of exercise training during pregnancy on adiponectin and leptin concentrations in maternal blood and cord blood in individuals with pre-pregnancy overweight/obesity.

METHODS: This is a secondary analysis of the Exercise Training in Pregnancy (ETIP) randomized controlled trial. ETIP was a parallel-group randomized controlled trial in pregnant individuals ($N = 91$) with a pre-pregnancy BMI ≥ 28 kg/m². We

offered the intervention group (n = 46) three weekly supervised exercise sessions (35 minutes of moderate-intensity endurance training and 25 minutes of strength training), starting in gestational week (GW) 12-18 and continuing throughout pregnancy. We collected maternal blood samples at baseline, in GW 34-37, and 3 months postpartum, and cord blood at delivery. Adiponectin and leptin concentrations were assessed by enzyme-linked immunosorbent assays (ELISA). We compared changes over time and between groups in maternal blood using linear mixed models and differences between groups in cord blood with t-tests.

RESULTS: Seventeen participants were lost to follow-up in the ETIP trial and 50% of the women in the exercise group adhered to the exercise protocol as prescribed a priori. We measured adiponectin in samples from 58 participants at baseline and in GW 34-37, and from 62 participants postpartum. There was no change in adiponectin concentrations from baseline to GW 34-37 (estimated mean difference [MD], -0.05 µg/mL, p = .91) or from baseline to postpartum (MD, -0.05 µg/mL, p = .90), and no differences between groups at any time-point. We measured leptin from 64 participants at baseline, 59 in GW 34-37, and 56 postpartum. Leptin increased from baseline to GW 34-37 (MD, 8.8 ng/mL, p < .001) and decreased between baseline and postpartum (MD, -16.2 ng/mL, p < .001), with no between-groups differences from baseline to GW 34-37 (MD, -4.0 ng/mL, p = .18) or from baseline to postpartum (MD, -0.8 ng/mL, p = .82). Cord blood adiponectin concentration was 24.4 µg/mL (standard deviation [SD] 5.4) in the exercise group (n = 22) and 24.8 µg/mL (SD 5.4) in the control group (n = 28, p = .77). There was no statistically significant difference in leptin concentrations in cord blood samples: 25.6 ng/mL (SD 22.0) in the exercise group (n = 19) versus 29.6 ng/mL (SD 17.9) in the control group (n = 25, p = 0.54).

CONCLUSION: Offering pregnant women with overweight/obesity supervised exercise training during pregnancy had no statistically significant effect on maternal or cord blood concentrations of adiponectin or leptin. The suboptimal adherence rates to exercise may explain these findings.

AN INDIVIDUALIZED AND UNLIMITED TRAINING PROTOCOL HAS A POSITIVE EFFECT ON FATIGUE AND PHYSICAL FITNESS IN PATIENTS WITH LONG-COVID: RELATIONSHIP TO RED BLOOD CELL MORPHOLOGY

KRÜGER, A., GRABOWSKI, J., BACH, N., HAIDUK, B., GRAU, M.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Physical activity may have a positive effect on the rehabilitation of patients with Long-COVID (LC) with mild to moderate disease severity. However, current approaches are often time-limited and may not fully restore daily living skills. Furthermore, the physiological processes that are improved by physical activity in LC are not fully understood. This study examines the effect of an individualized, time-independent exercise intervention on fatigue, physical fitness, degree of functional limitations and duration of the program. Finally, the findings will be related to RBC morphology.

METHODS: Ten LC (3 f, 7 m; age: 45±16 years) completed the TRIBAL program, a multiphasic, multidisciplinary training protocol. Training intensity was progressively increased based on individual performance to avoid post-exertional malaise. Sessions (2-3 times per week, 30 min) included 15 minutes on a whole-body ergometer and 15 minutes of breathing, strength, and stretching exercises. Patient-reported outcomes (Post-COVID functional status (PCFS) scale, FACIT-fatigue score) and objective parameters (repetitions of 1-minute sit-to-stand test (1MSTST), average wattage over 15 minutes with own pacing, blood samples) were analyzed at the beginning (pre) and after each of the five phases (post phase 5 = post). The Post-COVID score (PCS) was determined pre and post. RBC morphology was assessed using Pappenheim-stained blood smears and analyzed using microscopic evaluation. Statistical analyses included tests for normal distribution, t-tests, Wilcoxon tests, and Pearson correlation.

RESULTS: At the end of the protocol, the fatigue score improved by 27.1% (p<0.001); towards clinically normal values. The repetitions in the 1MSTST increased by 55% (p<0.001) and the wattage by 194% (z=-2.703, p=0.005). RBC morphological changes decreased by 5.1% (p<0.05) and an average of 92.2% RBC then showed normal cell shape. High positive correlation was calculated between wattage and fatigue r=0.669, p=0.001. Medium correlations were found between 1MSTST and fatigue r=0.399, p=0.041 and morphology and fatigue r=-0.403, p=0.049. The PCFS decreased from an average of 2 (minor functional limitations) to 1 (negligible limitations) and the PCS improved from moderate to no/mild LC (z=-2.703, p=0.007). LC patients completed the program in 37±10 weeks and corresponding 61±18 training sessions.

CONCLUSION: The unique time-unlimited, progressive and individualized TRIBAL protocol significantly improves physical fitness, reduces functional limitations and LC symptoms such as fatigue, which may be related to reductions in RBCs morphological abnormalities. It became apparent that a long period of time is necessary for LC therapy. However, by the end of the program, it was evident that the functional limitations were minimal, and the patients had fully regained their everyday skills, leading to a substantial improvement in their quality of life.

HOW TO REDUCE INJURY RISK AFTER RETURN-TO-PLAY IN ELITE FOOTBALL? SYNERGIES BETWEEN EXPERIENCE-BASED AND DATA-DRIVEN INSIGHTS

HECKSTEDEN, A., BERGER, J., MAZZOLARI, R., ZHANG, G., MEYER, T., BRINK, M., LEMMINK, K., KELLER, N., HAUSER, T.
UNIVERSITÄT INNSBRUCK

INTRODUCTION: In elite football, injury risk is considerable, especially in the weeks after return-to-play (RTP) from a previous injury. Consequently, optimal rehabilitation and well-informed decisions regarding the timepoint of RTP are crucial. Arguably, experiential knowledge as well as data-driven analyses may provide meaningful insights. This work aims to leverage their synergies to identify options for improving the rehab process and reduce injury risk after RTP.

METHODS: Following a mixed-methods approach, semi-structured interviews were conducted with 14 practitioners in elite European football (2 orthopaedic surgeons, 5 physiotherapists, 7 rehab and / or strength-and-conditioning (S&C) coaches). Areas of overlap in the interview data were identified by thematic analysis. Subsequently, media-based injury data from European top leagues were used to investigate novel themes where possible. Specifically, we used methods of causal inference and classifier development to assess the expert opinion that a reduction in injury risk may be expected when RTP is delayed.

RESULTS: 4 themes and 6 subthemes were identified. With the highest consistency and attributed importance, theme 1 posits that injury risk after RTP would be lower with longer rehab. Data analytics confirmed the previously reported negative association between rehab time and injury risk. However, this association is entirely accounted for by higher exposure after early return ("They return early for a reason."). Importantly, the virtual absence of high exposures after long rehab (for the respective diagnosis) impedes on predicting the effect of actively prolonging rehab time.

CONCLUSION: Taken together, our results point to surprisingly clear and simple options for improving rehab outcome in elite football. While data analytics did not provide evidence in favour of reduced injury risk with prolonged rehab, the massive increase in risk with high exposures after early return entails two important messages: (1) If an early return must be attempted exposure should be limited to the strict minimum. (2) If no injury occurred during initial match exposure(-s), luck should not be mistaken for evidence of low injury risk.

FACTORS FOR A SUCCESSFUL RETURN TO SPORT AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION: A 2-YEAR FOLLOW-UP COHORT STUDY ON REHABILITATION VOLUME, PSYCHOLOGICAL READINESS, AND MOTOR FUNCTION

NIEDERER, D., KELLER, M., JAKOB, S., WIEßMEIER, M., PETERSEN, W., SCHÜTTLER, K.F., EFE, T., MENGIS, N., ELLERMANN, A., GUENTHER, D., BRANDL, G., ENGEROFF, T., DREWS, B., ACHTNICH, A., BEST, R., PINGGERA, L., SCHOEPP, C., KRAUSE, M., GRONEBERG, D., STEIN, T.

GOETHE-UNIVERSITY FRANKFURT/MAIN ET AL.

INTRODUCTION: Return to sport (RTS) after an anterior cruciate ligament (ACL) rupture and reconstruction is successfully reached when one returns to the pre-injury level of sports participation. A multitude of individual and spatiotemporal factors interact during the rehabilitation and RTS process. Only if these potential factors are known, they can be considered and, where possible, modified to improve the RTS process. The objective of this study was to find contributors to RTS success or time until RTS in patients after an ACL reconstruction aiming to RTS.

METHODS: We performed a cohort study and secondary analysis of the data of two intervention studies. We included adults <36 years of age with a tendon autograft ACL reconstruction who were active in any type of sport prior to the injury and aiming to RTS. All participants were prospectively monitored for 24 months. At the end of the individual post-surgery rehabilitation and re-injury prevention programs, self-report- and objective functional outcomes were quantified. Main outcome measures were the potential RTS success (return to the same type of sports, frequency, intensity, and quality of performance as pre-injury), secondary injuries, and all rehabilitation and training measures were prospectively monitored. To determine the contributing factors, Cox regressions for traits and baseline factors and a logistic mixed model, which also included prospective time-dependent factors, were calculated.

RESULTS: Overall, 203 participants were included; 104 (51% of the total sample and 68% of the full cases) successfully returned to their sporting activity. The median duration until RTS was 302 days (interquartile range was 114 days). Contributing factors were the type of working (blue- vs. white collar: odds ratio (OR) for RTS = 0.51 [95% CI = 0.29 to 0.90]) and the athletic status (elite vs. non-elite: OR = 2.28 [1.03 to 5.03]). Prospectively, higher rehabilitation volumes until the end of the rehabilitation were predictive for RTS success: the OR per additional hour of rehabilitation was 1.004 [1.001 to 1.006]. Functional abilities such as the normalized knee separation distance during drop jump landing (OR = 0.961 [0.924 to 0.999]) were predictive at a later stage, at the end of the re-injury prevention. Psychological readiness for RTS was predictive at most of the timepoints: those who were confident to RTS were more successful to RTS at the end of the rehabilitation (OR = 1.029 [1.004 to 1.056]) and at the end of the re-injury prevention (OR = 1.038 [1.004 to 1.073]).

CONCLUSION: The most important factors for a successful pre-injury-level return to sport after anterior cruciate ligament reconstruction were the exercise volume, psychological readiness and functional hop/jump abilities. Whilst the impact of

these modifiable factors were robust against multilevel modeling, the impact of athletic and working status vanishes when the prospective factors are included.

TEMPORAL CHANGES IN TALOFIBULAR DISTANCE DURING ULTRASOUND-GUIDED ANTERIOR DRAWER TEST IN PATIENTS WITH ACUTE GRADE II LATERAL ANKLE SPRAINS

YUTO, U., MASASHI, K., YUSUKE, K., AKIRA, O., TAKUMI, K., YUTO, S., HIROYUKI, W., NAONOBU, T.

KITASATO UNIVERSITY GRADUATE SCHOOL OF MEDICAL SCIENCES

INTRODUCTION: Lateral ankle sprain (LAS) is the most common sports-related injury, with a re-injury rate exceeding 50% (1). Despite conservative management being the standard approach for grade II injuries (excluding recurrent cases), the timeline for the resolution of anterior displacement remains unclear. This study aimed to quantify temporal changes in talofibular distance using an ultrasound-guided anterior drawer test to determine the critical period for restoring ankle joint stabilization in patients with acute grade II LAS.

METHODS: This prospective observational study included 94 patients with acute grade II LAS who visited a single clinic between April 2021, and December 2023. All patients underwent splint fixation for 1–2 weeks without weight-bearing restrictions, followed by functional ankle brace until 6 weeks. Rehabilitation began at 3 weeks to facilitate functional recovery and return to sports. The ultrasound-guided anterior drawer test was conducted at initial consultation and follow-ups at 1, 3, and 5–6 weeks by a single examiner, assessing changes in talofibular distance (difference between maximum and minimum distances). Statistical analysis was performed using a mixed-model repeated-measures one-way analysis of variance, followed by Tukey's post-hoc test, with significance set at $p < 0.05$.

RESULTS: The mean change in talofibular distance on the affected side was 3.2 ± 1.8 mm at the initial consultation and 3.1 ± 1.7 , 1.6 ± 0.9 , and 1.6 ± 1.0 mm at 1, 3, and 5–6 weeks, respectively. A significant reduction was observed at 3 weeks ($p < 0.01$), with no further significant changes thereafter. The mean change in talofibular distance on the unaffected side was 1.3 ± 0.8 mm. The mean time to return to sports practice (excluding dropouts) was 41.2 ± 14.3 days from the initial consultation.

CONCLUSION: These findings identified mean change in talofibular distance on the affected side significantly decreased at 3 weeks post-injury and remained unchanged at 5–6 weeks. Previous studies reported that unrestricted activity from the initial consultation failed to restore joint stability, even at 3 and 6 weeks (2). Conversely, our results suggest that restricting activity to walking until 3 weeks facilitated ligament healing, thereby optimizing rehabilitation outcomes and preventing residual joint instability upon return to play at 5–6 weeks.

The critical recovery period for change in talofibular distance occurred between 1 and 3 weeks post-injury. These findings highlight the importance of managed activity limitation in the early phase in promoting ligamentous recovery and reducing re-injury risk in acute grade II LAS.

THE LYSHOLM SCORE CAN BE USED AS A SIMPLE METHOD TO EVALUATE THE BOXERS WITH CHRONIC KNEE PAIN: A CORRELATIVE ANALYTICAL STUDY

CHEN, J.1, LI, Y.Z.1, ZHANG, X.Y.2, WANG, D.1

1 SHANGHAI UNIVERSITY OF SPORT, SCHOOL OF ATHLETIC PERFORMANCE, CHINA; 2 WRESTLING, BOXING AND TAEKWONDO SPORTS CENTER OF HEBEI PROVINCIAL SPORTS BUREAU, CHINA

INTRODUCTION: Chronic knee pain (CKP) is defined as knee pain persisting for over three months, with a visual analogue scale (VAS) score of 3 or higher in the past month. Pain has the potential to induce deterioration in motor control capabilities, disrupt neuromuscular coordination and power output, increase athletes anxiety and depression levels, and subsequently impact their sporting form and competitive performance. Currently, the common assessment indicators for CKP encompass both subjective measures (e.g., VAS, Lysholm knee function score, etc.) and objective measures (e.g., muscle strength, range of motion (ROM), muscle circumference, knee stability, etc.). However, the complexity and time-consuming nature of these tests will, to a certain extent, affect the training and rest of athletes. Consequently, this study aims to investigate the correlations between subjective and objective measures to identify a simple and rapid testing method that can assist coaches in quickly monitoring the CKP status of boxers.

METHODS: Thirty-two boxers (22 males: 19.9 ± 2.3 y, 180.2 ± 8.3 cm, 71.0 ± 20.9 kg, trained for 5.3 ± 2.0 y, suffering from CKP for 19.0 ± 13.3 month; 10 females: 21.0 ± 1.0 y, 170.8 ± 6.9 cm, 63.5 ± 8.5 kg, trained for 6.2 ± 3.6 y, suffering from CKP for 20.2 ± 8.1 month) with CKP were recruited from 5 provincial boxing teams. After 5-minute jog and 5-minute dynamic stretching of warm-up, VAS of knee pain, Lysholm knee function score, ROM of knee flexion, maximal voluntary isometric contraction (MVIC) muscle strength of knee extensor and flexor, muscle circumference at 10cm above the upper edge of the patella and single-leg stance with eyes closed were measured. All data were analyzed using the Spearman rank correlation method. Correlation interpretations were as follows: $|rs| = 0.1$ small; $|rs| = 0.3$ medium; $|rs| = 0.5$ large.

RESULTS: The Lysholm score has a strong correlation with VAS ($r_s = -0.591$, $p < 0.001$), a medium correlation with MVIC muscle strength of knee extensor ($r_s = 0.309$) and flexor ($r_s = 0.372$, $p = 0.036$), and a small correlation with knee stability ($r_s = -0.210$), and no correlation with ROM ($r_s = -0.045$) and muscle circumference ($r_s = -0.083$). VAS has a small correlation with MVIC muscle strength of knee extensor ($r_s = -0.108$), muscle circumference ($r_s = 0.143$), and knee stability ($r_s = 0.157$), and no correlation with MVIC muscle strength of knee flexor ($r_s = -0.011$) and ROM ($r_s = 0.035$).

CONCLUSION: Lysholm knee function score could be an alternative comprehensive evaluation for objective measures for boxers with CKP.

EFFECTIVENESS OF NEUROCOGNITIVE TRAINING IN ENHANCING REHABILITATION OUTCOMES AFTER ACL RECONSTRUCTION: A SYSTEMATIC REVIEW

ZOTTER, S., MASCARENHAS, M., HUSSIN, R., OLIVEIRA, G., MEDINA, G.
MASSACHUSETTS GENERAL HOSPITAL

INTRODUCTION: Anterior cruciate ligament reconstruction (ACLR) is one of the most common knee surgeries, yet many patients fail to return to their pre-injury performance levels. [1] Emerging evidence suggests that deficits in neurocognitive processing may contribute to suboptimal neuromuscular control and increased re-injury risk. [2] We hypothesized that integrating neurocognitive training—through approaches such as cognitive-behavioral interventions, dual-task neuromuscular exercises, and operant conditioning protocols—can accelerate neuromuscular adaptations and enhance functional recovery in ACLR patients.

METHODS: A systematic review was conducted following PRISMA guidelines. Two databases were searched in January 2025, and studies evaluating neurocognitive training interventions in ACLR patients were included. Out of 400 records identified, 352 studies were screened after duplicates were removed, 8 full-text articles were assessed for eligibility, and 6 studies met the inclusion criteria.

RESULTS: Among the 6 studies included, two randomized controlled trials demonstrated that neurocognitive training facilitated faster load symmetrization, improved gait patterns, greater proprioception efficiency, and enhanced quality of life compared to conventional rehabilitation. Additionally, a pilot study employing a telephone-based cognitive-behavioral intervention showed promising improvements in return-to-sport readiness and psychological adaptation. Further, quasi-experimental and laboratory investigations reported that advanced neuromuscular training improved performance on visomotor reaction tests and single-leg hop tests, while an operant conditioning protocol induced acute increases in corticospinal excitability. An innovative aquatic proprioceptive training program was also associated with enhanced proprioception.

CONCLUSION: These preliminary findings suggest that neurocognitive training could serve as a feasible adjunct to traditional ACLR rehabilitation. However, due to the limited number of studies, varied study designs, and lack of standardized methodologies, the current evidence is not definitive. A larger, more robust body of research is needed to confirm these benefits and to establish optimal intervention protocols.

OP-MH33 Inflammation

REDUCING INFLAMMATION THROUGH PHYSICAL ACTIVITY IN MIDDLE-AGED AND ELDERLY POPULATIONS: EVIDENCE FROM CHARLS

YONGYU, H.1, ZUOSHENG, L.1, YAN, Y.2

1. SOUTH CHINA NORMAL UNIVERSITY, 2. SCHOOL OF PHYSICAL EDUCATION, SHENZHEN POLYTECHNIC UNIVERSITY, GUANGDONG, CHINA

INTRODUCTION: Chronic low-grade inflammation is a pathogenic mechanism underlying many chronic diseases such as type 2 diabetes and cancer [1]. C-reactive protein (CRP) is an important indicator reflecting systemic inflammation levels [2]. Previous studies have shown that Physical Activity (PA) helps reduce CRP levels, but most research has focused on younger adults, with relatively few studies specifically targeting middle-aged and elderly individuals [3]. Moreover, middle-aged and elderly people are more susceptible to chronic inflammation [4]. Therefore, exploring the association between PA and inflammation levels in the middle-aged and elderly population is necessary.

METHODS: We used data from the third wave (2013) of the China Health and Retirement Longitudinal Study (CHARLS) to test our hypotheses. Specifically, a total of 6,279 middle-aged and elderly individuals aged 45 years and above participated in this study, representing a weighted sample of 261,532,239 middle-aged and elderly people in China. According to the

WHO physical activity guidelines, we defined individuals with weekly PA expenditure of <600 MET-minutes as not meeting the standard, and those with ≥ 600 MET-minutes as meeting the standard. Furthermore, to verify whether inflammation levels continuously decrease with increasing PA levels, we divided physical activity expenditure into quartiles. Multiple linear regression was used to explore the association between PA and CRP levels; all analyses were adjusted for age, gender, education level, marital status, per capita household expenditure (PCE), smoking, alcohol consumption, and sleep duration.

RESULTS: After adjusting for age, gender, education level, marital status, PCE, sleep duration, alcohol consumption, and smoking, compared to individuals not meeting the guidelines, those meeting the guidelines had a significantly lower C-reactive protein level by an average of 0.772 mg/L ($\beta = -0.772$, 95% CI: -1.226 to -0.318, $p < 0.001$). Compared to the first quartile of PA, the CRP concentration in the second quartile decreased by an average of 0.366 mg/L ($\beta = -0.366$, 95% CI: -0.843 to 0.112, $p = 0.134$). In the third quartile, CRP concentration decreased by an average of 0.429 mg/L ($\beta = -0.429$, 95% CI: -0.915 to 0.057, $p = 0.083$). In the fourth quartile, CRP concentration significantly decreased by 0.731 mg/L ($\beta = -0.731$, 95% CI: -1.226 to -0.236, $p = 0.004$). These findings suggest a trend of decreasing CRP levels with increasing PA.

CONCLUSION: Our study results indicate that adequate physical activity can reduce systemic inflammation levels among middle-aged and elderly individuals in China, and as physical activity levels increase, inflammation levels further decrease. In the future, more policies and measures should be implemented to promote physical activity participation among the middle-aged and elderly population to maintain lower inflammation levels.

BIOMARKERS OF CARDIAC, MUSCULOSKELETAL STRESS AND INFLAMMATION IN EXTREME ENDURANCE ATHLETES: INSIGHTS FROM A MOUNTAIN ULTRAMARATHON

LE GOFF, C., GILLET, V., CALLOVINI, A., RABERIN, A., KAUX, J.F., BREVERS, E., RECCHAD, M., CAVALIER, E., MILLET, G.P.
UNIVERSITY HOSPITAL OF LIÈGE

INTRODUCTION: Extreme physical exertion, such as ultramarathons, places considerable physiological demands on the cardiovascular and musculoskeletal systems. Biomarkers like high-sensitivity Troponin I (hs-TnI), NT-proBNP, high-sensitivity C-Reactive Protein (hs-CRP), creatine kinase-MB (CKMB), Interleukin-6 (IL-6), and soluble ST2 (sST2) offer insights into myocardial stress, systemic inflammation, and skeletal muscle damage. This study assessed these biomarkers in athletes completing a 330 km mountain ultramarathon with a 24,000 m elevation gain to differentiate physiological adaptation from pathological risks.

METHODS: Blood samples were collected from 48 participants at three time points: pre-, mid- (148 km), and post- (330 km) race. Biomarker levels were measured using MAGLUMI X3 (Snibe®) and Alinity immunoassay systems (Abbott®). Pre-concentrations were compared with mid- and post- to evaluate the impact of extreme exertion.

RESULTS: All biomarkers showed significant increases during the race. hs-TnI levels rose from <5 ng/L at pre- to peaks of 12 ng/L at post-, indicating mild, transient myocardial strain without permanent damage. NT-proBNP increased from 50 pg/mL at pre- to >600 pg/mL at post-, reflecting acute cardiac volume overload. Inflammatory markers showed marked responses: hs-CRP levels increased from <1 mg/L at baseline to 30 mg/L at post-, while IL-6 increased to >200 pg/mL at mid- and remained elevated at post-, indicating early systemic inflammation.

sST2 showed notable elevations, with baseline levels (~30 ng/mL) close to thresholds indicating subclinical cardiac stress, rising to >100 ng/mL at post-, suggesting baseline myocardial stress exacerbated by exercise. CK levels rose to 5,000 U/L at post-, indicating acute severe skeletal muscle damage, while CKMB peaked at 60 U/L, requiring careful contextual analysis.

CONCLUSION: Extreme endurance events cause substantial physiological stress, as reflected in biomarker fluctuations. The alarming baseline and peak levels of sST2 highlight its utility in detecting early cardiac strain. Tailored monitoring and recovery strategies are vital to safeguarding the long-term health of athletes exposed to such challenges. Additionally, the significant rise in IL-6 and hs-CRP underscores the pronounced inflammatory response induced by extreme exertion, which may contribute to prolonged recovery and systemic stress.

CHRONOTYPE DOES NOT SOLELY EXPLAIN THE DIFFERENCES IN MARKERS OF CHRONIC INFLAMMATION IN HEALTHY, MALE AND FEMALE ADULTS: A CROSS-SECTIONAL STUDY.

DEMASHKIEH, M., PAINE, N.J., ROBERTS, M.J., LINSLEY, V.G., QOOJA, S., BISHOP, N.C.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Chronotype, or diurnal preference, spans from morning (M-type) to evening (E-type). It can be subjectively or objectively measured [1], and can be state- or trait-like [2]. E-types are linked to unhealthy lifestyles, such as irregular meals and lower physical activity (PA) [3], increasing their risk of low-grade inflammatory issues like cardiometabolic diseases [4]. Potential sex differences exist in chronotype and cardiometabolic risks [5]. This study examined differences in moderate-vigorous PA (MVPA), sex, and the chronotype-inflammation relationship in adults.

METHODS: Fifty-one healthy adults [19 male (M), 33 female (F); 18-41 years] wore a triaxial accelerometer for 8 days/nights to assess MVPA and chronotype via sleep midpoint. Fasted blood samples and anthropometric data were collected. Total and differential leukocyte counts were analysed. Monocyte subsets were identified via flow cytometry. Plasma interleukin-6 (IL-6) and LPS-stimulated IL-6 levels were measured using ELISA. T-tests and Mann-Whitney U tests assessed MVPA differences between chronotypes, and sex differences in inflammatory markers. Generalised linear models evaluated

chronotype-inflammatory markers associations, further adjusted for age. Effect sizes were calculated, and data presented as mean±SD or median (IQR). $P < .05$ indicate significance.

RESULTS: M-types were ~3 years older than E-types [26 (23-33) years vs. 23 (21-26) years; $p = .010$, $ES = .43$]. No MVPA-differences were noted between chronotypes ($p = .604$, $ES = .15$). LPS-stimulated IL-6 levels were ~6x higher in M than F ($p = .032$, $ES = .39$). M-type M had lower classical monocyte counts than E-type M [296.4 ± 81.3 vs. 355.6 ± 130.1 cells/ μ L; $p = .024$]. M-types showed lower plasma IL-6 [0.58 (0.42-0.75) vs. 0.89 (0.57-1.38) pg/mL; $p = .034$], lymphocyte [1.59 (1.40-1.77) vs. 1.87 (1.71-2.04) $\times 10^9$ /L; $p = .020$], and monocyte counts [0.37 (0.32-0.41) vs. 0.45 (0.40-0.50) $\times 10^9$ /L; $p = .017$] compared with E-types, but these differences became nonsignificant after age adjustment.

CONCLUSION: This study found no differences in MVPA between chronotypes. LPS-stimulated IL-6 levels were higher in M compared to F. M-types initially showed a more favourable inflammatory profile than E-types; however, this difference was not observed after adjusting for age, suggesting that age may be a major factor influencing chronic inflammation in young to middle-aged adults.

IBUPROFEN INTAKE PRIOR TO INTENSE ENDURANCE EXERCISE MIGHT NOT TRIGGER LPS-MEDIATED SYSTEMIC INFLAMMATION IN HEALTHY MALE ATHLETES: A RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED CROSSOVER STUDY

MOSER, J., SCHUHMANN, M.1, ONIKIENKO, O.1, TRISKA, C.1,2, MATHY, A.1,2, WESSNER, B.1

1 UNIVERSITY OF VIENNA ; 2 LEISTUNGSSPORT AUSTRIA

INTRODUCTION: Non-steroidal anti-inflammatory drugs (NSAID) are widely used in sports for pain management but can exacerbate gastrointestinal issues during exercise [1]. A previous analysis of this study showed that even low, over-the-counter available doses of NSAIDs affect the intestinal barrier. Increased permeability may allow lipopolysaccharide (LPS) to enter the bloodstream, triggering systemic inflammation [2]. LPS-binding protein (LBP) and soluble CD14 (sCD14) cooperate to recognise and respond to LPS initiating immune activation [3]. This study examines whether NSAID use during acute exercise impacts circulating LPS levels, LPS-associated immune responses and immune cell counts.

METHODS: In a randomized, double-blind, crossover study, eleven male subjects (29.2 ± 5.6 yrs; BMI: 24.4 ± 2.8 kg/m²; VO_{2max} : 52.6 ± 4.8 ml/min/kg) completed two 45-minute runs at 75% VO_{2max} , followed by an all-out run. Participants received either a placebo or 400 mg ibuprofen, with a one-week washout phase. Blood samples (pre, 0, 1, 3, and 24 h post-exercise) were analysed by ELISA for LPS, sCD14 and LBP, and a blood analyser was used to measure leukocyte subpopulations. Data were normalised to the baseline measurements prior to analysis using two-factor repeated measures ANOVA.

RESULTS: Although no significant condition*time interactions were observed for LPS ($p = 0.177$, $\eta^2 p = 0.224$), LBP ($p = 0.765$, $\eta^2 p = 0.044$), and sCD14 ($p = 0.736$, $\eta^2 p = 0.048$), significant time effects were revealed for LPS ($p = 0.018$, $\eta^2 p = 0.544$), LBP ($p = 0.015$, $\eta^2 p = 0.364$), and CD14 ($p = 0.005$, $\eta^2 p = 0.301$) highlighting the impact of exercise rather than ibuprofen on these parameters. Bonferroni-corrected post hoc test showed that LPS peaked immediately post-exercise (0h) and was lowest at 24h, although differences between time points were not significant. LBP decreased by 7.4% at 1h ($p = 0.050$) and 9.0% at 3h ($p = 0.013$) post-exercise, while sCD14 increased by 9.3% at 24h ($p = 0.024$). These changes paralleled well-documented increases in leukocyte counts (time: $p < 0.001$, $\eta^2 p = 0.751$; condition*time: $p = 0.502$, $\eta^2 p = 0.070$), particularly granulocytes (time: $p < 0.001$, $\eta^2 p = 0.801$; condition*time: $p = 0.795$, $\eta^2 p = 0.013$), and a biphasic lymphocyte response (time: $p < 0.001$, $\eta^2 p = 0.634$; condition*time: $p = 0.239$, $\eta^2 p = 0.132$).

CONCLUSION: Intense endurance exercise significantly modulates LPS, LBP, and sCD14 levels, as well as leukocyte subpopulations, demonstrating the exercise-induced impact on immune responses. Notably, these changes occurred independently of ibuprofen intake, suggesting that the low-dose ibuprofen-induced disturbance of the intestinal barrier (as demonstrated in the first study part) does not exacerbate systemic inflammatory processes. It remains to be determined whether this holds true for the higher doses that are frequently used.

THE EFFECTS OF EXERCISE THERAPY AND SELF-MANAGEMENT SUPPORT ON SYSTEMIC LOW-GRADE INFLAMMATION, GLYCAEMIC CONTROL, LIPIDS, AND BLOOD PRESSURE IN PEOPLE WITH MULTIMORBIDITY: A PRE-PLANNED SECONDARY ANALYSIS

BRICCA, A., NYBERG, M., LEGAARD, G.E., DIDERIKSEN, M., ZANGER, G., THYGESEN, L.C., SKOU, S.T.
UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: In this pre-planned secondary analysis of the MOBILIZE trial, we investigated the effect of a 12-week personalised exercise therapy and self-management support programme, in addition to usual care, on systemic low-grade inflammation, glycaemic control, lipids, and blood pressure in people with multimorbidity

METHODS: The statistical analysis plan for this pre-planned secondary analysis of the pragmatic, assessor-blinded, multi-center, parallel-group RCT (1:1 treatment allocation) was made available in OSF before any analyses commenced. We enrolled adult patients aged 18 or older with multimorbidity, defined as having at least two of the following conditions: knee or hip osteoarthritis (OA), chronic obstructive pulmonary disease (COPD), heart disease (heart failure or coronary heart disease), hypertension, type 2 diabetes mellitus (T2DM), and depression. Patients with additional comorbidities were not excluded. Individuals (n=228) were randomised (1:1) to the intervention group or usual care. Biomarkers, assessed at baseline and 4 months, included interleukin-1 receptor antagonist (IL-1ra), high-sensitivity C-reactive protein (hs-CRP), tumor necrosis factor-alpha (TNF- α), interleukin-6 (IL-6), hemoglobin A1c (HbA1c), fasting glucose, fasting insulin, high-density lipoprotein (HDL), low-density lipoprotein (LDL), triglycerides, and blood pressure. Between-group comparisons of change from baseline to the 4 months follow-up in continuous outcomes were analysed using repeated measures mixed-effects linear model. ClinicalTrials.gov registration: NCT04645732

RESULTS: Between January 18, 2022, and May 30, 2023, 228 were randomised. Participants were allocated to either the exercise therapy and self-management support intervention group (n = 115) or the usual care group (n = 113). In the total group, the average age was 69.8 years (SD 8.4), with a mean BMI of 30.9 (SD 5.7), 43% were female, and patients had an average of 7 chronic conditions (SD 3, range 2–19). The median session attendance for the exercise therapy and self-management support group was 76%. The intention to treat analysis showed that the intervention group had a statistically and clinically significant reduction in systolic blood pressure compared to usual care (mean difference: -4.7 mmHg, 95%CI: -8.8 to -0.6). No statistically significant differences were observed for other biomarkers, although favouring the intervention group. Per-protocol analyses: i) including only individuals attending 75% or more of the intervention sessions, ii) without individuals in the usual care group that received supervised exercise therapy sessions and individuals that in both groups undergo surgery in the 4-month follow-up

CONCLUSION: Personalised exercise therapy and self-management support reduced systolic blood pressure, but not other biomarkers, in individuals with multimorbidity. Further trials powered to investigate biomarkers related to ageing and cardiovascular health are needed in individuals with multimorbidity to confirm these findings.

Oral Presentations

AN EXPLORATION INTO WOMEN'S RELATIONSHIP WITH EXERCISE, BODY IMAGE BELIEFS, AND SOCIOCULTURAL FACTORS: A US/ITALY CROSS-CULTURAL COMPARISON STUDY

HADFIELD, J., TOSELLI, S., LEONARDI, C.
LOUISIANA STATE UNIVERSITY

INTRODUCTION: Today's world assesses the ideal female figure as not only thin, but also muscular, or more colloquially known as fit. Internalizing ideal body standards has been linked to various negative health outcomes. Exploring women's pursuits to achieve idealized body appearance and resultant health outcomes has been a salient and sought-after topic among behavioral health researchers. Considering that sociocultural factors significantly influence health outcomes such as disordered eating and disordered exercise, it is vital to assess the social and cultural determinants influencing behavioral dynamics within women's relationships of idealized aesthetics. Two cultures that share Westernized customs and beliefs yet have distinct value systems are the Italian and US cultures. These two distinct cultures hold varying family, peer, and media value systems inherently influenced by cultural impacts that arguably shape today's exercise culture and aesthetic ideals. This study cross-culturally explores Italian and US adult women's relationships with fit ideal body image beliefs and sociocultural factors.

METHODS: This sub-study is under a larger bilingual (Italian/English) multi-phase explanatory sequential mixed-methods design. This sub-study includes the phase that examines differences between sociocultural influences and body image in Italian and US women. Women (n=153) 18-45 living in Italy (n=105) or the USA (n=53) completed an online survey measuring demographic, body image, and sociocultural attitudes, namely the sociocultural attitudes towards appearance questionnaire and the Multidimensional Body-Self Relations Questionnaire. Sub-scales were compared between U.S. and Italian women using analysis of covariance. The model included age, race, income, and education as covariates to adjust for potential confounders between the two groups.

RESULTS: Italian women reported a higher internalization of general appearance than US women (2.60 vs. 2.47, $p=0.031$) and higher levels of familial pressures regarding appearance (4.36 vs. 3.64, $p=0.005$). Italian women reported lower fitness evaluations like feelings of being fit than US women (3.14 vs. 3.70, $p=0.001$) and fitness orientation, such as personal investment in being fit (2.99 vs. 3.30, $p=0.005$).

Conclusions

Italian and US women differ in the sociocultural internalized pressures toward appearance and general appearance beliefs. These two cultures also differ in how they evaluate and orient themselves to fitness. Since sociocultural factors inform health beliefs, behaviors, and, subsequently, health outcomes, it is warranted to explore further how these significant sociocultural factors and body image-related beliefs inform fitness/exercise behaviors among these women. Our findings may lead to a better understanding of the phenomenon of sociocultural determinants and their relationship with body image and exercise behaviors for optimal women's health outcomes on an internationalized scale.

WHAT ROLES DO SELF-CONSCIOUS EMOTIONS PLAY FOR ATHLETES? A SYSTEMATIC REVIEW BASED ON ECOLOGICAL SYSTEM THEORY

TSAI, C., LEISTERER, S., WINKLER, E., CHO, K., ELBE, A.M.

LEIPZIG UNIVERSITY

Objective: Self-conscious emotions, such as guilt, shame, pride, and embarrassment, play a key role in the performance outcomes of athletes in sport and training. This systematic review aimed to examine the interplay of personal and contextual sources influencing self-conscious emotions in athletes.

Methodology: We conducted a comprehensive search across Web of Science, Scopus, PubMed, and PsycINFO, covering the years 2004 to 2023. Using key terms such as "self-conscious emotions," "guilt," "shame," "pride," "embarrassment," "environment," "athlete*," and "sport*," we identified 31 studies that met the inclusion criteria: (a) focusing on self-conscious emotions, (b) written in English, (c) investigating factors influencing these emotions, (d) involving sports-related settings or participants, and (e) using qualitative or quantitative methods. Only studies from A&HCI, SCI, or SSCI-indexed journals were included to ensure quality, while theoretical reviews, non-English papers, and studies with non-athlete participants were excluded. Risk of bias was assessed using the Mixed Methods Appraisal Tool (MMAT).

Result: Based on Bronfenbrenners ecosystem theory, we categorized findings into individual ($n = 24$; e.g., perfectionism, moral disengagement) and microsystem ($n = 8$; e.g., coach, teammate) levels. Notably, gaps were identified in the mesosystem ($n = 3$; e.g., motivational climate), exosystem ($n = 1$; e.g., management style), and macrosystem and chronosystem levels, which remain unexplored.

Discussion: The study highlights the need for cross-cultural investigations of athletes self-conscious emotions, inclusion of additional stakeholders (e.g., parents, referees), and research on underexplored emotions such as pride and embarrassment. However, this review has limitations, including the exclusive focus on English-language and indexed journals, potentially excluding culturally diverse perspectives and non-indexed studies. Furthermore, the review was limited to studies published before December 2023, suggesting the need for periodic updates to capture emerging research.

Other: This systematic review was registered with PROSPERO (CRD42023494012) and received no external funding.

ACUTE EFFECT OF EXERCISE INVOLVING COOPERATIVE ACTIVITIES ON EMOTION RECOGNITION IN PREADOLESCENTS: MODERATING EFFECTS OF PSYCHOPATHOLOGY

BERGER, M., ISHIHARA, T., KAMIJO, K., GERBER, M., LUDYGA, S.

UNIVERSITY OF BASEL

INTRODUCTION: Emotion recognition refers to the ability to identify another individuals emotional state [1]. In school settings, better emotion recognition promotes positive peer relationships and academic success, while deficits are linked to problematic behaviors and various mental difficulties [1]. A single exercise session has the potential to temporarily enhance emotion recognition by implementing components of social skills training or by trigger a cascade of physiological effects underlying cognitive enhancements [2]. However, the effects may differ depending on the children's psychopathology due to varying adaptation reserves. We aimed to investigate the acute effect of exercise, with and without the integration of cooperative activities, on emotion recognition in children depending on their psychopathology, indicated by the Strength and Difficulties Questionnaire (SDQ).

METHODS: Using a between-participants-design, 140 children (age = 11.5 years) were randomly allocated (stratum: school class) to groups performing exercise involving cooperative activities (EX+CO, $n = 45$), exercise without cooperative activities (EX, $n = 45$), and a control group watching a video (CON, $n = 50$). The interventions lasted 20 minutes and were completed in a school setting. Prior and after the interventions, participants completed a computerized facial emotion recognition task, in which anger, fear and happiness had to be categorized. In addition, psychopathology was assessed using the SDQ sum score, dividing participants into normal (<16) and abnormal (≥ 16) behavioral difficulty groups.

RESULTS: A mixed ANCOVA revealed a significant interaction of group and psychopathology for post-test emotion recognition accuracy, while controlling for pre-test scores. Decomposition of the interaction showed that among participants with a normal range of behavioral difficulties, the EX group had a significantly greater accuracy ($M = .62$, $SE = .02$) compared to EX+CO ($M = .57$, $SE = .02$) and CON ($M = .57$, $SE = .02$) at post-test. The analysis of reaction time showed no indication

for a speed-accuracy trade-off. In contrast to participants with behavioral difficulties in the normal range, the exercise groups and the control group did not differ with regard to emotion recognition in those with abnormal scores on the SDQ.

Discussion: A single aerobic exercise session without the integration of cooperative activities temporarily enhances emotion recognition in children without behavioral difficulties. This finding offers initial insight into exercises potential use fostering this ability within school context.

THE PARADIGM SHIFTS OF PERSONAL VALUES DUE TO THE LONG-TERM CONFLICTS IN THE PROFESSIONAL BALLET COMPANY

CHOI, Y.

CHONNAM NATIONAL UNIVERSITY

INTRODUCTION: We study on the priorities of personal values that are changed due to the conflicts experienced among members of professional ballet company, in which the physical ability is playing a key role. Conflicts are inevitable phenomenon in the life of more than two persons or organizations [1]. The organization of ballet company are composed of artistic directors, dancers, and administrative staff, in there they form work roles, goals and various relationships. These members have personal or relational conflicts. Values are the principles or standards as like the flag of thinking, judgment, and behavior of individuals, therefore it is not willing to change [2]. The values have two main categories as the instrumentals and the terminals [2]. Nevertheless, by help of these research, the changing of personal values by conflicts can be clarified, which can lead to inconsistency with professional ethics in the organization.

METHODS: This research is deployed by the qualitative-intense interviews of 15 members in the ballet company.

For this study, first, the theoretical background of conflicts and individual values was explored, by help of 3 expert's pre-reviews, the conflict factors are 163 cases of 5 categories. Also, important personal values are 12-values of total 24 individual values. Second, both conflict experiences and changing values of members were interviewed. The 3-classified periods of employments as like, short, mid and long-terms, are <5yrs, 5-10 yrs, and >10yrs, respectively. Third, the relationship study was conducted on both conflict factors and the changed important personal values.

RESULTS: The main steps of the conflicts in the ballet company are the cause, phenomenon as the process, and results. First, the causes are based on the organizational, social and personal. Second, the members can undergo the conflict process such as less communications, a lack of the emotional understanding. Finally, the conflict has been done as shown leaving, injury, fighting, conform to the trend and work inefficiency, etc. Through the trajectory study on both personal values and conflicts experiences, the personal paradigm shifts, changing of personal values, are featured. The priority of personal values is more permissible to the instrumental values, imposed to the family and personal health, changing from professional ability and organizational goals as the terminal values. The members have experienced the decoupling between personal values and organizational goals.

Discussion: It provides an opportunity to enhance the understanding of conflicts in the professional ballet company as well as the perception of individual values. The personal paradigm shifts by conflicts can be occurred in team sports, such as football teams, cricket teams, etc.

COACHES BELIEFS ON THE CORE COMPONENTS OF PARENTAL SUPPORT IN YOUTH HOCKEY

LAVINS, R., FERNATE, A.

RIGA STRADINS UNIVERSITY

Introduction

Previous research has shown that young athletes experience stress due to parental expectations, problematic behavior, excessive involvement in training, and financial pressure related to their familys investment in athletic development. Coaches can form professional relationships and collaborate with parents to consciously reduce the pressure on young athletes, so coaches must be familiar with the involvement of parents of children and youth to foster a positive sports experience for children and youth athletes. This research aim is to explore coaches beliefs on the core components of parental support in youth hockey.

METHODS: 105 coaches (n=92 male, n=13 female; work experience – 7.8 ±0.87 years) voluntarily participated in the survey from several children and youth hockey clubs. A custom-designed questionnaire was developed to evaluate coaches' beliefs about the core components of parental support in youth hockey. The responses were given on a scale. The questionnaire survey has a Cronbach's Alpha coefficient of 0.87. The questionnaire was highly reliable because the results of the questionnaire survey are 0.80 – 0.90. Data were processed with SPSS 28; descriptive and inferential mathematical

statistics were used. The mean results are expressed as a percentage score; the coefficient of internal coherence (Cronbachs Alpha); the Kolmogorov-Smirnov test for the determination of the data distribution; the Spearman rank correlation for the examination of the relationship between variables.

RESULTS: Coaches believe that the more hockey plays a central role in the family, the more it becomes a key aspect of the lives of parents and guardians lives ($r_s = .795$; $p < .01$). If logistic support becomes more important to parents and guardians, financial support increases in importance to them ($r_s = .428$; $p < .01$). The coaches believe that parents and guardians who analysed their child's performance after practice are also inclined to do so after games ($r_s = .644$; $p < .01$). The higher the parents need for psychological and emotional support from the club, the higher the demand for general educational support as well ($r_s = .606$; $p < .01$) and for education support in hockey ($r_s = .606$; $p < .01$).

Discussion

Coaches recognize that parents who invest time and resources to facilitate their child's participation in hockey become more deeply involved with the sport, both practically and psychologically. When logistical responsibilities (such as transportation, scheduling, and attendance) become increasingly vital, parents and guardians also place greater emphasis on financial contributions. Parental involvement in performance analysis can have both positive and negative effects, while constructive feedback can aid player growth, excessive scrutiny could contribute to excessive pressure and stress. Clubs and coaches can use this knowledge to promote support systems that address logistical, financial, emotional, and educational needs.

OP-SH27 Physical Activity and Health

BEYOND THE STEPS: THE ROLE OF HARMONIOUS PASSION AND EMOTIONAL EXPERIENCES IN FEMALE RECREATIONAL DANCERS

MARINI, S.1, BORTOLI, L.1, ROMANO, G.2, DI LIBORIO, M.3, ROBAZZA, C.1

1 G. DANNUNZIO UNIVERSITY OF CHIETI-PESCARA; 2 AZIENDA OSPEDALIERA UNIVERSITARIA FEDERICO II DI NAPOLI; 3 ACCADEMIA ITALIANA OSTEOPATIA TRADIZIONALE, PESCARA.

INTRODUCTION: Dance involves perceptual and motor aspects, requires the memorization of motor sequences, and has an artistic component combined with music, which underlines its socio-cultural dimension. The combination of motor skills, physicality, relationality, artistic and expressive ability makes dance a tool that can give its own particular contribution within the broad scope of motor activities. The purpose of the present study was to investigate the interplay between passion, self-confidence, emotional arousal control, worry, concentration disruption, and functional psychobiosocial experiences among amateur female dancers.

METHODS: A convenience sample of 160 Italian women, aged 16 to 36 years ($M = 20.63$, $SD = 4.93$), practicing dance at a nonprofessional level, was recruited from main dance schools in central and south Italy. The recreational dancers had between 1 and 22 years of dance experience ($M = 7.52$, $SD = 3.44$) and practiced dance 3 to 5 times a week. Assessment was conducted in small groups before practice sessions. The Passion Scale [1,2] was used to assess two dimensions: Harmonious passion (6 items,) and Obsessive passion (6 items). Performance-related feelings were assessed using the subscales of the emotion higher-order factor of the IPPS-48 [3], which consists of 24 items covering 4 factors: Self-confidence, Emotional arousal control, Worry, and Concentration disruption subscales. The Psychobiosocial Experience Semantic Differential scale in sport [4] was administered to assess psychobiosocial experiences. This instrument is composed of 30 bipolar items representing 10 modalities with 3 items. Statistical analysis was performed using hierarchical regression with a step-wise method. In the first step, Self-confidence and Emotional arousal control were entered, followed by Harmonious Passion and Obsessive Passion in the second step.

RESULTS: Participants reported higher mean scores for Harmonious passion ($M = 4.08$, $SD = .49$) than Obsessive passion ($M = 3.01$, $SD = .87$; $p < .001$), indicating a predominance of harmonious passion. In the first step of the regression model, Self-confidence and Emotional arousal control together accounted for 28.2% of the variance in psychobiosocial experiences, with Self-confidence being the primary predictor in this step ($\beta = .51$, $p < .001$) explaining 26.0% of the variance. After entering Harmonious passion in the second step ($\beta = .17$, $p < .032$), the overall model explained 30.3% of the variance.

CONCLUSION: In summary, preliminary study findings suggest that, for female recreational dancers, self-confidence and harmonious passion for dance are important contributors to positive psychobiosocial experiences. This could imply that dance, when engaged in with a healthy mindset and accompanied by feelings of competence, can be a valuable physical activity for promoting overall well-being.

UNDERSTANDING THE BENEFITS OF PHYSICAL ACTIVITY PROMOTION ON MENTAL HEALTH OF PRESCHOOLERS: A QUALITATIVE STUDY

LIN, S., AU, W., LEUNG, C., FONG, D., WONG, S., CHAN, D., CAPIO, C., YU, C., WONG, S., CHEN, Y., THOMPSON, W., SIU, P.
THE UNIVERSITY OF HONG KONG

Introduction: Physical activity (PA) positively impacts childrens psychological health, especially in reducing depression, anxiety and improving well-being. According to the World Health Organization and United Nations Childrens Fund report, around one in seven children and adolescents are affected by mental health issues. Previous studies suggested that childrens PA might enhance psychosocial functioning and guard against internalizing (e.g., depression and anxiety) and externalizing (e.g., aggression and impulse control) symptoms. Given the current situation of young childrens physical inactivity, increased sedentary time, and accelerating mental health problems, active physical activity promotion at a young age is crucial to prevent deteriorating effects on the psychological development of young children. This study qualitatively explores the feasibility and potential effects of a one school year preschool-based PA intervention on increasing awareness of PA and improving childrens psychological health from childrens and parents perspectives.

Methods: Fifty children were randomly selected from each of the intervention and control groups of the KID-FIT study, which investigated the efficacy of a preschool-based PA intervention on improving physical fitness and health in preschoolers. One hundred children and their parents were interviewed in semi-structured interviews at the end of a preschool year to understand childrens psychological changes over the period. The recorded audio content was transcribed verbatim and analyzed by thematic content analysis using Thematicoder software.

Results: The preliminary analysis included 34 children (INT: 17, CON: 17). Interview results highlighted the increased awareness of the importance of PA, and parents from the intervention group expressed that their children were more willing to try different kinds of sports. Among the children in the intervention group, the childrens emotions were more stable after doing different types of sports and being more willing to share their feelings with parents was shown to have more positive effects than the control group.

Discussion: The findings revealed the importance of promoting PA in children and facilitating positive experiences that contribute to their enjoyment of various sports and psychological development. Parents in the intervention group reported that their children showed an increased willingness to try different sports, influencing their attitudes towards PA and encouraging them to explore new activities they may enjoy. Furthermore, these children were more willing to share their feelings with their parents, emphasizing the potential emotional and communication benefits of regular physical activity and the positive effects of parental involvement in promoting childrens mental health. These findings provide valuable insights for developing effective interventions to promote childrens physical and psychological health.

FITNESS APPS PROMOTING COLLEGE STUDENTS' FITNESS LEVEL: DIFFERENCES IN THE EFFECTS OF INTERNAL AND EXTERNAL MOTIVATION

HAN, Y., LI, L.S.

SHANGHAI INTERNATIONAL STUDIES UNIVERSITY

INTRODUCTION: Research indicates that the use of fitness apps can promote physical exercise behaviors and enhance fitness level. Based on this, most Chinese universities have adopted mandatory exercise check-in tasks to increase students' physical activity time, aiming to cultivate regular exercise habits among college students. However, some issues persist in the implementation of this mandatory measure. Students exhibit resistance and engage in cheating behaviors, such as proxy running or shaking phones while cycling to falsify exercise data, which make the effectiveness questionable consequently.

METHODS: This study conducted a questionnaire survey among 201 college students in Shanghai and analyzed the results using SPSS 28.0. The questionnaire was based on the Theory of Planned Behavior and Self-Determination Theory, using the Exercise Fitness Scale and the Self-Determination Motivation Scale to measure the factors influencing college students' intention to use fitness apps. The sample included undergraduate students from several well-known universities in Shanghai. The questionnaire has passed reliability and validity tests, with all scale items' Cronbach's alpha coefficient and KMO value being greater than 0.6.

RESULTS: According to the results of descriptive statistics, the average fitness level of 201 college students was 2.82. Among them, the average physical fitness level of students who used fitness apps and those who did not were 2.94 and 2.67, respectively. Additionally, the average fitness level of students who used the apps to complete the school's mandatory exercise check-in tasks was 2.67. According to the results of the correlation analysis, among students who used fitness apps, the Pearson correlation coefficients between attitude, subjective norm, perceived behavioral control, and self-determination motivation and the intention to use fitness apps were 0.534, 0.509, 0.427, and 0.665 ($p < 0.01$).

Discussion: The average fitness level of students who used fitness apps was higher than the overall average fitness level, which indicates that the use of fitness apps can, to a certain extent, improve the fitness level of college students. However, the average fitness level of students who used fitness apps to complete the schools' mandatory exercise check-in tasks was the same as that of students who did not use fitness apps, which suggests that the school's mandatory exercise check-in measures may not be effective in enhancing the fitness level of college students, and the type of motivation for using the app can influence the effect on promoting students' fitness level. Besides, the correlation analysis revealed that self-determination motivation had the highest positive predictive effect on the intention to use fitness apps, further proving that the internal motivation of college students to use fitness apps plays an important role in promoting their fitness level.

EFFECTIVENESS OF PHYSICAL ACTIVITY FOCUSED MHEALTH INTERVENTIONS ON MENTAL HEALTH OUTCOMES IN ADOLESCENTS: A SYSTEMATIC REVIEW AND META-ANALYSIS

BAUMANN, H., SINGH, B., STAIANO, A., GOUGH, C., AHMED, M., FIEDLER, J., TIMM, I., WUNSCH, K., BUTTON, A., YIN, Z., VASILOGLOU, M., SIVAKUMAR, B., PETERSEN, J., DALLINGA, J., HUONG, C., SCHOEPPE, S., KRACHT, C., SPRING, K., MAHER, C., VANDELANOTTE, C.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Adolescence is a critical period for the onset of mental disorders that adversely affect well-being and academic and social functioning (Polanczyk et al., 2015). Emerging evidence indicates that modifiable lifestyle factors—particularly physical activity—can improve mental health (Kandola et al., 2019). Mobile health (mHealth) interventions offer a scalable approach to promote physical activity and optimize sedentary behaviour, sleep, and nutrition. This review focuses on the effectiveness of mHealth interventions for adolescents (11–21 years) with emotional, behavioural, and eating disorders, with special emphasis on physical activity components.

Methods: A systematic review and meta-analysis were conducted following PRISMA guidelines (PROSPERO ID: CRD42024591285). A comprehensive search of eight databases was performed to identify randomized controlled trials (RCTs) published up to October 2024. Eligible studies involved adolescents with clinically relevant mental health disorders and assessed interventions targeting lifestyle behaviours, including physical activity. Data extraction was completed independently by reviewers, and risk of bias was evaluated using the ROB2 tool.

Results: Nine RCTs with a total of 3,219 participants met the inclusion criteria. Physical activity was incorporated in 55% of the interventions. For emotional disorders, mHealth interventions that combined mindfulness, cognitive-behavioural therapy, and physical activity significantly reduced depressive symptoms (pooled effect size = -0.35 , 95% CI: -0.50 to -0.20) and anxiety symptoms (-0.22 , 95% CI: -0.37 to -0.07). In interventions targeting behavioural disorders, those integrating physical activity with cognitive tasks yielded a moderate reduction in symptoms (pooled effect size = -0.40 , 95% CI: -0.62 to -0.18). In contrast, interventions for eating disorders produced mixed outcomes, indicating a need for more adaptive designs.

Discussion: The findings suggest that mHealth interventions, particularly those incorporating physical activity, hold promise in reducing mental health symptoms among adolescents. The benefits observed in reducing depression, anxiety, and behavioural problems support the integration of exercise components into digital interventions. Future research should refine these approaches, assess long-term sustainability, and explore integrated, multi-component strategies that complement traditional care to enhance mental health outcomes in this vulnerable population.

Plenary Session

PS-PL03 Exercise science and medicine in the era of incretins and exercise mimetics

THE OZEMPIC OLYMPICS: EXERCISE TRAINING AND CHRONIC DISEASE PREVENTION IN THE INCRETIN ERA

GREEN, D.

THE UNIVERSITY OF WESTERN AUSTRALIA

The world is embracing an exciting new era of chronic disease prevention and management: the age of Ozempic or Incretin therapies. There has never been a class of drugs that so effectively targets brain and behaviour to induce profound, rapid and life-changing decreases in body weight. Early intervention targeting obesity, a recognised gateway to multiple chronic diseases, can impact fatness, with beneficial pleiotropic impacts on blood pressure, cholesterol, blood glucose, insulin, heart and artery function, and perhaps even cognition. Beyond the glucagon-like peptide-1 receptor agonists (GLP-1ra) which induce rapid and substantial weight loss (liraglutide and semaglutide), newer and perhaps even more effective weight loss therapies are co-targeting glucose-dependent insulinotropic polypeptide (GIP) receptors (tirzepatide - dual agonist), and glucagon receptors (retatrutide - triple agonist). However, these agents cause rapid and significant loss of lean mass, comparable to a decade of ageing. Maintaining muscle mass and function as humans age is crucial to avoiding sarcopenia and frailty, which are strongly linked to morbidity and mortality. This talk will discuss the results of contemporary studies showing that supervised resistance exercise training interventions elicit increases in lean mass and strength in men and women across the lifespan. A compelling rationale will be presented for including strategies that retain lean mass during incretin therapy, to enhance fat loss and blunt body weight (and fat) re-gain on cessation of weight loss pharmacotherapy. De-prescribing is an important but challenging and complex goal for patients who achieve target changes in body composition. This talk will also address the global impact of targeted and personalised

exercise interventions, during and after incretin therapy, in the prevention of chronic disease in humans. Insights derived from the Tirzepatide and Resistance Exercise (T-REX) trial, focussed on the impact of combined exercise and incretin therapy in older overweight and obese adults, will also be shared. Finally, the talk will conclude by considering the opportunity afforded by this once-in-a-generation class of drugs for the development of Clinical Exercise Physiology (CEP) as an allied health profession globally. To this end, a strategic roadmap will be presented based on the Australian and more recent UK experiences of establishing national CEP regulatory frameworks, practitioner registries, proficiency standards, and higher education curricula for the global advancement of this nascent allied health profession, which is so crucial to future cost-effective preventative healthcare delivery worldwide.

EXERCISE MIMETICS: A “POLYPILL” TO COMBAT THE EROSION OF PHYSICAL ACTIVITY IN THE 21ST CENTURY?

HAWLEY, J.

MARY MACKILLOP INSTITUTE FOR HEALTH RESEARCH

Almost two decades ago it was reported that an oral ‘exercise mimetic’ (GW1516, an AMP-activated protein kinase agonist) administered to sedentary mice for 4 weeks induced a muscle ‘endurance gene signature’ and enhanced treadmill running capacity by 44%. Since publication of that study there has been growing scientific and commercial interest in the identification of bioactive oral compounds that mimic or potentiate the effects of exercise, so-called exercise pills or exercise mimetics. This pursuit has been driven, in part, by the application of molecular techniques to exercise biology that have provided greater understanding of the complexity of cellular networks involved in exercise responses and increased our knowledge of the mechanisms by which muscle ‘communicates’ with other organs and mediates the beneficial effects of exercise on health. As such, the first part of this talk considers how this myocentric approach has often failed to consider the wide-ranging effects that exercise exerts in tissues and organs other than skeletal muscle. Indeed, it is both perplexing and frustrating to many exercise scientists that the focus of these ‘mimetics’ has been exclusively on promoting mitochondrial biogenesis in skeletal muscle, when there is a much larger and more compelling landscape for the benefits of exercise in humans. While the idea of taking a pill (or a ‘polypill’) to acquire the benefits of exercise in the absence of voluntary physical movement and energy expenditure has great appeal for many sedentary individuals who, for a variety of reasons, do not obtain sufficient physical activity to improve their general health, it is also attractive for ‘big pharma’ who view physical inactivity as an ever-growing market to be medicated for profit. As such, the second part of this talk will examine whether an exercise pill is a bio plausible, realistic or desirable goal. It will be argued that exercise training provokes widespread perturbations in numerous cells, tissues and organs, conferring multiple health-promoting benefits, with the multiplicity (and redundancy) of these responses and adaptations making it highly improbable that any single pharmacological approach could ever mimic such wide-ranging effects. Finally, given that some calls for an ‘exercise pill’ stem from a response to the perceived failure of the majority of the population to comply with national recommendation for exercise prescription, the last part of this talk will address potential barriers that underpin the global decline in physical inactivity and novel strategies to overcome them.

KINEMATIC ANALYSIS OF CENTRE OF MASS DYNAMICS DURING THE TURNING PHASE OF JUDO UCHIMATA

HAMAGUCHI, K., DEGUCHI, T.

HIROSHIMA UNIVERSITY

INTRODUCTION: Uchimata is a frequently utilised technique in judo competitions, requiring precise balance control as it involves throwing the opponent while using a single leg as a pivot. The turning phase, preceding the execution of the throw, is crucial for Kuzushi (balance breaking) and Tsukuri (preparatory positioning). While previous studies have examined the biomechanics of judo techniques, the role of centre of mass (COM) momentum in differentiating skill levels remains unclear. This study aimed to compare COM dynamics between high- and low-skilled judokas during the turning phase.

METHODS: Twenty male judokas (10 high-skilled, 10 low-skilled) were categorised based on uchimata execution frequency and effectiveness in competition and training. A 14-camera Mac3D motion capture system (250 Hz) recorded three-dimensional movement, with 47 reflective markers tracking both linear and angular motion. The turning phase was defined as the period between the initial lift of the supporting leg and the moment the sweeping leg left the ground. The highest-quality trial was selected for analysis based on the thrower's self-evaluation and assessments by experienced judo coaches using predefined criteria [1]. COM momentum was analysed in the anteroposterior (x-axis), mediolateral (y-axis), and vertical (z-axis) directions, and opponent trunk angular momentum was also assessed. Statistical parametric mapping (SPM) was used to compare time-series data between groups, and Welch's t-tests ($p < 0.05$) with effect sizes (Cohen's d) were applied to evaluate peak differences.

RESULTS: High-skilled judokas showed significantly greater peak COM momentum in all directions: x-axis (0.60 vs. 0.41 m/s, $p = 0.027$, $d = 1.07$), y-axis (0.92 vs. 0.63 m/s, $p = 0.012$, $d = 1.26$), and z-axis (0.79 vs. 0.60 m/s, $p = 0.047$, $d = 1.00$). Opponent trunk angular momentum was also higher when thrown by high-skilled judokas (2.90 vs. 1.75 kg·m²/s, $p = 0.038$, $d = 1.15$). SPM analysis found no significant time-series differences ($p > 0.05$).

CONCLUSION: These findings indicate that high-skilled judokas generate greater COM momentum, contributing to more effective Kuzushi and smoother throw transitions. The increased trunk angular momentum observed in opponents highlights the role of rotational force in balance breaking. Consistent with previous research, our results suggest that high-skilled judokas achieve more effective kuzushi by actively shifting their centre of mass [2]. This implies that controlled COM shifts are fundamental to optimising balance breaking in judo. Coaches should emphasise these aspects in training to enhance judokas performance.

THE EFFECTS OF PASSIVE LEG PRESS TRAINING TO MUSCLE FAILURE AT DIFFERENT TRAINING SPEEDS ON THE MUSCLE MASS, ENDURANCE STRENGTH AND KICKING PERFORMANCE FOR TAEKWONDO ATHLETES

WANG, H., LIU, C.H., LIU, Y.L.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Passive leg press (PLP) training can overcome the problem that general resistance training cannot accurately control the "movement speed" and cannot train at a fast speed when carrying heavy loads. PLP training has been proven to enhance velocity and explosive power in athletes. However, do different training speeds of PLP training to muscular failure enhance skeletal muscle mass, muscular endurance and kicking performance? Not confirmed by research. The aim of the present study was to identify which of three training speeds of PLP training leads to the best training effects on skeletal muscle mass, endurance strength and kicking performance in Taekwondo athletes.

METHODS: thirty taekwondo athletes were recruited and divided into high training speed group (HTSG, $n=10$), normal training speed group (NTSG, $n=10$), low training speed group (LTSG, $n=10$). All subjects complete 12 weeks, 3 times a week training program which consisted of 60% MVIC load but three different training speed and perform to muscle failure. Before and after training, muscle mass, dynamic endurance (average height of continuous countermovement jumps), static endurance (duration time of $>80\%$ MVIC), specific continuous kicking ability (speed and average peak force of con-

tinuous kicking) were collected for statistical analysis. The Paired Samples t-Test was used to compare the difference between pre-test and post-test. Percentage of training effects among groups were analyzed with Analysis of Variance, ANOVA and Bonferroni post hoc test. The level of significance was set at $\alpha = .05$.

RESULTS: Muscle mass did not significantly improve in LTSG ($P > .05$), but all other dependent variables were significantly enhanced ($P < .05$). All dependent variables were significantly enhanced in both of NTSG and HTSG ($P < .05$). Besides, the percentage of training effect of kicking speed in HTSG were significantly greater than in the LTSG.

CONCLUSION: The training methods of passive leg press training to muscle failure at different training speeds could improve dynamic endurance, static endurance, and specific continuous kicking ability. Training speed during resistance training is a key factor that affects improvement of muscle mass. Low speed training cannot significantly improve muscle mass. The speed during resistance training is also a factor that affects the improvement of specific kicking speed. High speed training is the optimal training intensity when the coach wants to transfer the effects of resistance training to specific kicking abilities.

EEG ANALYSIS OF NEUROPLASTICITY IN TRANSTIBIAL PROSTHESIS USERS DURING OVERGROUND WALKING

THARAWADEEPIMUK, K., NANBANCHA, A., SHOOMBATONG, W., LIMROONGREUNGRAT, W.

MAHIDOL UNIVERSITY

INTRODUCTION: Lower-limb amputees often rely on prostheses for daily activities and environmental adaptation, while transtibial prosthesis (TTP) users experience greater motor control challenges and cognitive impairments than able-bodied individuals (1). Thus, this work aims to investigate neuroplasticity in TTP users through the analysis of electroencephalogram (EEG) signals recorded during overground walking in order to understand neural mechanisms of adaptation, which are capable of informing advanced rehabilitation strategies.

METHODS: Herein, firstly, we recorded the 32-channel EEG and inertial measurement unit (IMU) data derived from five TTP users and five able-bodied participants during 2 minutes of overground walking. Secondly, this dataset was used to identify the stride cycle from thigh angle peaks (Segment Thigh RT-orientation-y from IMU). Then, EEG data defined by these peaks were extracted and structured into a 30x100 matrix (30 electrode placements, 100 time points representing the percentage of gait cycle). Finally, the EEG signals were analyzed across delta, theta, alpha, and beta frequency bands. Two-sample t-tests using statistical non-parametric mapping (SnPM) were performed to identify differences in continuous EEG data across the gait cycle between TTP users and able-bodied participants.

RESULTS: Experimental results indicated the EEG theta frequency band during the walking gait cycle revealed a significant difference at the Pz electrode position ($p = 0.032$) during the mid-swing sub-phase of the gait cycle. Additionally, a significant difference in the alpha frequency band was identified at the CP2 electrode position ($p = 0.044$) during the loading response sub-phase. The average stride cycle across participants was 57.

CONCLUSION: Activity at the Pz position aligns with its established role in proprioception and the integration of sensory information from the body and external environment (2). Similarly, activity at the CP2 position highlights its involvement in processing proprioceptive feedback, particularly related to motor control and sensory input from the lower limbs (3). The findings reveal adaptive neuroplasticity in TTP users, with distinct cortical activity patterns during gait cycle, reflecting increased reliance on cortical regions for motor control and sensory integration. These results highlight the need for rehabilitation strategies to enhance gait efficiency and cortical activities.

MUSCLE ACTIVITY AND KINEMATICS OF FIN SWIMMING IN PROFESSIONAL DIVERS

CHALCHAT, E., ALGOURDIN, P., SERRALHEIRO, A., CASTAGNA, O., SCHMID, B., JOLIFF, Y., OSTRE, B.

INSTITUT DE RECHERCHE BIOMÉDICALE DES ARMÉES

INTRODUCTION: Scuba diving is an activity that is increasingly practiced, whether in a sport, professional, or military context. Among the well-known criteria that influence diver performance, body kinematics and muscle activity are particularly important. These two parameters are directly related to the energy cost of the diver, which is an important factor in performance. Understanding the biomechanics of this atypical sport in ecological conditions allows for correcting improper posture, thereby improving performance. However, the literature on the subject is still limited. Recent advances, such as the development of new waterproof sensors, promise significant progress in the field of kinematic and muscle activity analysis. The purpose of this study is to describe the kinematics and muscle activation patterns of fin swimming in professional divers.

METHODS: Eight professional military divers participated in the study. Participants swam underwater for 30 min in a counter-current pool at a pace of 4 min per 100 meters. Divers performed swimming trials using diving fins while wearing waterproof sensors to record both kinematic and muscle activity data. Kinematics were measured using seven inertial measurement units (IMUs) placed on both feet, both shins, both thighs, and on the pelvis. Muscle activity was recorded using surface electromyography (EMG) on the rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF), semitendinosus (ST), gastrocnemius medialis (GM), soleus (Sol), tibialis anterior (TA), and the gluteus maximus (Glut). EMG data were normalized to the maximum activation obtained during a maximal voluntary contraction (MVC). Cardio-respiratory data, including heart rate (HR) and oxygen consumption (VO₂), were also monitored.

RESULTS: The kicking cycle was divided into two phases: the downward phase (0-50 %) and the upward phase (50-100 %). The joint amplitudes for ankle, knee, and hip were $25 \pm 10^\circ$, $85 \pm 12^\circ$, and $10 \pm 4^\circ$, respectively. The maximum angle for

the knee was reached at the start of the stroke cycle. The maximum angles for the ankle and hip were reached at 15 % and 18 % of the stroke cycle, respectively. The minimum angles for the knee, ankle, and hip were reached at 50 %, 78 %, and 70 % of the stroke cycle. The average peak EMG activation occurred during the downward phase for the RF (33 ± 14 %MVC), VL (17 ± 6 %MVC), and TA (15 ± 8 %MVC) muscles, and during the upward phase for the GM (32 ± 11 %MVC), Sol (29 ± 10 %MVC), BF (47 ± 19 %MVC), ST (21 ± 4 %MVC), and Glut (4 ± 3 %MVC) muscles. After 5 minutes, the HR and VO₂ stabilized, averaging 105 ± 10 bpm and 18.1 ± 2.0 mL·min⁻¹·kg⁻¹, respectively.

CONCLUSION: This study provides a detailed analysis of both kinematics and muscle activity during scuba diving kicking. This knowledge is essential for teaching proper technique and providing appropriate training protocols to enhance the performance of sport, professional, or military divers.

RELATIONSHIP BETWEEN REBOUND JUMP PERFORMANCE AND SPRINT PERFORMANCE IN JUNIOR SPRINTERS

EMA, R.

SHIZUOKA SANGYO UNIVERSITY

INTRODUCTION: In sprinting, minimizing the decline in speed during the latter stages of the race is crucial for achieving high performance, in addition to maximizing peak speed. Even elite sprinters experience a reduction in speed before reaching the finish line (1). Because this decline directly affects overall sprint performance, identifying its underlying causes is essential for developing effective training methods. Rebound jump (RJ) performance, which involves repeated jumps with minimal ground contact time (typically around 160 ms) (2), may be relevant in this context. The contact time per step in a 100 m sprint is comparable to that in RJ tasks (3), suggesting that the ability to generate high force in a short period may be common to both tasks. Thus, inferior RJ performance may be associated with longer contact times during the latter phase of sprinting, thereby contributing to speed decline. This study examined the relationship between RJ ability and the maintenance of sprint speed in junior sprinters.

METHODS: Participants were 22 elementary school sprinters undergoing regular training. Each participant performed a 100 m sprint at maximum effort, during which total time and 20 m split times were recorded using a photoelectric timing system. RJ performance was assessed using a mat switch during five consecutive jumps, with participants instructed to jump as high as possible while minimizing ground contact time. The RJ index was calculated as the ratio of jump height to contact time. Pearson's product-moment correlation coefficients were computed, and statistical significance was set at $P < 0.05$.

RESULTS: The RJ index was significantly negatively correlated with the 100 m sprint time ($r = -0.594$). Additionally, when the 80–100 m split time was normalized to the total 100 m time, a significant negative correlation with the RJ index was observed ($r = -0.464$).

CONCLUSION: Superior RJ performance is associated with better 100 m sprint performance and a reduced decline in speed during the latter stages of the sprint in junior sprinters.

NEUROMUSCULAR RECRUITMENT STRATEGIES OF THE LOWER LIMB BETWEEN SPRINTERS AND DISTANCE RUNNERS DURING MAXIMAL SPRINT RUNNING

KAKEHATA, G., GOTO, Y., ISO, S., LOW, C.Y., KANOSUE, K.

WASEDA UNIVERSITY

INTRODUCTION: A previous study found that thigh muscle activation timing is associated with sprint performances. However, no research has investigated the individual differences in the multiple muscle activation patterns in sprint running. Therefore, the purpose of this study was to investigate the difference in strategy in the neuromuscular activation patterns of the lower limb muscles between sprinters and distance runners during maximal sprint running.

METHODS: Twenty well-trained male athletes (ten sprinters and ten distance runners) ran 50 m with maximal effort. The spatiotemporal variables (e.g., running speed, step frequency, and step length) were measured over a distance from 42 m to 50 m using a high-speed camera (250 Hz) and timing gate systems. Electromyography (EMG) signals were obtained using wireless EMG sensors (2000 Hz) from eight lower limb muscles (rectus femoris: RF, biceps femoris: BF, semitendinosus: ST, gluteus maximus: Gmax, vastus lateralis: VL, tibial anterior: TA, gastrocnemius: GAS, and soleus: SOL). The running cycle was divided into four phases from foot-strike and foot-off timings from both feet that consisted of contact, early-swing, mid-swing, and late-swing phases. Root mean squares (RMSs) were calculated every four phases. The RMSs were normalized maximal voluntary contraction value (%MVC).

RESULTS: Sprinters showed significant greater spatiotemporal variables than distance runners. RMS of hip extensors (Gmax and BF) during mid- to late swing phases, hip flexor (RF) early to mid-swing phases, and ankle dorsiflexor (TA) during early-swing phase in sprinters were significantly greater than distance runners ($P < 0.05$). However, the RMS of ankle plantar flexors (SOL and GAS) and knee extensor (VL) were found to be similar between both groups of runners.

CONCLUSION: A previous study demonstrated that sprinters showed greater thigh movements than recreational athletes. In this study, it was also observed that sprinters showed greater both hip extensor and flexor activation than distance runners. However, there was no significant group differences in knee extensor and ankle plantar flexors. These results suggest that sprinters generated rapid and greater leg movements by recruiting more hip muscles. Furthermore, sprinters showed higher ankle dorsiflexor activation during early-swing phase. This suggests that sprinters would have a specific technique that keeps ankle joint more dorsiflexed position to reduce the moment of inertia of the legs during early-swing

phase. The results concluded that sprinters have specific neuromuscular adaptations of both hip extensor and flexor, and ankle dorsiflexor to distance runners.

EFFECTS OF MOUTHGUARD USE ON SHOULDER ISOKINETIC STRENGTH: AN ELECTROMYOGRAPHIC ANALYSIS

SUGAJIMA, Y., TANAKA, T., ISHIDA, N., TOSHIKAZU OMORI, T., KATO, T., YAMAMOTO, H.

ASAHI UNIVERSITY

INTRODUCTION: Para-powerlifting, a bench press competition for individuals with disabilities, requires smooth and stable movements to lift maximum weights. In competitive sports, mouthguard (MG) use is recommended to protect oral structures and improve occlusion. Moreover, the use of MGs has been reported to potentially enhance muscle strength. This study aimed to explore the effects of MG use on shoulder isokinetic strength using electromyographic (EMG) analysis.

METHODS: This study included 11 male university rugby players. Shoulder isokinetic strength was measured using a Biodex system at angular velocities of 60°/s, 120°/s, and 180°/s, with participants performing five consecutive concentric arm-raising and -lowering movements. The following four conditions were tested: (1) right arm without an MG, (2) left arm without an MG, (3) right arm with an MG, and (4) left arm with an MG. Surface EMG was performed on the masseter, deltoid, and pectoralis major muscles using bipolar electrodes. Muscle strength, range of motion (ROM), and integrated EMG values were analyzed. Two-way ANOVA was conducted with MG use and velocity as factors for isokinetic strength evaluation. Additionally, Tukey's post-hoc tests were used. Paired t-tests were used to compare the integrated EMG values between the use and non-use of MG.

RESULTS: No significant differences in muscle mass or ROM were observed between the dominant and non-dominant sides. However, shoulder isokinetic strength showed significant improvements with MG use, as the non-dominant/dominant ratio of peak torque approached 100%, and peak torque per body weight and rise torque were significantly higher. Time to peak torque was significantly shortened, indicating that MG use may enhance initial strength generation and improve muscle balance between the dominant and non-dominant sides.

A significant increase in masseter activity was observed with MG use, as indicated by integrated EMG values. This suggests that clenching may enhance spinal excitability and, consequently, increase muscle activity, potentially influencing the shoulder-related muscle groups. However, no significant changes were noted in the average integrated EMG values of the deltoid and pectoralis major during five consecutive contractions. Given their antagonistic functions, the time-averaging method used in this study may have limited applicability. Future research should focus on analyzing specific movement phases for more detailed insights.

CONCLUSION: While the primary role of MG use is to protect oral structures, the findings of this study suggest that MG use may also enhance the initial strength output of muscles and improve muscle balance in shoulder isokinetic strength.

ACCURACY VERIFICATION OF MARKERLESS MOTION CAPTURE DURING KENDO EQUIPMENT WEAR

NISHIKAWA, K., TSURUTA, O., SUZUKI, C., MURASE, N., SAKURAI, S.

CHUKYO UNIVERSITY

INTRODUCTION: In recent years, studies utilizing markerless motion capture have become increasingly common. Traditional optical motion capture provides high measurement accuracy but requires the attachment of reflective markers to the entire body. This makes it difficult to conduct kendo research in a practical setting, as practitioners must wear Dogi (traditional training attire), Hakama (pleated skirt-like trousers), and Bogu (protective armor consisting of a helmet, gloves, chest protector, and waist protector).

Markerless motion capture eliminates the need for reflective markers, reducing restrictions related to measurement time and environmental conditions. Previous studies have reported that markerless motion capture can measure three-dimensional movement, such as throwing, jumping, and walking, with an accuracy of approximately 30 mm compared to optical motion capture (Nakano et al. 2021). However, the effect of wearing kendo-specific attire and protective gear on measurement accuracy remains unclear.

Therefore, this study aims to examine the accuracy of markerless motion capture in kendo by analyzing Men strikes (a frontal strike to the head) under different clothing and equipment conditions.

METHODS: One male kendo practitioner participated in this study. The subject performed Men strikes while facing a striking target positioned 1.9 m away from his right foot. The experiment was conducted under four conditions:

1. Wearing only spats (baseline condition)
2. Wearing spats along with Men (helmet), Kote (protective gloves), and Do (chest protector)
3. Wearing spats with Men, Kote, Do, and Tare (waist protector)
4. Wearing a full kendo outfit: Dogi, Hakama, Men, Kote, Do, and Tare

The subject performed 15 trials per condition. Motion data were captured using the markerless motion capture system (Miquis, 250 Hz). The analysis focused on the 200 frames preceding the moment of impact (when the Shinai [bamboo sword] reached the target). Coordinate values were calculated using Visual3D software, and the mean and standard deviation of the differences between condition (1) and the other three conditions were analyzed.

RESULTS: The mean and standard deviations of the maximum differences between condition (1) and conditions (2), (3), and (4) were as follows:

- Condition (2): 5.3 ± 2.3 cm
- Condition (3): 5.7 ± 4.2 cm
- Condition (4): 21.5 ± 17.19 cm

CONCLUSION: When using condition (1) as a baseline, measurement accuracy remained relatively high under conditions (2) and (3). However, in condition (4), the presence of Dogi and Hakama significantly affected measurement accuracy, likely due to fabric movement interfering with body tracking.

These findings suggest that while markerless motion capture can be useful in kendo research, the accuracy is affected by protective gear and traditional attire. By limiting equipment usage or restricting analysis to specific body segments, motion capture in more practical kendo settings may become feasible.

BIOMECHANICAL RESEARCH PROGRESS IN TRAMPOLINE SPORTS: MECHANISMS, METHODS, AND CHALLENGES

SHUTING, L., WEI, L.

BEIJING SPORT UNIVERSITY

INTRODUCTION: Trampoline is an important sport in both competitive athletics and mass fitness. Since its inclusion as an official Olympic event in 2000, trampoline has been characterized by its high technical difficulty and inherent risks (1). Biomechanical research in trampoline is crucial for enhancing athletic performance (2), optimizing technical movements (3), and preventing sports injuries (4). The increasing complexity of competitive movements, such as triple twists and quadruple tucks, has created an urgent need for biomechanical analysis. This article systematically reviews the current state of biomechanical research in trampoline, focusing on the kinetic characteristics of the takeoff-flight-landing phases, mechanisms of human posture control, injury risk factors, and technical assessment methods. It also explores future research directions. Studies indicate that the integration of multimodal sensors and computer modeling techniques is becoming a key breakthrough in this field.

METHODS: This study conducted a literature search using authoritative databases such as Web of Science, Scopus, CNKI, and PubMed, with keywords including "trampoline," "technical analysis," and "kinematics." The search included all literature on trampoline biomechanics up to 2025.

RESULTS: Key Findings on Movement Execution Mechanisms:

Takeoff Phase: Elite athletes achieve vertical ground reaction forces up to 8-10 times their body weight. Force curve displays a "double peak": first from net deformation energy storage, second from lower limb explosive extension. Coordination between knee extension and net rebound velocity is crucial; a >50 ms delay increases energy loss by 15%.

Flight Phase: Athletes control angular momentum via head positioning and asymmetric arm movements. A 5° head deviation increases somersault axis deviation by 1.2 rad/s. Tuck position reduces moment of inertia by 60-70%, but premature tightening can disrupt timing.

Landing Phase: Forefoot bears $>65\%$ of impact force; incorrect posture increases ankle dorsiflexion moments by 37%, raising sprain risk. A 10% increase in net tension boosts peak knee compression force by 22%.

CONCLUSION: Movement Optimization Theory: Takeoff Phase: Precise control of "energy storage-release" timing is crucial, with knee extension velocity synchronized to net rebound velocity (error window <30 ms). Flight Phase: Fine adjustments in head positioning and dynamic regulation of limb moment of inertia enhance stability during multiple somersaults.

Innovations in Technical Diagnosis: The "sensing-modeling-feedback" system enables real-time movement assessment, but signal drift in high-speed rotations remains a challenge. Deep learning algorithms show promise for action recognition but need expanded sample libraries of high-difficulty movements to improve generalization.

GAIT INITIATION CONTROL AND COGNITIVE PERFORMANCE IN MULTITASKING SITUATIONS FOR MILD COGNITIVE IMPAIRMENT ELDERLY

LEE, H., SUN, Q.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: With an aging population, the prevalence of neurodegenerative diseases, including dementia, has increased. Older adults with mild cognitive impairment (MCI) are at higher risk for both dementia and falls. This study investigates biomechanical differences in gait initiation between older adults with MCI and cognitively healthy individuals, aiming to provide insights for diagnosing, preventing, and managing MCI and fall risks.

METHODS: This study employs three experimental conditions: spontaneous, cue-induced, and dual-task gait initiation. In the first two conditions, we analyze how MCI status and gait initiation speed (comfortable vs. maximum) affect gait performance. In the dual-task condition, we assess the impact of cognitive tasks (countdown, subtraction, and semantic fluency) on gait initiation. Thirty elderly participants (11 with MCI, 19 cognitively healthy) were recruited for this cross-sectional observational study. Gait initiation performance was measured using infrared motion capture and force plates to assess movement time, center of pressure (COP) displacement and velocity, center of mass (COM) displacement, balance stability, and overall gait. Repeated two-way ANOVA was used for statistical analysis.

RESULTS: Under spontaneous gait initiation, no significant differences were observed between the MCI and control groups. However, during cue-induced and dual-task conditions, participants with MCI showed shorter gait initiation times,

longer COP displacement, and faster COP velocities. Gait initiation speed influenced biomechanical parameters in all conditions, while the semantic fluency task had the most significant effect during dual-task conditions.

CONCLUSION: These results suggest that individuals with MCI may experience altered gait initiation under specific conditions, particularly when cognitive load is involved. This highlights the need for clinical interventions that incorporate dual-task training and faster gait initiation requirements to improve gait performance. Additionally, fall prevention strategies should focus on reducing cognitive load and time pressure during gait tasks. Future studies should explore the effects of dual-task conditions and gait initiation across different MCI subtypes and environmental contexts, incorporating physiological indicators like EEG and EMG. This research underscores the importance of addressing cognitive and motor challenges in older adults with MCI to reduce fall risk and improve quality of life.

EFFECTS OF 6-WEEK PLYOMETRIC TRAINING ON ANKLE KINEMATICS IN THE FIRST FIVE STEPS OF SPRINT START IN SPRINTERS

ZHANG, Y., YAN, J., ZHAO, S., LYU, D.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: In accordance with Valamatos et al. (2022), plyometric training is widely recognized for enhancing athletic performance by optimizing the stretch-shortening cycle (SSC), improving neuromuscular coordination, and increasing explosive power. Previous research (e.g. Eraslan et al. 2021) has demonstrated its benefits in sprint acceleration, particularly in enhancing lower-limb power output. Since ankle motion plays a crucial role in propulsion and step length regulation, understanding its adaptations to plyometric training could provide valuable insights for sprint performance optimization. Therefore, the aim of this study was to investigate how a 6-week plyometric training influence ankle kinematics in the first five steps of a sprint start.

METHODS: Six male Chinese elite sprinters (Age: 19 ± 0 years, Height: 1.78 ± 0.03 m, Weight: 67.7 ± 6.5 kg, 100 m PB: 10.94 ± 0.15 s, Training Experience: 3.25 ± 1.94 years) who were coached by the same trainer participated in this study. All participants underwent a six-week training program (3 times/week) incorporating hurdle jumps, drop jumps, and bounding exercises. 14-camera Qualisys system (Qualisys, Gothenburg, Sweden) were used to collect the trajectories of the passive reflective markers of the first five steps of the sprint start at 200Hz. Kinematic parameters of the ankle joint were calculated by using Visual 3D 4.0 (C-motion, Maryland, USA). Sprinters' velocity at the fifth step before (Vpre) and after (Vpost) the training program were used to represent the sprint performance.

RESULTS: Sprinters had a better performance after the training program (Vpre = 6.53 ± 0.39 m/s, Vpost = 6.70 ± 0.38 m/s, $p = 0.004$). The first flight time (PRE: 0.09 ± 0.02 s vs. POST: 0.07 ± 0.02 s, $p = 0.033$), first step time (PRE: 0.09 ± 0.02 s vs. POST: 0.07 ± 0.02 s, $p = 0.033$), and second step time (PRE: 0.26 ± 0.02 s vs. POST: 0.25 ± 0.02 s, $p = 0.038$) significantly decreased after training. The reduction in first flight time and step times suggests improved ground contact efficiency, which is a hallmark of enhanced SSC function. The third step length (PRE: 1.20 ± 0.15 m vs. POST: 1.23 ± 0.14 m, $p = 0.009$), angular velocity at toe-off of the first step (PRE: $-863.65 \pm 141.71^\circ/\text{s}$ vs. POST: $-1085.44 \pm 117.54^\circ/\text{s}$, $p = 0.014$), and mean extension angular velocity during the first step (PRE: $-329.58 \pm 80.61^\circ/\text{s}$ vs. POST: $-453.04 \pm 120.43^\circ/\text{s}$, $p = 0.004$) significantly increased after the training program indicated that training enhanced ankle joint propulsion ability, which may further improve sprint start efficiency.

CONCLUSION: This study confirmed that six weeks of plyometric training improved the ankle joint kinematics during the sprint start, characterized by faster take-off angular velocity, shorter ground contact time, and longer step length. These findings suggest that incorporating plyometric training into sprint programs can enhance propulsion efficiency and optimize early acceleration performance.

HIP EXTENSION RANGE OF MOTION IS ASSOCIATED WITH IMPULSE DURING THE LATE CONCENTRIC PHASE OF VERTICAL JUMPING

SASABE, K., MOTEKI, T., AKIYAMA, K., HIROSE, N.

WASEDA UNIVERSITY

INTRODUCTION: Previous studies have reported a relationship between lower limb flexibility and vertical jump (VJ) height; however, few studies have focused on the differences in kinematics and kinetics during VJ in athletes with varying levels of lower limb flexibility. The present study aimed to categorize participants into flexible and non-flexible groups based on their lower limb flexibility and examine differences in force output characteristics during VJ.

METHODS: Thirty-two male American football players participated in this study. Each participant performed three range of motion (ROM) tests (hip flexion, hip extension, and ankle dorsiflexion ROM). Participants performed two types of VJ, countermovement jump (CMJ) and squat jump (SJ), on a force plate while being filmed with a high-speed camera. Pearson's correlation analysis was conducted to examine the relationship between jump height and each ROM test. Participants were divided into two groups (flexible vs. non-flexible) based on the median values of ROM tests showing a significant moderate or higher correlation ($r > 0.3$), and kinetic and kinematic variables were compared using an independent t-test. Effect size (Cohens d) was also calculated, with a significance level set at 5%.

RESULTS: A significant moderate correlation was observed between both CMJ and SJ height and hip extension ROM ($r = 0.37 - 0.49$, $p < 0.05$). No significant correlation was found between jump height and ankle dorsiflexion ROM or hip flexion ROM. Between-group comparisons of hip extension ROM revealed that the flexible group showed significantly greater impulse in the late half of the propulsion phase during CMJ and SJ compared to the non-flexible group ($d = 0.80 - 1.14$, $p <$

0.05). The joint angles of the lower limbs at the second peak of the force-time curve in CMJ were significantly larger in the flexible group ($d = 0.83 - 1.21$, $p < 0.05$), indicating that they generated force at more extended joint angles.

CONCLUSION: This study clarified the relationship between hip extension ROM and power output characteristics during VJ. Previous research has shown that limited hip extension ROM results in reduced gluteus maximus activation (1). Similarly, participants with restricted hip extension ROM in this study may have had difficulty generating torque with the gluteus maximus in the late half of the propulsion phase. Previous studies have demonstrated that plyometric training enhances power output during the early phase of the concentric contraction; however, strategies for improving power output during the latter phase remain insufficiently explored (2). The results observed in this study, when further investigated in future research, may lead to the establishment of a comprehensive approach that includes improvements in force output during the latter phase of the concentric contraction.

EFFECT OF LOWER LIMB MUSCLE STRENGTH AND ACTIVITY ON POSTURAL STABILIZATION DURING LANDING IN FEMALE ARTISTIC GYMNASTS

KATERINA, P., BIZOVSKÁ, L., GONOSOVÁ, Z., JANURA, M.
PALACKY UNIVERSITY OLOMOUC

INTRODUCTION: Performance in artistic gymnastics requires a significant level of physical fitness (1), including high lower limb muscle strength (2). Gymnasts have to meet numerous requirements when performing the landing, including aesthetic execution and the ability to absorb large reaction forces to ensure safety (3). Optimal muscle activity plays an important role in influencing the execution of the landing (4). Therefore, the aim of the study was to assess the relationship between lower limb muscle strength and activity and postural stabilisation during the landing in female artistic gymnasts.

METHODS: Thirty-one female gymnasts were included in the study. An inertial sensor placed on the lower back was used to determine postural stabilisation by using dynamic stability index (DSI) and time to stabilization (TTS) in the sagittal plane for one and three second intervals from contact with the mat. Surface electromyography was used to assess muscle activity of the m. vastus medialis, m. rectus femoris, and m. biceps femoris. Gymnasts performed three valid drop landings, forward somersaults, backward somersaults, and acrobatic series on the floor. To assess eccentric isokinetic muscle strength, the IsoMed 2000 (D. & R. Ferstl GmbH, Hemau, Germany) for the hip and knee joints at a speed of 180 deg. s⁻¹, and a leg-press module with a test speed of 400 mm.s⁻¹ were used. Statistical analysis was performed using Spearman's correlation coefficients.

RESULTS: For the drop landing, significant correlations were found between the three-second interval TTS and m. biceps femoris activity before landing ($r = -0.40$), as well as after landing ($r = -0.46$, $r = -0.54$, for one and three second intervals respectively).

For the forward somersault, significant correlations were found for TTS and hip work (both $r = 0.52$) and one-second interval TTS and hip peak torque ($r = 0.46$). For the backward somersault, a significant correlation was found for the three-second interval TTS and hip peak torque ($r = -0.55$).

Significant correlations were found for the acrobatic series between DSI and m. biceps femoris activity before landing ($r = 0.54$, $r = 0.44$, for one and three second intervals respectively) and DSI and legpress work ($r = -0.49$, $r = -0.48$).

CONCLUSION: The results show that in simple movement tasks such as drop landing, higher muscle activity of the m. biceps femoris before and after the landing positively influences postural stabilization. On the contrary, in the acrobatic series, a complex involvement of the whole lower limbs is required during the deceleration phase. Achieving high values of peak torque when performing the eccentric movement at the hip joint seems to be important for stabilisation after the backward somersault, probably because of the lower heights achieved.

ANTHROPOMETRIC DETERMINANTS OF SKATING SPRINT KINEMATICS IN BANDY

POJSKIC, H., TILLAAR, R.V.D., ANDERSSON, H.
LINNAEUS UNIVERSITY

INTRODUCTION: Sprint skating is a crucial bandy skill for effectively performing game-specific tasks [1,2]. Previous studies showed the step frequency (SF) during the acceleration (ACC) and maximum sprint (MAX) phases, and the glide length (GL) obtained during the MAX phase were the most important spatiotemporal (ST) metrics in predicting the maximal skating velocity [3]. However, no studies have examined the correlation between anthropometrics and ST parameters for skating sprints in bandy. Thus, this study investigated the correlation between ST parameters and anthropometrics in bandy players during skating sprints.

METHODS: Thirty-two well-trained male bandy players [age: 17.8 ± 1.2 years; height: 1.80 ± 0.06 m; body mass (BM): 75.7 ± 1.2 kg; BMI: 23.3 ± 2.2 kg/m²; leg length (LL): 100.6 ± 5.2 cm] completed two 80m skating sprints. 9 timing gates and two skate-mounted IMUs were synchronised to calculate velocities and obtain glide-by-glide kinematics. The skating ST kinematics at each step included SF, GL, glide time (GT), double support time (DST), double support length (DSL) and step length (SL). All ST variables were analysed separately in the ACC and MAX phases (i.e., over the first and last six steps). Partial correlation (r) with an alpha level (p) of 0.05 was used to investigate the strength and direction of correlation between LL, BMI, and ST in the ACC and MAX phases.

RESULTS: When controlling for BMI, LL showed a positive and moderate correlation with GT, GL, and SL ($r = 0.40$ - 0.49 , $p < 0.05$) while exhibiting a negative correlation with SF in both phases ($r = -0.47$, $p < 0.05$). When accounting for LL, BMI correlated positively only with the max velocity attained in the ACC phase ($r = 0.40$, $p < 0.05$).

CONCLUSION: Given that a higher SF during the ACC and MAX phases and a longer GL during the MAX phase determine maximal skating velocity [3], it is logical to conclude that LL may affect skating speed by negatively impacting SF while positively influencing GL, GT, and ST. Therefore, the results suggest that a longer LL might be a disadvantage in the ACC phase but an asset in the MAX sprint phase, where the GL is a crucial determinant. Players with a higher BMI demonstrated better acceleration ability, which may be attributed to their greater muscle mass and enhanced ability to exert force and power. Such a conclusion is supported by the understanding that a higher BMI in the athletic population signifies a greater proportion of muscle relative to fat mass [4]. The increased muscle mass enables players to overcome body inertia more effectively and, thus, accelerate more rapidly [1-3]. The current study indicates that a higher BMI may indicate a greater muscle mass in a homogenous group of well-trained bandy players. Coaches should consider players' anthropometrics when optimising skating technique, where an individualised ratio between SF and GL is adapted to maximise skating speed in the ACC and MAX phases.

CONTRIBUTION OF BODY-SEGMENT ROTATION TO MECHANICAL ENERGY IN POLE VAULTING USING EMBEDDED INERTIAL MEASUREMENT UNITS

RESTRAT, V., BIDEAU, N., NICOLAS, G., DUMONT, G.

/NRIA

INTRODUCTION: Performance in pole vaulting is highly related to energetic parameters during both the run-up and the jump phases [1,2]. Most studies used a mass-point model to describe the motion of the athlete's center of mass. This does not allow to quantify the fraction of mechanical energy associated with body-segment rotations [3]. The aim of this study is thus to investigate the influence of the segmental rotations on the mechanical energy of the pole vaulter using a 3D multi-body biomechanical model based on inertial motion capture.

METHODS: Data were collected from a female pole vaulter (1.77m, 61 kg). 7 trials were performed using a 4.15m pole with a bending index of 59 and a crossbar set at a height of 3.50m. Kinematic data were collected using the Xsens MVN Awinda® system (Xsens Technologies B.V, The Netherlands) composed of 17 body-worn IMUs sampled at 60 Hz. Kinetic (KE), Potential (PE) and mechanical (ME) energies were studied at take-off (TO), maximal pole bend (MPB) and bar clearance (BC) and were computed using a full-body biomechanical model [4].

RESULTS: The results indicated that the energy associated with the rotation of the body-segments accounts for ($14\% \pm 0.92$) of the total kinetic energy at TO, ($27\% \pm 4.02$) at MPB and ($39\% \pm 4.39$) at BC. Considering the ratio of rotational energy relative to the total mechanical energy, it represents ($9.5\% \pm 0.62$) at TO, ($8.5\% \pm 0.70$) at MPB and ($4.3\% \pm 0.61$) at BC. The decreasing trend in the proportion of segment rotational energy to total mechanical energy is associated with the progressive increase in potential energy across the different phases (32% at TO, 68% at MPB, and 89% at BC). Focusing on BC, 4.3% of the total mechanical energy calculated using the multibody model corresponds to approximately 97J. Given the athletes characteristics and the height at which the bar was cleared, this would correspond to an additional centre of mass height of 16cm. Furthermore, the increase in the standard deviation of kinetic energy from TO to BC suggests greater variability in technique up to bar clearance, which may be associated with precise segmental adjustments (quantified by body segment rotational kinetic energy).

CONCLUSION: Our results suggest that considering body segment rotations is essential when analysing the energy content of movement. This study suggests the importance of the pole vaulters body segment adjustments in interaction with the pole, particularly during bar clearance.

REFERENCE DATA OF DOUBLE AND SINGLE-LEG POSTURAL STABILITY MEASURED WITH AN INERTIAL SENSOR: PRELIMINARY RESULTS.

RUSSO, L., POLI, L., PONTI, M., MOLINARO, L., CENTRONE, C., FISCHETTI, F.

ECAMPUS UNIVERSITY: UNIVERSITA DEGLI STUDI ECAMPUS

INTRODUCTION: Postural stability is a global health key factor in the maintenance of upright standing balance. The most used instruments for measuring double and single-leg stability are usually platforms. In the last ten years, inertial sensors are growing up as stability measuring tool. The different technology of the inertial sensor in measuring stability requires

reference data in order to use them to classify stable and unstable individuals. This study aims to show the preliminary results of a larger study for assessing reference data of stability measured through inertial sensors.

METHODS: One hundred thirty-seven healthy volunteers (55 male and 82 female, height 165.4 ± 11.1 cm; weight 62.1 ± 15.4 kg; age 27.7 ± 14.4 yo) were recruited and tested for double and single leg stability. All subjects were right leg dominant. An inertial sensor (Beyond Inertial, Motustech, Italy) was applied on the lumbo-sacral region to assess stability, measuring sway path length (PL) and oscillation ellipse area (EA), both in open and closed eyes conditions (OE, CE respectively). Double and single leg stability tests lasted 30" and 10", respectively. For single leg stability dominant (DL) and not-dominant (NDL) leg was tested. Preliminary data analysis involved a descriptive statistic approach with percentiles and a Student T-test for a paired and independent sample to measure significant differences. The significance level was set at $P < 0.05$.

RESULTS: For the whole sample, in double legs test OE-AE was 4.2 ± 7.5 cm² (percentiles 25th 1.3; 50th 2.2; 75th 4.1) and CE-AE was 3.6 ± 4.1 cm² (percentiles 25th 1.2; 50th 2.2; 75th 3.9); OE-PL was 51.0 ± 30.3 cm (percentiles 25th 35.6; 50th 44.3; 75th 59.4) and CE-PL was 55.1 ± 22.2 cm (percentiles 25th 41.4; 50th 51.1; 75th 61.7). CE-PL was significantly greater respect OE-PL ($p 0.017$). In single leg test DL-AE was 37.9 ± 62.8 cm² (percentiles 25th 9.2; 50th 17.4; 75th 34.1) and NDL-AE was 22.2 ± 35.6 cm² (percentiles 25th 7.2; 50th 11.1; 75th 23.8); DL-PL was 37.2 ± 22.7 cm (percentiles 25th 24.2; 50th 31.3; 75th 41.5) and NDL-PL was 32.9 ± 17.0 cm (percentiles 25th 22.6; 50th 28.3; 75th 37.8). Both DL-AE and DL-PL were significantly greater respect NDL-AE and NDL-PL ($p 0.000$ and 0.001 , respectively). Male showed higher values respect female for DL-PL and NDL-PL (41.9 ± 24.3 and 34.0 ± 21.0 cm $p 0.044$; 37.1 ± 17.6 and 30.2 ± 16.0 cm and 0.019 , respectively).

CONCLUSION: The preliminary results of this ongoing study, allow concluding that the need for reference data is high due to the significant differences between conditions and gender. The study will allow professionals and researchers to use inertial sensors to test double and single-leg stability in all that contexts where the use of stabilometric platforms is limited.

DIFFERENCES IN STRENGTH UTILIZATION OF LOWER LIMBS IN DIFFERENT LEVEL PÉTANQUE PLAYERS AT VARIOUS SHOOTING DISTANCES

LIN, H., TSAI, Y.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: The original meaning of French Pétanque is "throwing the ball with both feet on the ground", so the lower limbs play an important part in the entire throwing process. Lower extremity strength is the primary source of power in most throwing sports (1). However, when tossing the ball in pétanque training or competition, some players may not properly apply lower extremity force, and more upper arm strength is required. This may lead to either insufficient throwing force or frequent directional deviations even easy to injury. The purpose of this study is to compare the body segment coordination, lower limb kinematics characteristics, center of pressure transfer, and muscle activation between elite players and amateurs while throwing various distances.

METHODS: 10 elite players and 10 amateurs were recruited for this study. Insole foot pressure, markerless motion analysis system, and surface electromyography were applied for data collection while players executed formal throws at six to nine-meter distances. Two-way ANOVA was applied to test the differences in joint kinematics, foot pressure distribution, center of pressure displacement, and maximum muscle activation between the two groups at different distances during different throwing phases.

RESULTS: Both groups throwing patterns were similar, increasing their backswing angle, release angle, and trunk horizontal displacement with distance increasing. However, the amateurs have significantly larger releasing angles than elite players. During backing, the contact area and foot pressure in the forefoot and midfoot of the non-throwing side in amateurs were larger than in elite players. The elite players put more pressure on the hindfoot on the throwing side. When releasing the ball, the contact area, contact pressure, and peak contact pressure in the forefoot of the throwing side in elite players were larger than in amateurs. The elite players were with less medial-lateral displacement of the center of pressure in the throwing side during throwing. Regarding muscle activations during throwing, higher wrist extensors were found in amateurs, however, higher rectus femoris and vastus medialis were found in elite players.

CONCLUSION: Better foot pressure distribution and center of pressure transfer patterns enable better performance in throwing. To increase stability during the throwing, skill training should follow the motion patterns identified in this study, and strength training may focus on core muscle groups to improve trunk and pelvic stability to have better performance.

A PILOT STUDY ON KNEE AND ANKLE MUSCLE CO-CONTRACTION PATTERNS DURING SINGLE LEG DROP JUMP AFTER PEOPLE FOLLOWING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION.

ITO, S., SAITO, H., MATSUSHITA, K., KAKEHATA, G., OTSUDO, T., NAKAYAMA, T.

TOKYO UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Single leg drop jump (SLDJ) is widely used in the assessment of post-anterior cruciate ligament reconstruction (ACLR) performance. The Co-contraction Index (CCI) is a valuable metric that evaluates the degree of simultaneous contraction between agonist and antagonist muscles using electromyography (EMG) signals. In general, a high CCI indicates excessive co-contraction of the antagonist muscle, which contributes to joint stability but may decrease energy efficiency. Conversely, a low CCI suggests reduced antagonist muscle involvement, improving movement efficiency but

potentially compromising joint stability. This study aims to investigate the differences in knee and ankle muscle co-contraction patterns between the reconstructed limbs (RL) and non-reconstructed limbs (NRL) during SLDJ in ACLR patients.

METHODS: Three males patients following ACLR (mean age: 18.7 years, mean height: 176.7 cm, mean weight: 74 kg) performed SLDJ five times both RL and NRL. EMGs were recorded from six lower limb muscles: vastus lateralis (VL), vastus medialis (VM), biceps femoris (BF), semitendinosus (ST), soleus (SOL), and tibialis anterior (TA) using wireless surface EMG system (Ultium, Noraxon) with 2000 Hz. Foot strike (FS) and foot-off timing were identified using a force plate (AMTI). We divided into five distinct phases: Pre-activation phase (50 ms before foot strike to FS), landing phase 1 (FS to foot-off), first-half of flight phase (foot-off to mid-swing), second-half of flight phase (mid-swing to the second FS), and the landing phase 2 (second FS to 100 ms after second FS). CCI was calculated using the ratio of agonist muscle activity to antagonist muscle activity multiplied by 100%. The CCI values for each phase were compared between RL and NRL to analyze differences in neuromuscular control.

RESULTS: The results revealed that in the lateral knee muscle group (LM/BF), CCI in the reconstructed limb was lower during the landing phase 1 (FS to foot-off) compared to the non-reconstructed limb (NRL: 403% vs. RL: 87.1%). However, no differences were observed in the other phases. In contrast, no differences were found between the RL and NRL in the medial knee muscle group (VM/ST). In the ankle muscle group (SOL/TA), RL exhibited higher CCI during the landing phase 1. (215.8% vs. 128.9%), indicating excessive co-contraction.

CONCLUSION: The reduced CCI in the lateral knee muscle group of the RL during the landing phase may indicate decreased knee joint stability post-ACLR. This lower co-contraction would lead to inadequate shock absorption upon landing. The excessive co-contraction observed in the ankle joint of the RL during the landing phase suggests a compensatory mechanism, where the ankle attempts to counterbalance knee instability.

Based on these results, rehabilitation strategies for ACLR patients should prioritize improving knee muscle activation during landing to enhance stability while simultaneously addressing excessive ankle co-contraction to encourage proper neuromuscular control.

EVALUATION OF MUSCLE ACTIVITY AND RECOVERY PROCESS BEFORE AND AFTER MUSCLE FATIGUE TASK BY MC SENSOR METHOD

TANAKA, S.1, HATASHIMA, K.1, YOKOZAWA, S.2, HIRATSUKA, K.3

1 KOKUSHIKAN UNIVERSITY, TOKYO, JAPAN; 2 HEISEI INTERNATIONAL UNIVERSITY, SAITAMA, JAPAN; 3 HACHINOHE GAKUIN UNIVERSITY, AOMORI, JAPAN

INTRODUCTION: The muscle contraction sensor (MC sensor) method has been used to evaluate the mechanical activity of muscles during muscle contraction. In previous studies, it has been shown that muscle tension in the biceps brachii muscle and knee extensor muscles measured by the MC sensor method are an indicator that can estimate the elbow flexion and knee extension muscle force levels (1, 2, 3). However, muscle fatigue and its recovery process have not been clarified. Therefore, the purpose of this study was to investigate the muscle activity and its recovery process before and after the muscle fatigue task by eccentric contraction by the MC sensor method.

METHODS: Eight males without disabilities to knee joint were participated in this study. The isometric knee extension torque at the knee joint angle of 80 degrees in before, after the fatigue task and four days after were measured by a dynamometer (Biodex co.). At the same time, the muscle tension as an index of muscle activity at rectus femoris (RF), vastus lateralis (VL), vastus medialis oblique (VMO) were measured by Muscle Contraction Sensor (TMG-BMC) method. The subjects were performed fatigue task with knee extension exercises consisting of 5 sets of 20 maximal effort eccentric contractions with 90 seconds of rest.

RESULTS: The knee extension torque decreased significantly after the fatigue task, with a decrease of approximately 23.4%. In four days after the fatigue task, the knee extension torque had recovered to the same value as before the fatigue task. The maximum muscle tension measured by the MC sensor method decreased by about 30% in all muscles after the fatigue task. 4 days after the fatigue task, maximum muscle tension in RF and VL had recovered to the same value as before the fatigue task. However, maximal muscle tension of VMO had not yet recovered.

CONCLUSION: The knee extensor torque was reduced due to the high intensity fatigue task caused by eccentric contraction. The muscle tension in the RF, VL and VMO muscle were also reduced in a similar value. In previous studies, it has shown that muscle tension measured by the MC sensor method estimates the muscle force levels (1, 2, 3). In this study, knee extensor torque and muscle tension also showed similar decreases before and after the fatigue task. On the other hand, it was observed that muscle recovery from fatigue differed by each muscle. These results suggest that differences in the contribution of the muscles participating in the knee extension may affect the recovery from fatigue.

COMPARISON OF KINEMATIC CHARACTERISTICS ON HITTING MOTION TO THE FAST AND SLOW BALL VELOCITIES IN SOFTBALL PLAYERS

TANABE, G., HATASHIMA, K., AKIBA, S., TANAKA, S.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: Baseball and softball hitters must respond to a various pitches and velocities thrown by the pitcher. It has been there are several reports to examine the focus on timing of the baseball hitting motion (1, 2, 3). In hitting motion, the step is an important movement for timing. Therefore, differences in step length are thought to affect lower limb and trunk motion. The purpose of this study was to examine that the step and kinematic characteristics of torso movement on hitting motion to the fast and slow ball velocities in soft ball players.

METHODS: The subjects were 14 male university softball players. Batters hit fastballs (FB:26.6±2.3m/s) and slow balls (SB:20.4±0.9m/s) thrown randomly by the pitcher. Bat swing speed was measured with a swing speed measurement system (BLAST Mizuno). Hitting motions were captured using 3D motion capture system (Xsens MVN, Movella co.) and two high-speed cameras (Degimo co.). The analysis phase was from the batters take back (TBM) to impact (IMP), and the release (RLS), toe ground contact (TC), and heel contact (HC) times were extracted. The analysis trials were hits in the center direction both FB and SB. The analysis items were stride length, upper and lower torso rotation angles, center of gravity displacement in the direction of the pitcher.

RESULTS: Stride length from TBM to IMP for FB and SB was significantly greater for SB than FB in TBM-TC phase and HC-IMP phase. The angles of rotation of the upper and lower torso in FB were significantly greater than that of SB in both RLS-TC phase. The distance on center of gravity toward the pitcher direction was greater SB than FB in from TBM to IMP phase, and the difference was especially significant from HC to IMP phase.

CONCLUSION: In this study, the kinematic characteristics of hitting motion to the fast and slow ball velocities in softball players. The response was to change the stride length and delay the timing of the upper and lower torso rotations at the time of SB hitting compared to the time of FB hitting. Also, compared to FB hitting, SB hitting may respond with a center of gravity displacement toward the direction of the pitcher during the HC-IMP phase.

EFFECTS OF RESISTANCE TRAINING TO STRENGTH AND SPRINT TIME IN COLLEGE RUGBY PLAYERS

HIDEKATSU, S., SHIMOSAKA, H., FURUTA, H., KUMAGAWA, D., TANAKA, S.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: In contact sports such as rugby and american football, intense contact play with tackles, scrums, and mauls are repeatedly performed during a game (1). And also, rugby players need to be able to sprint ability for move quickly to take their positions in attack and defense (2). Therefore, training programs aimed at improving strength and sprint ability are important in rugby players (3). The purpose of this study was to investigate the effects of resistance training (RT) on muscle strength and sprint ability in rugby players.

METHODS: The subjects were 16 university rugby players (Age:20.8±0.4 yrs, Hight:174.1±6.3cm, BW:81.4±10.0kg, LBW:64.6±7.7kg). RT was performed 4 times per week for 12 weeks. RT was programmed conceit of 5-weeks for hypertrophy period (middle load and high repetitions), 4-weeks for strength period (middle load and middle repetitions), and 3-week for strength and power period (low load and high repetitions). The maximal strength of lower body was tested at Squat (SQ) 1RM and Deadlift (DL) 1RM restrictively. The maximal strength of Upper body was tested by Bench Press (BP) 1RM and Pullup (PU) 1RM in all subjects. In addition, Sprint time was tested at 30 m time and 10m lap times. These parameters were tested before (Pre) and 12 weeks after (Post) the RT. Moreover, the change ratios were calculated in all subjects.

RESULTS: As a result, SQ and DL1RM in Post were showed significant higher values compered to Pre. And BP and PU showed for Post to Pre. These change ratios ranged from 104.8 to 107.3%. On the other hands, 30m sprint time and 10m lap times were not observed significant deferens between Pre and Post.

CONCLUSION: SQ, DL, BP, and PU are important physical fitness components, especially for Rugby, which involves repetitive heavy collisions and sprinting. The planned training program in this study was effective in improving the strength of SQ, DL, BP, and PU. On the other hand, the RT in this study did not improve sprint ability. Therefore, it is suggested that training at the field level is necessary to improve sprint ability in rugby players.

SELF-ORGANISATION AND MUSCLE SYNERGIES IN PARACANOE PERFORMANCE

BENINCASA, M., ALBANO, D., COPPOLA, S., SERRA, E., COIRO, F., COSTA, C., VASTOLA, R.

UNIVERSITY OF VERONA; UNIVERSITY OF SALERNO

INTRODUCTION: Paddling technique is fundamental to kayaking performance and varies with body coordination adaptation (1). Athletes dynamically adapt through self-organisation, forming synergies to optimise movement. They exploit degeneration, the ability to use different structures for the same output (2). In the ecological-dynamic approach, muscle synergies emerge as self-organising mechanisms, simplifying motor control and reducing degrees of freedom (3). Studying synergies helps understand neuromuscular control. This study aims to investigate paddling muscles synergies in paracanoe athletes, an unexplored area, to clarify how they optimise performance through degeneration, ensuring flexibility and adaptability.

METHODS: Three paracanoe athletes (KL3: 2, KL1: 1; two men, one woman; 31 ± 10.5 years) performed two 30-second maximal sprints on a paddle ergometer. The electromyographic activity (sEMG) of six ipsilateral muscles, biceps brachii (BB), triceps brachii (TB), pectoralis (PECT), middle deltoid (MD), upper trapezius (UT) and latissimus dorsi (LD), was recorded with wireless electrodes (BTS S.p.A., Italy). sEMG data were filtered, rectified, and normalised to the paddling cycle, defined by two successive paddle inputs into the water, identified using an optoelectronic system (BTS S.p.A., Italy). Non-Negative Matrix Factorization (NMF) extracted muscle synergy modules, identifying contributions and temporal activation. k-means analysis grouped the modules by similarity. Cosine similarity (CS) assessed the similarity in contributions and activation across athletes.

RESULTS: Three modules for athlete were extracted and classified into three clusters, indicating that the central nervous system facilitates paddling through three modular structures. Clusters of muscle contributions and temporal activation were similar among athletes ($CS > 0.80$). Cluster 1 involved the UP, MD (bilateral) and right BB, active between 10-30% of the cycle (pulling phase). The UT and MD stabilise the scapula, while the BB balance the TB in Cluster 3. Cluster 2 involved the left LD, left BB, right PECT and left TB, active between 40-60% of the cycle (input phase and traction of the opposite limb). Cluster 3 involved the right LD, right TB and left PECT, active at 0-20% and 90-100% of the cycle (water entry phase). The TB reduced elbow flexion, while the LD was the primary motor for shoulder extension and internal rotation.

CONCLUSION: The muscle synergies identified confirm common strategies to optimise paddling, simplifying motor control recurring modules ensuring stability and adaptability. The similarity in activation patterns suggests shared biomechanical principles despite individual differences. This evidence provides a basis for analysing variations in the motor skills of paracanoe athletes and offers insights for training optimisation.

MUSCLE SYNERGIES IN SQUATTING: AN ECOLOGICAL-DYNAMICS PERSPECTIVE ON NEURAL CONTROL AND TASK CONSTRAINTS

COIRO, F., ALBANO, D., COPPOLA, S., SERRA, E., BENINCASA, M.T., COSTA, C., VASTOLA, R.

UNIVERSITY OF SALERNO

INTRODUCTION: The front squat and back squat are widely used strength training exercises across various sports (1). Different barbell placements result in variations in movement biomechanics (2). However, the extent to which these variations influence motor control remains unclear.

The complexity of motor control, due to the abundance of degrees of freedom, is managed through synergies, as proposed by Bernstein. Within the ecological-dynamics framework, muscle synergies represent the self-organization of the movement system as a result of the continuous interaction between the organism, task, and environmental constraints, facilitating movement toward specific goals (3).

This study aimed to investigate whether different barbell placements in squats act as constraints that influence the emergence of distinct muscle synergies.

METHODS: Four healthy male participants performed three sets of five repetitions at their 10RM load for back and front squats.

Eight sEMG sensors were placed on the following muscles: gluteus maximus (GM), biceps femoris (BF), semitendinosus (ST), gastrocnemius lateralis (GL), rectus femoris (RF), vastus lateralis (VL), vastus medialis (VM), and tibialis anterior (TA). An inertial sensor was used to define squat cycles. Raw sEMG signals were band-pass filtered, rectified, and their envelopes were extracted. Muscle synergies were extracted using non-negative matrix factorization (NMF) and clustered using k-means analysis. Cosine similarity (CS) analysis was performed to assess the similarity of muscle synergies among subjects and squat variation.

RESULTS: Two motor modules were extracted for both squat variations in all subjects, grouping into two clusters. No subject exhibited individual-specific clusters. Cluster 1 primarily included GM, BF, ST, and GL muscles, peaking at 80% of the squat cycle. Cluster 2, comprised RF, VL, VM, and TA muscles, with peak activation between 30% and 75% of the squat

cycle. Muscle synergies remained highly similar across subjects and squat variations, with median CS values exceeding 0.85, indicating that squat variations did not alter the underlying synergy structure.

CONCLUSION: The findings could advise that motor control in squatting emerges as a self-organized process, where the central nervous system simplifies movement execution through two robust muscle synergies, independent of barbell placement.

Furthermore, the absence of significant differences in muscle contribution or temporal activation patterns between variations suggests that barbell position could not impose sufficient task constraints to induce distinct synergy structures.

MUSCULAR SYNERGIES AND SELF-ORGANIZATION IN RHYTHMIC GYMNASTICS TRAINING: AN ECOLOGICAL-DYNAMIC ANALYSIS

COSTA, C., COPPOLA, S., ALBANO, D., BENINCASA, M.T., SERRA, E., COIRO, F., VASTOLA, R.
UNIVERSITY OF VERONA; UNIVERSITY OF SALERNO

INTRODUCTION: In the ecological-dynamic approach, muscle synergies are referred to as self-organization, that is the organization of the different degrees of freedom of the body in relation to a goal (1). Studying the synergies in rhythmic gymnastics (RG) jumps, performed free body and with overloads, is useful for improving performance, as jumps require considerable inter and intramuscular coordination (2). Ankle weights are commonly used in RG jump training, but there is no scientific research on this topic. The aim of this study is to investigate, through the analysis of muscle synergies, the effectiveness of using ankle weights in the split leap training to identify conditions of specificity and transfer with the competitive context.

METHODS: Six competitive gymnasts (16.5 ± 2.7 years) performed five trials of the free body split leap and five trials of the same jump with 0.5 kg ankle weights. The BTS Bioengineering S.p.A. integrated multifactorial optoelectronic system was used, consisting of seven force platforms and six surface EMG sensors applied on the rectus femoris (RF), biceps femoris (BF) and gastrocnemius lateralis (GL) muscles. After identifying two events, the foot contact with the platforms and the take-off, synergy modules were extracted using non-negative matrix factorization (NMF). Average values of temporal activations and muscle contributions of the clusters identified through cluster analysis were highlighted. To compare the trials with and without ankle weights, the Pearson correlation was made.

RESULTS: Two synergic modules associated with two clusters were identified for each condition. Cluster 1 of the split leap with ankle weights and cluster 2 of the split leap without ankle weights show high levels of correlation in both muscle contributions ($|r|=1$) and temporal activations ($|r|=0.98$). The synergic muscles are the right RF, the right and left BF and the right GL. The greatest muscle activation occurs around 50% of the cycle. Cluster 1 of the split leap without ankle weights and cluster 2 of the split leap with ankle weights also show a strong correlation in both muscle contributions ($|r|=0.99$) and temporal activations ($|r|=1$). The synergic muscles are the left RF and the left GL. The peak of muscle activation occurs around 15% of the cycle. From the results of Pearson correlation, very strong correlation relationship ($|r|=0.99$) (3) between the two conditions emerged.

CONCLUSION: The results show that, despite the small size of the sample, the 0.5 kg ankle weights don't seem to alter self-organization and muscle coordination in the split leap. From an ecological-dynamic perspective, it is hypothesized that they represent a useful overload to support specificity and transfer between training and competition contexts in RG. Ankle weights, therefore, could be used for improving the performance of the split leap.

CHARACTERISTICS AND COMPARISON OF POSTURE ESTIMATION AI MODELS FOR EVALUATING CHILDRENS RUNNING MOTION

KOKUDO, S., SANO, T., UEDA, K.
CHUKYO UNIVERSITY

INTRODUCTION: The authors have developed an observational evaluation method for assessing childrens running motion. In this evaluation, we hypothesize that combining qualitative assessments based on motion observation with AI-driven motion recognition can enable the development of a machine learning and deep learning-based AI capable of highly accurate motion analysis. However, current AI technology has not yet achieved sufficient accuracy in extracting key motion features from continuous movements or conducting precise evaluations. As a preliminary step in evaluating running motion, this study aims to examine the characteristics and accuracy of multiple posture estimation AI models by analyzing identical image datasets.

METHODS: In this study, we visually compared the accuracy of four posture estimation AI models available in Python: HRNet, MediaPipe, YOLO11, and MMPose. The evaluation was conducted by using these models to estimate skeletal structures and key body parts in images of two runners running simultaneously. The images were captured from a lateral perspective at 60 FPS in high-definition resolution.

RESULTS: HRNet and YOLO11 estimated a total of 17 key body points, including the nose, eyes, ears, shoulders, elbows, wrists, hips, knees, and ankles. MMPose was capable of estimating the feet in addition to these, while MediaPipe could estimate both hands and feet, making it the most comprehensive in terms of detected body parts.

Regarding estimation accuracy, YOLO11 exhibited low reliability, correctly estimating knees and ankles in only 20–30% of frames, rendering it unsuitable for large-scale motion analysis such as running evaluation. MediaPipe failed to estimate posture in approximately 10% of frames, despite detecting the runners with Norfair. Among the estimated frames, knees were accurately estimated in 80% of cases and feet in 60%.

HRNet and MMPose demonstrated superior accuracy, correctly estimating 13 body points (excluding feet and legs) in over 97% of frames. Additionally, they achieved 95% accuracy for knee and ankle estimation. MMPose further excelled in foot estimation, achieving 85% accuracy. However, occasional misclassification of left and right body parts was observed.

CONCLUSION: HRNet and MMPose appear to be the most effective AI models for posture estimation, with MMPose being particularly advantageous when foot movement data is required. However, the current results remain insufficient for precise running. Further refinement is necessary, including correcting left-right misclassifications, filtering out inaccurate estimations, and supplementing missing data. In conclusion, while HRNet and MMPose exhibit high accuracy in skeletal estimation, their precision remains inadequate for detailed running motion analysis.

ESTIMATION OF GROUND REACTION FORCE FEATURES USING INERTIAL SENSORS DATA IN RUNNING: ACCURACY ASSESSMENT AND SENSITIVITY ANALYSIS WITH RESPECT TO GAIT EVENT IDENTIFICATION OF 12 ALGORITHMS

LUBRANO, M., BASILE, V., CIACCI, S., CUPPINI, C., FANTOZZI, S.

UNIVERSITÀ DI BOLOGNA

INTRODUCTION: Running is a widely practiced activity with significant health benefits but also a high risk of lower limb injuries. The study of Ground Reaction Force (GRF) is essential for performance optimization and injury prevention. Traditional GRF measurement instruments ensure high estimation accuracy, but are restricted to laboratory settings, while wearable alternatives like force insoles represent a more practical tool but face durability and foot-shoe interaction issues. Inertial Measurement Units (IMUs) provide a portable solution for in real-world applications, yet their accuracy and robustness in relation to gait event identification relying exclusively on IMU data has not been investigated. This study evaluates the performance of 12 IMU-based algorithms for GRF estimation using Loadsol® insoles as gold standard, aiming to refine estimation techniques for a portable and fully independent alternative to traditional measurement tools.

METHODS: Eleven amateur runners (9M2F, age: 26 ± 4 years) performed sprints at 15, 20 and 25 km/h. Two IMUs (OPAL, $\pm 200g$, $\pm 2000 \text{deg/s}$, 800Hz) were attached on the participant's right shank and lower back (L5) and secured with adhesive tape and a belt for the lower back sensor. Loadsol® insoles (Novel, 200Hz) served as gold standard. A total of 1177 steps were analysed separately for each speed. The GRF features examined were the first and second peak, loading rate, average load, impulse, and GRF time series. Algorithms were classified based on sensor placement (shank: 4, sacrum: 8) and methodology (Neural Networks (NN: 2, traditional approaches: 10). A linear mixed-effects model was used for statistical comparison. Additionally, sensitivity analysis was performed by varying initial contact (IC), final contact (FC) timings and stance window, with starting time points identified by selected IMU-based algorithm, assessing their impact on estimation errors.

RESULTS: While no single algorithm consistently outperformed the others across all metrics, NN-based methods generally showed better performance, with lower bias and dispersion (e.g. -0.3kN/s bias and limits of agreement 48.9kN/s for the loading rate metric with Kim method at 20km/h). The sensitivity analysis highlighted that estimation errors depended on both the analyzed GRF metric and the specific algorithm. NN-based approaches were more affected by FC misidentifications, while traditional methods showed higher sensitivity to IC and stance window variations. An overall worsening of algorithms' performances was observed at increasing speeds.

CONCLUSION: NN-based algorithms demonstrated the highest accuracy in GRF estimation. Traditional methods proved to be less reliable, particularly for peak force and loading rate measurements. The study highlights the importance of accounting for test speed and ensuring accurate gait event detection, as variations in IC and FC timing significantly affected GRF estimates.

ENERGY COST AND EFFICIENCY OF SEMI-TETHERED SWIMMING WITH A PARACHUTE

COLORETTI, V., LUBRANO, M., NIGRO, F., BOSETTO, P., FANTOZZI, S., ZAMPARO, P., CORTESI, M.

ALMA MATER STUDIORUM, UNIVERSITÀ DI BOLOGNA

INTRODUCTION: Swimming parachutes are commonly used for resisted swim training. Their effects on the hydrodynamic resistance encountered by the swimmer (I) as well as on his/her technique have been investigated and reported (2,3). Their use can be expected to affect also swimming economy (C) and efficiency (η), but this has not been investigated yet. The aim of this study was to determine C and η during swimming with and without a parachute (at comparable effort).

METHODS: Fifteen swimmers (14M/1F, 565.4 ± 118.4 of World Aquatic Points) completed two series of incremental pace trials: semi-tethered swimming while towing a squared-shape parachute of 900 cm^2 (para) and free-swimming (free); each trial lasted 4 min and was swam at constant speed (v). In the free condition, v was set at 60, 65, 70, 75 and 80% of the swimmer's best 400 m front-crawl performance and the corresponding F_d values were calculated as $k_{\text{free}} \cdot v_{\text{free}}^2$ by knowing the speed-specific drag in active condition (k_{free}), that was estimated through the residual thrust method (4). To maintain an equal effort (F_d) when towing the parachute, the values of v were recalculated based on values of k measured when towing the parachute, as reported by (1) ($v_{\text{para}} = \sqrt{F_d/k_{\text{para}}}$). The aerobic contribution (E_{aer}) to total energy expenditure (E_{tot}), was determined by measuring oxygen uptake, while the anaerobic lactic contribution (E_{anL}) was estimated based on the net increase in blood lactate concentration assessed at the end of the trial. The energy cost of swimming (C) was calculated as the ratio between metabolic power ($E'_{\text{tot}} = E_{\text{tot}}/\text{trial duration}$) and v , while drag efficiency was calculated as the ratio between drag power ($P_d = F_d \cdot v$) and metabolic power ($\eta = P_d/E'_{\text{tot}}$). Stroke rate (SR) was assessed using inertial measurement units placed on the swimmers wrists, as an indicator of swimming technique.

RESULTS: To maintain the same effort (F_d : $p=0.336$) the participants swam at reduced speeds when towing the parachute ($p<0.001$; $v_{\text{para}}=0.93\text{-}1.24 \text{ m/s}$; $v_{\text{free}}=0.65\text{-}0.86 \text{ m/s}$). No differences in total energy expenditure were observed (E_{tot} : $p=0.475$; $\text{para}=149\text{-}275 \text{ kJ}$; $\text{free}=143\text{-}279 \text{ kJ}$), and this confirms that the participants were swimming at equal effort in the two conditions. Yet C (the energy expended per unit distance) was found to increase significantly ($p<0.001$; $\text{para} = 0.95\text{-}1.32 \text{ kJ/m}$; $\text{free}=0.64\text{-}0.91 \text{ kJ/m}$) and drag efficiency to decrease ($p<0.001$; $\text{para} = 4\text{-}5\%$; $\text{free} = 5\text{-}8\%$) in resisted swimming.

CONCLUSION: Towing a parachute slows down a swimmer, but the decrease in speed is associated with an increase (rather than a decrease) in the energy cost of locomotion. In addition, even if the swimming technique can be assumed to be unchanged (no differences in SR: $p=0.272$), a reduction in drag efficiency is observed: the capability to transform metabolic power into useful mechanical power is thus impaired during resisted swimming.

ANGULAR VELOCITY AND ANGULAR ACCELERATION OF PELVIC ROTATION AND KNEE ROM OF THE KICKING LEG DURING DIFFERENT ROUNDHOUSE KICKS IN JU-JITSU ATHLETES

GIUSTINO, V., VICARI, D.S.S., PATTI, A., ROSSI, C., BRUSA, J., LIUZZA, R., MANNONE, L.V., STANKOVIC, N., ROKLICER, R., DRID, P., PADUA, E., MESSINA, G., BIANCO, A.

UNIVERSITY OF PALERMO

INTRODUCTION: In ju-jitsu fights, athletes compete using various technical gestures including kicks to the head and abdomen of the opponent and the points obtained depend on the part of the body hit (i.e., three points for a kick to the head and one point for a kick to the abdomen). This technical gesture requires a rapid axial rotation of the pelvis and kicking leg to attack. This study aimed to analyse the angular velocity and angular acceleration of the pelvic rotation and the knee ROM of the kicking leg during the roundhouse kick to 3 different heights and from 3 different distances in ju-jitsu athletes.

METHODS: Firstly, the length of the dominant leg (trochanter-malleolus distance in cm) in 16 black belt ju-jitsu athletes were recorded. Then, using a system of inertial sensors applied to specific anatomical points (pelvis, thigh, tibia, metatarsus) each participant performed 9 roundhouse kicks (i.e., 3 kicks to each height from all 3 distances) in a random order. The 3 heights of the target (i.e., head, abdomen, and knee) were calculated based on the height of each participant and the 3 distances from the target (i.e., short, medium, and long) were calculated based on the length of the dominant leg of each participant (i.e., medium distance: equal to the trochanter-malleolus distance; short distance: trochanter-malleolus distance minus 1/3; long distance: trochanter-malleolus distance plus 1/3).

RESULTS: For the pelvic rotation, we found a significant increase in the maximum angular velocity between the roundhouse kicks performed from short distance and those from long distance ($p<0.01$). No significant differences were found in the maximum angular acceleration of the pelvic rotation among the different roundhouse kick. For the knee joint of the kicking leg, we found a significant increase in the maximum angular velocity of the knee flexion and extension between the roundhouse kicks performed to the head and to the knee ($p<0.05$), and between the roundhouse kicks performed to the abdomen and to the knee ($p<0.05$). Moreover, we detected a significant increase in the maximum angular acceleration of the knee flexion and extension between the roundhouse kicks performed to the abdomen and the roundhouse kicks performed to the knee ($p=0.01$).

CONCLUSION: These results indicate that, during the execution of the roundhouse kick, both the kicking height and the kicking distance can influence the kinematics of the pelvis and kicking leg. Knowing the biomechanics of kicking could help to better plan the fight, taking into account the score of the match, the time remaining until the end of the fight, and the characteristics of the athlete.

KINEMATIC EFFECTS OF LEG CONSTRAINT IN FRONT-CRAWL SWIMMING WITH A PULL BUOY

BOSETTO, P., COLORETTI, V., RUSPI, M.L., LUBRANO, M., FANTOZZI, S., CORTESI, M.

UNIVERSITY OF BOLOGNA

INTRODUCTION: The upper limbs are the main contributors to propulsion in swimming [1]. To enhance their arm stroke technique, swimmers perform specific training sessions that exclude leg propulsion by using a pull buoy, sometimes paired with an ankle band to inhibit flutter kicking. This specific training technique reduces both velocity and energy cost of locomotion [2] while preserving hand kinematics and enhancing hand propulsion [3, 4]. Additionally, it is demonstrated that the pull buoy aids buoyancy, sinking the swimmers legs and reducing drag [5]. However, the effect of keeping the legs still with an ankle band on total body kinematics has not yet been analyzed. Therefore, this study aims to analyze kinematic differences in front-crawl swimming with a pull buoy or a pull buoy and ankle band using an underwater motion-capture system.

METHODS: After a routine warm-up, six male national swimmers performed a 25 m front-crawl under three conditions of tools: arm stroke with a pull buoy (P), arm stroke with a pull buoy and ankle band (PB) and arm stroke without a pull buoy and ankle band (C). The swimming speed was set at 80% of the maximum velocity for each condition and controlled using a pacing light (Indico Tech, Italy). The protocol was repeated twice. Their movements were captured using 9 synchronized underwater cameras (Qualisys, Sweden) collecting at a frame rate of 100 Hz. The calibrated volume was $7 \times 2.5 \times 1.3$ m, capturing at least one full stroke cycle per trial, defined from entry to re-entry of the third finger marker. Thirty-five reflective markers were attached to the swimmer's body to enable a complete 3D reconstruction. Hand position in the pool reference frame, hand velocity, shoulder roll, hip roll and knee angle were included in the analysis for each trial. The comparison between intensity conditions was examined using correlation analysis and RMSD.

RESULTS: Knee angle changes in both P e PB compared to C ($r = 0.44$ and 0.07 ; RMSD 7.45 and 10.45 deg for C vs P and C vs PB, respectively). In contrast, shoulder and hip roll remain steady (r medio = 0.90 ; RMSD max 15.1 deg). Similarly, hand displacement and hand velocity were consistently highly correlated across tools conditions (r medio = 0.87 and 0.70 , respectively; RMSD max 0.22 m and 0.72 m/s).

CONCLUSION: The use of a pull buoy between the legs does not affect upper limb technique or body roll compared to swimming without a pull buoy, but it decreases leg movement by reducing the knee angle. Adding an ankle band further limits leg movement, but does not affect the kinematics of the upper limbs or trunk. The coach can use the pull buoy and the ankle band without concerns about adjustments in swimming technique.

THE EFFECT OF STUD DESIGN ON GROUND REACTION FORCE AND SUBJECTIVE PERCEPTION IN FOOTBALL-SPECIFIC MOVEMENTS

AZZOLINI, G., FANTOZZI, S., PREATONI, E.

UNIVERSITÀ DI BOLOGNA

INTRODUCTION: Anterior cruciate ligament (ACL) injuries are a common concern in football. They often require surgery, lead to lengthy recovery, can cause long-term knee instability, and prevent from returning to the same playing standard. Current research has suggested that football boot studs may play a role in determining lower limb loading and therefore affecting ACL injury factors [1], but evidence upon the effects of stud design on biomechanical factors related to injury is limited. We assessed the effect of stud mechanical features on lower limb loading and subjective perception during lab-based football-specific movements.

METHODS: We measured the effects of three different stud types on 3D ground reaction forces (GRF) and subjective perception of comfort, stability, grip and overall appreciation. Seven male recreational football players (29.7 ± 6.0 y.o.; height 1.81 ± 7.4 m; weight 77.4 ± 6.6 kg) performed 90° and 180° cutting manoeuvres [2], in 3 different stud conditions, presented in random order: STD, standard; FLX, flexible; and VFL, very flexible studs. SASpik (saspi.it) provided FLX and VFL. All participants wore standard 8-stud boots (Mizuno Morelia Neo IV β Elite), sprinted from ~ 5 m and landed with their dominant foot on a force plate (Kistler 9287CA, 2000 Hz), covered in artificial turf. Repeated measure non-parametric ANOVA (Friedman test) and statistical parametric mapping (www.spm1d.org) were used to compare scalar quantities (subjective feedback via Visual Analog Scales - VAS, GRF loading rates) and timeseries (the first 40 ms of the GRF curves) across conditions ($\alpha=0.05$).

RESULTS: Subjective evaluations of overall appreciation showed higher scores for FLX ($+32.5\%$, $P=0.028$) than STD. Comfort (STD= 6.3 ± 2.3 ; FLX= 8.4 ± 1.1 ; VFL= 7.7 ± 2.7), Stability (STD= 5.8 ± 2.3 ; FLX= 7.9 ± 1.2 ; VFL= 6.7 ± 2.4), and Grip (STD= 6.7 ± 1.9 ; FLX= 7.2 ± 2.2 ; VFL= 7.2 ± 2.7) did not show statistical differences from the sample tested.

The vertical loading rate was higher in STD (226.03 ± 134.36 BW/s) compared to FLX (127.88 ± 81.45 BW/s; -43.4%) during the 90° cut ($p=0.022$). No significant differences were found in any of the three GRF components for any movement through SPM timeseries analysis.

CONCLUSION: These preliminary findings suggest that football boots equipped with flexible studs are overall better perceived by users. Adding in-built flexibility to the 8 studs in the boot reduced the vertical force loading rate in 90° cutting, and did not appear to influence other features of the GRF during the initial contact phase of cutting and pivoting tasks. However, the small sample size analysed and variability of the outcomes observed warrant further research of the interplay between stud design and mechanical loading.

FORCE AND PRESSURE DISTRIBUTION IN SNOWPLOUGH TURNS: A CASE STUDY COMPARING SKI SLOPE AND SKI TRACK SIMULATOR

BON, I., OCIC, M., CIGROVSKI, V., RUŽIC ŠVEGL, L., ŠVEGL, M.

UNIVERSITY OF ZAGREB FACULTY OF KINESIOLOGY

INTRODUCTION: From the perspective of recreational skiers, alpine skiing is a seasonal sport typically practiced during the winter months. Due to the lack of suitable climatic conditions, skiers often travel to distant locations for their skiing experiences. Along with costs for travel, accommodation, and equipment, novice skiers also invest in ski schools. However, many choose to skip formal instruction and attempt to master skiing techniques independently, which increases the risk of falls and injuries. The snowplough turn, a fundamental technique for recreational skiers, is essential for speed control and stability. A key factor contributing to injuries is the poor physical preparation, as skiing involves specific movements that are unfamiliar to novices. To maximize the ski learning process, a certain level of physical preparedness is essential, and the ski simulator aids in learning the basics of alpine skiing technique. While a novice skier may not fully be able to conquer the ski slope, they will perform specific movements biomechanically resembling those on the skiing terrain and become acquainted with the equipment. In this process, understanding pressure distribution and forces under the feet becomes essential, as these factors play a key role in analyzing weight shifting during different phases of the snowplough turn execution. This study aims to compare differences in foot pressure forces and distribution during different phases of the snowplough turn on a ski simulator and ski slope.

METHODS: Turns were performed by one alpine ski ISIA-level instructor who had previous experience with ski simulators. To measure the kinetic variables, insoles designed for pressure detection (Novel) were used. Mixed model ANOVA was used to detect differences in kinetic parameters between three phases of the turn executed on the simulator and on the slope.

RESULTS: The results indicate a statistically significant difference in the overall force exerted by the outside and inside foot when comparing snowplough turns performed on a ski slope and a ski track simulator ($p < 0.05$). However, the analysis of pressure distribution shows a similar pattern across both conditions in all regions (medial, lateral, and heel). These findings suggest that although the overall force differs between the ski slope and the simulator, the pressure distribution pattern remains consistent, indicating potential biomechanical adaptations to different skiing conditions.

CONCLUSION: Based on the results of this study, it can be concluded that it is possible to use the simulator for learning the basics of weight shifting necessary to perform a snowplough turn. Additionally, a simulator can serve excellently for specific conditioning preparation. However, one must be aware of the limitations in imitating the conditions of a ski slope, particularly in terms of friction and the fact that the skier remains stationary while the treadmill moves, unlike on a ski slope where the skier moves on a stationary surface.

IMU-BASED CHARACTERIZATION OF LOCOMOTOR DEVELOPMENT IN VERY PRETERM TODDLERS

TOMADIN, A., BISI, M.C., ACETI, A., BENVENUTI, E., CORVAGLIA, L.T., STAGNI, R.

UNIVERSITY OF BOLOGNA

INTRODUCTION: Preterm children have a high risk of motor impairment, with very-preterm (VPT, i.e., gestational-age < 32 weeks) being at higher risk of motor delay [1]. Sensor-based gait analysis resulted effective in distinguishing gait performance between 24-month-old preterm and full-term (FT) toddlers, and among preterm at varying risks of motor delay [2]. However, to implement effective longitudinal monitoring of motor development and identify deviations from typical path, it is essential to understand how motor differences evolve during the early years. Using the approach described in [2], this study aimed to compare VPT and FT children at 18 and 24 months (18m and 24m), considering both their corrected age and walking experience (WE).

METHODS: Fifty-two VPTs and nineteen (12 18-month-old and 7 24-month-old) FTs participated in the study. VPT data were collected longitudinally resulting in fifty-two tests at 18m and thirty-one at 24m. Children walked along a corridor while wearing 3 inertial sensors (MMR, mBient, USA) on the lower back and on the ankles [1]. Gait temporal parameters, their variability, and nonlinear metrics of trunk kinematics (i.e. harmonic ratio, recurrence quantification analysis, multiscale entropy) were extracted. Children were divided based on corrected age (18m and 24m) and on WE (0-2months, 3-5months, > 5 months). As the relatively low sample size did not allow multi-factorial analysis, results were compared among age/WE groups separately (Wilcoxon-rank-sum test, 0.05). **RESULTS:** No difference was found in normalized stride-time among groups. VPT exhibited longer double-support and stance than FT at 18m, 24m, and with a WE > 5 months. VPT also showed higher variability in temporal parameters across all comparisons, including at WE < 5 months. At 24m, VPT showed lower medio-lateral (ML) harmonic-ratio, while no difference was found at 18m or when analyzed with respect to WE. VPT showed lower multiscale entropy values in ML direction across all comparisons, with no difference observed in antero-posterior and vertical one. Regardless of age and WE, VPT recurrence parameters were lower in the sagittal plane, and the recurrence-rate higher in ML direction.

CONCLUSION: VPT children exhibited less mature motor performance during gait, characterized by lower stability (i.e., longer support phases) and higher variability. However, this variability did not indicate a structured exploration of more complex movements, as evidenced by lower recurrence in the sagittal plane and lower entropy in ML. The ongoing longi-

tudinal data collection for both VPT and FT participants will increase the sample size and provide an effective means to monitor early locomotor development to support possible early rehabilitative intervention.

IS GLENOHUMERAL INTERNAL ROTATION DEFICIT HAZARDOUS FOR ELBOW JOINT LOADING IN BASEBALL PITCHERS?

CHOU, P., LIN, Y., HUANG, T., LIN, W., CHOU, Y.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Epidemiologic studies reported overhead athletes with Gleno-Humeral Internal Rotation Deficit (GIRD) have higher risk of shoulder and elbow injuries. However, there is very little information on the effect of GIRD on elbow joint loading of the throwing arm in overhead athletes. The purpose of this study is to investigate the influence of GIRD on elbow joint loading in baseball pitchers.

METHODS: Twenty elite baseball pitchers from high school and university were divided into two groups of ten pitchers: 1) GIRD group (loss of internal rotation (IR) of the throwing shoulder of 20 degrees or more as compared with the non-throwing shoulder); 2) Normal group. After regular warm up routine, each pitcher was asked to throw 15 maximum-effort fastball pitches on the outdoor throwing mound at a distance of 18.4 m. Eight CCD cameras (Motion Analysis Inc., Santa Rosa, CA, U.S.A.) were used to capture the throwing motion at a sampling rate of 300Hz. Kinetic data between the two different groups of pitchers were calculated for comparison. A repeated-measure analysis of variance was used for statistical analysis.

RESULTS: In the late cocking phase, elbow medial force ($236.75 \pm 22.51\text{N}$), and maximum elbow varus torque ($51.21 \pm 8.18\text{N-m}$) of the GIRD group were significantly greater than that of the Normal group ($185.58 \pm 17.44\text{N}$), ($43.27 \pm 7.66\text{N-m}$) ($p < 0.05$), respectively.

In the acceleration phase, elbow varus torque ($32.0 \pm 6.89\text{N-m}$) of the GIRD group was significantly greater than that of the Normal group ($20.82 \pm 5.87\text{N-m}$) ($p = 0.046$). Although not significant, the elbow medial force ($144.08 \pm 23.09\text{N}$) of the GIRD group was greater than that of the Normal group ($96.26 \pm 20.29\text{N}$) ($p = 0.097$).

CONCLUSION: Literature showed that excessive torque on the medial elbow is a significant contributing factor to elbow injuries among overhead athletes. In this study, baseball pitchers with GIRD have higher elbow joint loading during throwing motion. This increase in elbow joint loading will generate more stress on the flexor/pronator and ulnar collateral ligament of the elbow, and further increase the chance of injury. Therefore, specific training program should be designed for pitchers with GIRD to improve their throwing techniques, and decrease the risk of upper extremity injuries

KINEMATIC ANALYSIS OF KNEE MOTION ACROSS SINGLE-LEG SQUAT TESTS USING INERTIAL SENSORS

MANDALIDIS, D., CHATZILIAS, V., KAFETZAKIS, I.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: The single-leg squat is a closed kinetic chain movement used for strength training and as a diagnostic tool to assess joint alignment and bilateral differences in various attributes, such as muscle strength. It can be performed in different ways, with the position of the non-supporting leg playing a key role in the loads exerted on the knee of the supporting limb. Inertial sensors have been utilized to assess lower limb kinematics; however, related data on single-leg squat variations remain scarce. This study aimed to investigate knee kinematics during three commonly used single-leg squat tests using inertial sensors.

METHODS: Twenty-two uninjured college students (10 males and 12 females), with a mean $\pm$ SD age of 23.2 ± 3.4 years, body mass of 67.2 ± 11.8 kg, height of 1.7 ± 0.1 m and BMI of 22.7 ± 2.4 kg/m required to perform (i) a freely performed single-leg squat (SLSQT) while maintaining the thigh as vertical as possible, (ii) a single-leg squat performed during the anterior excursion in the Star Excursion Balance Test (ASEBT), and (iii) a forward single-leg step-down squat (SLFSD). Knee kinematics were assessed by calculating yaw (for knee flexion), pitch (for knee abd/adduction), and roll (for knee rotation) using two inertial sensors positioned on the lateral side of the thigh (reference) and leg, respectively, at one-third of the distance from the knee to the lateral malleolus. A web camera, synchronized with inertial sensors unit, was placed on the side of the participant enabling detection of the maximum knee flexion achieved by participants. Statistical analysis was performed based on the average of three attempts completed by each individual in different testing conditions. One-way ANOVA for repeated measures and Pearson's r correlation coefficients were used to identify differences and relationships, respectively between the three testing conditions.

RESULTS: Statistical analysis revealed significant differences between tests only for yaw on the right knee (SLSQT: $66.7^\circ \pm 15.3^\circ$ vs. ASEBT: $71.3^\circ \pm 15.6^\circ$ vs. SLFSD: $73.3^\circ \pm 14.1^\circ$, $p < 0.05$). Non-significant were the differences between tests for yaw on the left knee (SLSQT: $66.5^\circ \pm 13.0^\circ$ vs. ASEBT: $68.9^\circ \pm 14.7^\circ$ vs. SLFSD: $71.4^\circ \pm 15.9^\circ$), absolute pitch for the right (SLSQT: $12.4^\circ \pm 10.2^\circ$ vs. ASEBT: $12.2^\circ \pm 11.6^\circ$ vs. SLFSD: $13.5^\circ \pm 11.7^\circ$), and left knee (SLSQT: $13.9^\circ \pm 11.6^\circ$ vs. ASEBT: $14.4^\circ \pm 11.3^\circ$ vs. SLFSD: $12.9^\circ \pm 10.9^\circ$), as well as roll for right (SLSQT: $13.9^\circ \pm 9.8^\circ$ vs. ASEBT: $12.0^\circ \pm 8.5^\circ$ vs. SLFSD: $15.0^\circ \pm 8.9^\circ$) and left knee (SLSQT: $13.8^\circ \pm 8.8^\circ$ vs. ASEBT: $12.9^\circ \pm 8.5^\circ$ vs. SLFSD: $12.9^\circ \pm 9.6^\circ$). Statistically significant correlations were found between tests ($p < 0.01$), with Pearson's r ranging from 0.74 to 0.90 for yaw, 0.93 to 0.98 for pitch, and 0.73 to 0.88 for roll in both limbs.

CONCLUSION: Our findings suggest that although small differences are expected in knee flexion (yaw) for the right limb, the single-leg squat test variations used in the present study can be used interchangeably in the assessment of knee kinematics using inertial sensors.

EFFECTS OF FOOTWEAR ON KINETICS DURING MAXIMUM-SPEED SPRINT RUNNING

FUCHS, P., HSIAO, H.W., CHUANG, W.H., HOBARA, H., NAGAHARA, R.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Footwear influences sprint running performance and injury risk by affecting critical kinetic variables such as ground reaction forces (GRF) and impulse, particularly during maximum-speed sprinting. While prior studies have mainly focused on the effects of footwear during acceleration at a single step, limited research has examined footwear effects on kinetics across multiple steps at maximum speed. The objective of this study was to investigate how footwear conditions affect GRF and impulse during maximum-speed sprinting.

METHODS: Seventeen male competitive sprinters (age: 19.5 ± 1.4 years, body height: 1.73 ± 0.06 m, body mass: 66.8 ± 4.5 kg, 100-m personal best: 11.2 ± 0.4 s) implemented standardized warm-ups before completing three 60-m sprints under different conditions (i.e., barefoot, regular running shoes, spiked sprint shoes) in a randomized order. Fifty force platforms (1000 Hz) embedded in a tartan track obtained body mass-normalized horizontal (braking and propulsive) and vertical mean GRF and impulse for each step across 50 m. Additionally, inter-step variability was assessed via standard deviations across steps. Maximum-speed phase was identified based on instantaneous speed (calculated as distance between contacts divided by time). Repeated-measures one-way ANOVA examined footwear effects on GRF, impulse, and their inter-step variability.

RESULTS: Participants reached maximum speed within 40 m, with 4.8 ± 1.9 steps captured at maximum speed. Spiked shoes resulted in higher speeds (9.49 ± 0.34 m/s) compared to barefoot (9.38 ± 0.31 m/s) and running shoes (9.26 ± 0.35 m/s) ($p < .001$, $\eta^2 = .60$). Spiked shoes exhibited greater propulsive GRF ($p < .01$, $\eta^2 = .30$), propulsive impulse ($p < .01$, $\eta^2 = .37$), braking GRF ($p < .01$, $\eta^2 = .35$), and braking impulse ($p < .01$, $\eta^2 = .37$) than running shoes. Vertical GRF did not differ among conditions ($p = .24$, $\eta^2 = .08$), but spiked and running shoes produced greater vertical impulse than barefoot ($p < .001$, $\eta^2 = 0.51$). Spike shoes had the highest inter-step variability in vertical GRF, while barefoot had the lowest ($p < .001$, $\eta^2 = .77$). Braking GRF variability was higher in running shoes than barefoot ($p < .05$, $\eta^2 = .19$). Variability of other kinetics did not differ among conditions ($p \geq .11$, $\eta^2 < .13$).

CONCLUSION: Spiked shoes enhanced sprint performance by generating the largest GRF and impulse, which may be associated with increased mechanical stress on joints and tissues. In contrast, cushioned running shoes absorbed horizontal GRF and impulse, reducing performance. Barefoot sprinting produced the smallest vertical impulse (a major contributor to mechanical load), while achieving moderate performance. The findings support the use of spiked shoes for competition and suggest barefoot training as a potential strategy to reduce mechanical overload on the ankle and knee joints. Future studies examining maximum-speed kinetics should consider the revealed effects of footwear on inter-step variability.

DIFFERENCES BETWEEN HOW BASKETBALL REFEREES DESCRIBED VIEWING GAME FILMED USING FIXED CAMERA IMAGES AND USING VR IMAGES

YASUYUKI, N.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: The purpose of this study was for basketball referees to describe a game they viewed using fixed camera images and VR images (recorded with a 360-degree omnidirectional camera) and to identify differences in how these types of images are viewed based on the differences in how the game was described.

METHODS: The study involved two certified referees from the Japan Basketball Association. A college basketball practice game was recorded using a fixed video camera (equipped with a wide-angle lens covering all players) and a 360-degree omnidirectional camera. These cameras were positioned at three locations: on the bench side (Point A), on the side opposite the bench (Point B), and under the goal (Point C).

Two subjects (Mr. H and Mr. L) gave descriptions while watching images recorded using a fixed video camera ("the fixed camera images") and images recorded using a 360-degree omnidirectional camera ("the VR images"). Mr. H watched the fixed camera images first, in order of Location A, Location B, and Location C. Mr. L watched the VR images first, in the order of Location C, Location B, and Location A. The subjects freely talked about what they thought of the recorded images of the games.

RESULTS: The descriptions were categorized into six groups: "situation description," "prediction," "retrospect," "foul judgment," "question," and "delegation (delegating to another referee's judgment)". Perhaps this was to be expected for Mr. H and Mr. L, who are experienced referees, but the pair recorded high percentages for descriptions matches on "foul judgments" (over 90%) in both the fixed camera images and the VR images in all three locations. For "situation description," the fixed camera images tended to have more descriptions matches than the VR images at Locations A and B. This is likely because the participants were viewing the phenomenon as bystanders rather than as referees. On the other hand, for

"prediction," the VR images tended to have more descriptions matches than the fixed camera images, and this was especially noticeable at Location C. This is likely because Location C was positioned under the goal, where fouls are more likely to occur, resulting in a greater number of predictions. For "delegation," the VR images at Locations A and B tended to have more descriptions matches than the fixed camera images. A game is usually judged by three referees, and the position and range of each referee's views are generally fixed. The fact that a lot of "delegation" were described suggests that the judges were making judgments as referees.

CONCLUSION: - While watching fixed videos, viewers tend to perceive events objectively, adopting the perspective of bystanders rather than that of referees.

- While watching VR videos, viewers tend to make decisions as referees in situations resembling those in actual games.

COMPARISON BETWEEN UNILATERAL AND BILATERAL PLYOMETRIC TRAINING IN PREADOLESCENT MALE HANDBALL PLAYERS

NOUTSOS, K., MELETAKOS, P., PAPAVALSILEIOU, A., SOUGLIS, A.G., TAVLARIDIS, A.

NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Plyometric training can play an important role in the development of young handball players. It can also be safe and effective in improving speed, power, and change-in-direction ability in children, provided that age-appropriate instructions are followed [1]. The purpose of the study was to investigate and compare 8 weeks of unilateral, bilateral plyometric training on selected motor characteristics of handball players of developmental age.

METHODS: A total of 57 preadolescent male handball players (age: 12.9 ± 0.5 years, maturity offset: -1.80 ± 0.7 years) voluntarily participated in this study. The sample was randomly divided into the intervention group performing unilateral plyometric training (UG, $n = 18$), the intervention group performing bilateral plyometric training (BG, $n = 21$) and the control group (CG, $n = 18$) performing general handball training. The parameters of linear speed of 5, 10 and 20 meters and Modified Agility T-test were evaluated for all 3 groups. A two-factor analysis of variance with repeated measures (repeated ANOVA 3x2) was used.

RESULTS: From the comparison of the performances at linear speeds of 5, 20 and 30 meters between the three groups, no statistically significant differences were observed. Although the differences are not significant in the parameters examined, a greater improvement is observed in the performance of the unilateral plyometric training group, followed by the bilateral plyometric training group. In the Modified Agility T-test, a significant difference was found only between UG and CG ($p=0.005$, $d=1.224$).

CONCLUSION: After 8 weeks of training, results showed that the unilateral plyometric training group recorded better performance. Therefore, it appears that using unilateral plyometric training in preadolescent handball players can improve handball performance.

CLARIFYING THE FUNCTIONAL DIFFERENCES BETWEEN TSURI-TE AND HIKI-TE IN JUDO KUMITE

ITO, S., SAKAMOTO, M., ITEYA, M.

NANZAN UNIVERSITY

INTRODUCTION: Judo, originating in Japan, is a martial art where the objective is to defeat the opponent, often through throwing techniques (Nage-waza). The importance of breaking the opponents balance (Kuzushi) before executing a throw is emphasized. Throwing techniques involve controlling the opponents judogi with the arms, and several studies have focused on the role of the arms during throws. However, two-thirds of a judo match is spent fighting for grips (Kumite), and recent rule changes have placed greater emphasis on Kumite. Although there are studies on grip dynamics in combat sports like wrestling, there has been little research specifically on the role of the arms in judo kumite. Furthermore, factors such as weight class, competition level, and gender could influence arm usage. This study aims to clarify the role of each arm in Kumite to enhance judo performance.

METHODS: A questionnaire survey was conducted with 239 Japanese collegiate judokas using Google Forms. The survey asked participants about the most important movements in Kumite and how they use their Hiki-te (pulling hand) and Tsurite (lifting hand) during Kumite. Competition levels and weight classes were recorded, and participants were divided into high-performance and other groups based on competition experience. Statistical analysis was performed using chi-square tests, with a p-value of <0.05 considered significant.

RESULTS: Participants were divided by competition level, gender and weight class. The chi-square tests showed no significant difference in arm use based on competition level, gender, or weight class. However, there was a significant difference in the most important movements for the Hiki-te and Tsurite ($\chi^2(4) = 38.014$, $p < 0.001$), with the Tsurite focusing more on "lift" and "relax" and the Hiki-te focusing on "pull."

CONCLUSION: The results indicated that while the role of each arm did not vary based on competition level, gender, or weight class, the primary function of the Tsurite and Hiki-te differed. The Tsurite is crucial for lifting and relaxing the opponent, while the Hiki-te is mainly used for pulling the opponent. This aligns with the fundamental judo technique of Kuzushi, where pulling with the Hiki-te helps destabilize the opponent. The relaxation of the Tsurite was highlighted, as it contributes to smoother execution of throws. This aspect is consistent with research in other sports, where muscle relaxation is key for efficient movement. Understanding these roles is vital for judokas and coaches to refine their Kumite practice and improve performance.

This study suggests that judokas use the Tsurite for lifting and relaxing, while the Hiki-te is used for pulling. The role of each arm did not differ significantly by competition level, gender, or weight class, indicating that these movements are fundamental techniques. Understanding these roles is vital for judokas and coaches to refine their Kumite practice and improve performance.

DETERMINANTS OF SUBJECTIVE TOTAL ATHLETIC ABILITY

KATO, K., SHO, I., KEISHI, S.

NANZAN UNIVERSITY

INTRODUCTION: The awareness of subjective athletic ability significantly influences participation in sports and physical activities, which provide health and academic benefits. Athletic ability, often vaguely defined, generally refers to physical strength, skill, and performance across various sports. Research in physical education and sports psychology highlights "motor competence"—confidence in physical activity—as a key factor tied to self-efficacy theory, where prior successes and social support foster skill development. Studies suggest that motor competence and athletic ability are shaped by lifestyle, family environment, and sports experience. Personality traits such as grit, resilience, and a growth mindset also play essential roles in persistence and skill improvement. This study focused on college students, exploring how personality, family factors, and prior sports participation influence subjective athletic ability.

METHODS: This study surveyed 406 participants (mean age: 19.31 years) from Nanzan University to investigate subjective athletic ability. Participants provided consent, and ethical approval was obtained. The questionnaire collected demographic data, sibling composition, family income, sports experience, and personality traits (grit, resilience, growth mindset). Subjective athletic ability was assessed using an 11-point scale, along with questions on participants' awareness of their athletic ability and feedback from others. Data analysis included correlation and regression models to identify factors influencing subjective athletic ability, such as personality, leisure activities, sports experience, and family background.

RESULTS: The study analyzed factors influencing subjective athletic ability using nine linear models. Subjective general athletic ability was strongly correlated with proficiency in soccer, volleyball, basketball, and short-distance racing. Grit, resilience, and a growth mindset positively influenced subjective athletic ability. In contrast, leisure activities such as gaming and studying showed a negative correlation with athletic ability. Being the youngest sibling and having prior sports experience positively impacted subjective ability. Additionally, the number of sports learned, athletic performance, and household income were significant factors. Furthermore, parental athletic ability, frequent praise, and faster skill acquisition were associated with higher subjective athletic ability. Diagnostic tests confirmed the validity of the models, with no major violations of statistical assumptions.

CONCLUSION: Grit, resilience, sports experience, and diverse activities positively influenced athletic ability, while sedentary activities had a negative impact. Parental athletic ability, household income, and feedback from others also played a role. Limitations include reliance on self-reported data and a cross-sectional design. Future research should incorporate longitudinal studies and objective measures.

ANALYSIS OF THE DISTANCE COVERED AT THE START OF THE IN-SEASON BY A TEAM OF SEMI-PROFESSIONAL SOCCER PLAYERS

THOMAKOS, P., ALEXIOU, V.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Distance covered (m) by soccer players during a match can provide useful information about their performance [1]. Additionally, there is a relationship between the level of physical fitness and the distance covered during a match [3]. Team formation also influences the distance covered during a match [3]. Players' position roles and their range of velocities can be used to evaluate the performance during in-season [4]. The aim of the current study was to evaluate the distance covered by soccer players based on their positional roles, identifying who covers more distance in both halves to assess intensity and performance.

METHODS: In the present study, semi-professional football players from a team in the Greek third national division league participated and were examined over the first 12 games of in-season, which lasted 3 months. They were allocated into five positional groups: full-backs (FB, $n=23$), central defenders (CD, $n=23$), midfielders (M, $n=34$), wingers (W, $n=22$), and forwards (F, $n=12$). The total distance covered in meters (m), distance per minute (m/min), and distance covered in 4 velocity zones (zone 3: 13.0–15.9 km/h, zone 4: 16.0–19.9 km/h, zone 5: 20.0–25.5 km/h, zone 6: ≥ 25.6 km/h) were recorded using GPS during both halves. A repeated measures ANOVA was used to detect changes between the positional roles of players in both halves. Significant main effects were followed up with Unequal N HSD post-hoc. Significance level was set at $p < 0.05$.

RESULTS: Significant differences were found between the 1st and 2nd halves, regardless of the position played. Distance covered ($p < 0.001$) and distance per minute ($p < 0.001$) were higher in the 1st compared to the 2nd half. Additionally, distances in zones 3 to 6 ($p < 0.001$) were higher in the 1st half. Significant differences were found between positional roles at full time. Specifically, distance covered was higher ($p < 0.05$) for FB and M compared to others. Also, distance per minute for M was higher ($p < 0.05$) than others. At high intensity running in zone 3 FB, CD and M covered more distance than W ($p < 0.001$) and F ($p < 0.01$) and zone 4, M was higher ($p < 0.05$) than other positional roles. At very high intensity running in zone 5, CD covered less distance ($p < 0.001$) than others. Finally, in zone 6 (sprints), only W covered more distance than CD ($p < 0.05$).

CONCLUSION: These findings provide insight into the teams playing style and approach during matches. Full-backs and midfielders covered more distance than other positional roles. Wingers covered more distance in sprint compared to central defenders. In the second half, all variables significantly decreased. It appears the team in second half played a more defensive style or needed to improve their fitness levels. To draw more accurate conclusions, the half-time score should also be taken into account.

THE EFFECTS OF VIDEO MODELLING ON STRADDLE JUMP LEARNING IN YOUTH GYMNASTS

KYSELOVICOVÁ, O., LAMOŠOVÁ, A., ZEMKOVÁ, E.

COMENIUS UNIVERSITY IN BRATISLAVA, FACULTY OF PHYSICAL & EDUCATION AND SPORT

INTRODUCTION: Effective motor learning, particularly for young athletes, depends on appropriate feedback. In aerobic gymnastics, the acquisition of high-level skills relies heavily on coach-provided feedback. Coaches often utilize video, which allows learners to review their performances (self-modelling) or observe expert athletes (expert-modelling). This study investigates the effects of video modelling on straddle jump learning in youth gymnasts.

METHODS: Eight gymnasts competing in the national development category (age 9 ± 1.5 years; sports age 4 ± 1.5 years) underwent a 24-day intervention program, focused on self-modelling followed by verbal feedback for the straddle jump. The intervention sessions, each lasting 30 minutes, were integrated into the gymnasts regular 90-minute training schedules, occurring three times per week. Before and after the intervention program, the straddle jump (the same element used in the intervention) was performed. A Samsung Galaxy s7 tablet and the Coach's Eye app were used to provide video feedback. The gymnasts reviewed the recordings of their performances on the tablet. Each video was presented only once at normal speed and once in slow motion, immediately after the gymnast performed. Gymnasts performed six trials, of which the three best, based on specific criteria (e.g., height, form, landing, etc.), were chosen for expert technical analysis. Four international FIG-certified aerobic gymnastics judges evaluated the execution of the elements, divided into five subphases. In each subphase, they assigned deductions according to given instructions, based on the current Code of Points. The final score for each gymnast was calculated by averaging the scores from their three selected trials for pre- and post-tests.

RESULTS: A significant improvement ($p \leq 0.05$) between the pre- and post-test measurements was observed in the overall execution score (8.30 pts.) of the element. Notably, the approach and culmination subphases showed significant technical improvements ($p \leq 0.05$), with the culmination subphase (+0.40 pts.) being critical for perfect form. Cohens d, calculated for the overall execution score, indicated a large effect ($d = 0.74$). A large effect size was observed in the approach ($d = 0.80$) and culmination subphases ($d = 0.83$).

CONCLUSION: Self-modelling, followed by verbal feedback, significantly improves the execution of the straddle jump in young aerobic gymnasts. This specific technique is essential for coaches when teaching new skills. Our findings have important practical implications for athletes and coaches, highlighting the value of incorporating specific feedback methods to enhance athletic performance. **Acknowledgments:** This work was supported by the Scientific Grant Agency of the Ministry of Education, Research, Development and Youth of the Slovak Republic and the Slovak Academy of Sciences (Nos. 1/0725/23 and 1/0712/24).

WHAT DIFFERENTIATES WIN FROM LOSS IN EUROPEAN MEN'S HANDBALL TOURNAMENT

MELETAKOS, P., NOUTSOS, K., PAPAVALSILEIOU, A., SOUGLIS, A., PAPAVALIS, G.

UNIVERSITY OF ATHENS

INTRODUCTION: Analysis of sports performance utilizing game data is an important parameter in modern sports that provides knowledge of the structure and development of team sports. Seeking patterns of play that lead to success is what is required at the top level.

The aim of the present study was to highlight the features that differentiate winners from losers in high-level men's handball.

METHODS: Out of 130 games from the 2022 and 2024 Men's Euro Handball, 120 that had winners were analyzed. This included all efficacy parameters for both the goalkeepers and court players as well as defensive and offensive technical variables. All variables were checked for differences between the winning and losing teams using the Independent Samples t Test. The level of significance was set at 0.05. Also reported are Cohen's d effect sizes.

RESULTS: Overall, winning teams scored 31.3 ± 4.2 goals while losing teams scored 26.0 ± 3.9 goals. The winning teams' goalkeepers had significantly higher efficacy than those of the losing teams in wing shots (34.7 ± 20.4 vs. 24.7 ± 19.2 , $p < 0.001$, Cohen's $d = 0.501$), nine-meter shots (44.1 ± 19.3 vs. 36.7 ± 18.5 , $p = 0.003$, Cohen's $d = 0.395$), seven-meter shots (23.2 ± 26.5 vs. 15.2 ± 23.0 , $p = 0.015$, Cohen's $d = 0.322$) and six-meter shots (26.9 ± 15.2 vs. 23.0 ± 15.4 , $p = 0.05$, Cohen's $d = 0.255$). Likewise, court players of the winning teams had significantly higher efficacy than those of the losing teams in wing shots (69.1 ± 20.3 vs. 58.4 ± 21.1 , $p < 0.001$, Cohen's $d = 0.516$), nine-meter shots (49.5 ± 18.2 vs. 40.3 ± 14.8 , $p < 0.001$, Cohen's $d = 0.551$), seven-meter shots (79.9 ± 25.1 vs. 71.5 ± 28.3 , $p = 0.017$, Cohen's $d = 0.317$) and six-meter shots (71.6 ± 16.2 vs. 67.3 ± 17.0 , $p = 0.047$, Cohen's $d = 0.259$). Winning teams had significantly more assists (16.1 ± 4.8 vs. 13.0 ± 4.0 , $p < 0.001$, Cohen's $d = 0.707$), steals (3.6 ± 2.3 vs. 2.2 ± 1.7 , $p < 0.001$, Cohen's $d = 0.693$) and blocks (1.9 ± 1.4 vs. 1.4 ± 1.3 , $p = 0.002$, Cohen's $d = 0.406$) and at the same time significantly less turnovers (4.8 ± 1.9 vs. 7.0 ± 3.1 , $p < 0.001$, Cohen's $d = 0.864$).

CONCLUSION: There seems to be a logical consistency between court players and goalkeeper efficacy with regards to wing, nine-meter, seven-meter and six-meter shots. Nonetheless, judging from the effect sizes, turnovers, assists and steals also appear to have an important impact on the outcome of high-level handball games. Further analysis is warranted to clarify which parameters are more consequential in games where the goal differences are minimal.

ANALYSIS OF GAZE PATTERNS DURING FENCING FIGHTING : A COMPARISON BETWEEN OFFENSIVE AND DEFENSIVE SCORING SITUATIONS

KATO, T., TANIO, S., ISHIGURE, U., ARAI, Y., TAKAMI, K., YAMAMOTO, H., SUGAJIMA, Y.

ASAHI UNIVERSITY

INTRODUCTION: In our previous research, we have conducted eye movement analyses across the three fencing disciplines (i.e., foil, épée, and sabre) when points were scored. As an interpersonal combat sport, fencing generally favors the offensive side in all three disciplines. However, by analyzing eye movement dynamics when responding to an opponent's attack, we may be able to develop more advantageous fighting strategies in the future. Furthermore, understanding individual eye movement characteristics could potentially allow fencers to apply their strengths across different disciplines.

METHODS: A total of 22 university fencing club members (10 sabre fencers and 6 fencers from each of the other two disciplines) participated in the study. They wore an eye-tracking device (Tobii Pro Glasses 3, Tobii Technology) while engaging in a five-point bout against an opponent. Each fencer fought the same opponent twice, once while wearing the eye-tracking device and once without it. The time taken to score each point was measured using Wondershare FilmoraX (Wondershare Inc.). Eye fixation locations were classified into four categories: mask and neck, chest and shoulders, arms and hands, and others. Eye fixation durations were measured in seconds using a frame-by-frame analysis (1/60 seconds per frame). All data were expressed as mean $\pm$ SD, and significance difference tests between disciplines and between retention sites were analyzed using one-way ANOVA in SPSS, with Tukeys HSD used for multiple comparisons.

RESULTS: The analysis revealed that for the sabre, there was almost no difference in eye fixation areas between scoring and conceding points. In contrast, for the foil, the most frequent fixation area during scoring was the chest and shoulders (45.3%), while for the épée, the arms and shoulders (40.1%) had the highest fixation rate. However, during point concessions, the fixation rate in these areas significantly decreased to 26.3% in épée and 32.8% in foil (a reduction of approximately 10%). Given that the valid target area in foil is the torso, and in épée the entire body, the results suggest a tendency for eye gaze to shift downward when conceding points in both disciplines. Regarding the time taken to score points for the sabre, among the 66 analyzed scoring instances, 19 points (29%) were scored in offensive situations, with an average duration of 5.9 ± 3.2 seconds. Sixteen points (24%) were scored in defensive situations, averaging 6.7 ± 2.5 seconds. Thirty-one points (47%) were scored immediately after the start signal ("Allez"), with a significantly shorter average duration of 2.1 ± 1.1 seconds.

CONCLUSION: There was no significant difference in scoring time between offensive and defensive situations, but the points scored immediately after the start signal were significantly quicker. Although sabre showed no noticeable changes in eye fixation areas between scoring and conceding points, in foil and épée, the findings indicate a shift in gaze direction upward when conceding points.

THE POTENTIAL BENEFITS OF RECOVERY WEAR FOR IMPROVING SLEEP IN COMPETITIVE SWIMMERS

WADA, T., YAMAMOTO, N., OTOBE, A., TAGAKI, S., KASHIWAGI, Y., HIRANO, T., NISHINO, S.

KOKUSHIKAN UNIVERSITY

INTRODUCTION: Sleep disturbances and disrupted circadian rhythms have become increasingly recognized as significant health concerns. In the general population, insufficient sleep and sleep debt can impair daytime productivity and increase the risk of accidents. Competitive swimmers, due to the physical demands of intensive training—often conducted early in the morning or late at night—are particularly vulnerable to compromised sleep quality and recovery. Poor sleep may negatively impact both training effectiveness and performance. This study aimed to investigate whether wearing recovery wear made of PHT (Platinum Harmonized Technology) fabric (manufactured by Venex) enhances sleep quality in competitive swimmers experiencing insufficient sleep.

METHODS: Eight healthy male collegiate competitive swimmers participated in the study (age: 20.0 ± 2.0 years, height: 173.0 ± 7.0 cm, weight: 66.0 ± 8.0 kg). Sleep was assessed under two conditions: three consecutive nights with and without wearing recovery wear. Sleep monitoring was conducted using an activity-based sleep monitor (MTN-221, Acos Co.), worn on the waist except during training and bathing. Sleep parameters were analyzed using SleepSignAct2 software (Kissei Comtec Co.). Body water content and composition were measured using the bioelectrical impedance method (InBody770). Body temperature was recorded before sleep and upon waking using a smartwatch (Inspire 3, Fitbit Co.). Statistical analyses were performed using t-tests.

RESULTS: Wearing recovery wear significantly improved sleep quality. Sleep onset latency was significantly shorter when wearing recovery wear (18.7 ± 6.6 min) compared to the non-wear condition (33.8 ± 10.8 min). Wake after sleep onset (WASO) was also significantly reduced (31.7 ± 10.4 min vs. 61.2 ± 17.0 min). Additionally, the number of nighttime awakenings was significantly lower (2.6 ± 1.6 vs. 7.3 ± 2.7). Sleep efficiency was significantly higher with recovery wear ($86.4 \pm 2.2\%$) than without ($70.9 \pm 3.7\%$). No significant differences were observed in body temperature changes between conditions (pre-sleep: $36.6\text{--}37.0^\circ\text{C}$, post-sleep: $36.1\text{--}36.2^\circ\text{C}$). While body water content exhibited a slight decreasing trend with recovery wear, the difference was not statistically significant.

CONCLUSION: These findings suggest that wearing PHT-based recovery wear (Venex) may enhance recovery efficiency by improving sleep quality in competitive swimmers. Further research is necessary to elucidate the underlying mechanisms responsible for these effects.

THE INFLUENCE OF MATURITY OFFSET ON COACHES' RATINGS AND SELECTION IN U15 SOCCER: AN ECOLOGICAL DYNAMICS PERSPECTIVE

SERRA, E., COPPOLA, S., ALBANO, D., COIRO, F., VASTOLA, R.

UNIVERSITY OF VERONA; UNIVERSITY OF SALERNO

INTRODUCTION: The ecological dynamics framework and the Constraints-Led Approach (CLA) emphasize that motor performance and learning emerge from the interaction of organismic, task, and environmental constraints [1-2]. In youth sports, coaches act as "learning environment designers" [3], yet they often rely on chronological age rather than biological maturation, which may not accurately reflect an athlete's developmental status. Biological maturity can be estimated through peak height velocity (PHV) and maturity offset [4].

This study examined whether maturity offset influences coaches' performance ratings across technical, tactical, physical, and creative domains and whether it affects player selection (starters vs. non-starters) in Under 15 (U15) soccer players at national and regional levels.

METHODS: A cross-sectional study was conducted on 46 male U15 outfield players (national: $n = 23$, age = 13.8 ± 0.7 years; regional: $n = 23$, age = 14.3 ± 0.5 years). Anthropometric measures (height, seated height, body mass) were recorded to calculate maturity offset [4]. Both teams were coached by UEFA B-licensed trainers, who underwent training on a validated 5-point Likert scale questionnaire [5]. Inter-rater reliability was tested ($ICC[2,1] = 0.77$) on 20 external subjects. Coaches rated players across four performance domains and designated starters. Spearman's correlation assessed relationships between maturity offset and performance ratings, while Mann-Whitney U tests examined differences in maturity offset between starters and non-starters.

RESULTS: In the regional group, maturity offset positively correlated with tactical ($\rho = 0.58$; $p < 0.01$), technical ($\rho = 0.71$; $p < 0.001$), physical ($\rho = 0.79$; $p < 0.001$), and creative ($\rho = 0.76$; $p < 0.001$) abilities. Starters (median = 0.25) had significantly higher maturity offset than non-starters (median = -0.70) ($U = 112.5$; $p < 0.01$).

In the national group, only physical ability showed a significant correlation with maturity offset ($\rho = 0.84$; $p < 0.001$), while tactical ($\rho = 0.21$; $p = 0.33$), technical ($\rho = -0.02$; $p = 0.92$), and creative ($\rho = 0.18$; $p = 0.40$) abilities had no significant relationships. No significant difference was found in maturity offset between starters (median = 0.70) and non-starters (median = 0.30) ($U = 83.5$; $p = 0.26$).

CONCLUSION: The results suggest that biological maturation status acts as an organismic constraint, potentially favoring more mature players, particularly at the regional level. In line with existing literature [6-8], these findings highlight the importance of considering biological age in player selection and training load planning to ensure fair evaluation and development. Strategies such as bio-banding and individualized training could support a more equitable and effective youth development system.

A NEW THEORETICAL FRAMEWORK FOR TRAINING AUTO-REGULATION

BRACCI, A., ZOFFOLI, L., MARCORA, S.M.

UNIVERSITY OF BOLOGNA

INTRODUCTION: The goal of this framework is to develop a new theoretical model for training auto-regulation.

METHODS: A systematic review of literature that highlights different auto-regulated training constructs and their relationship guided by a new theoretical framework.

RESULTS: Our theoretical framework conceptualizes the model as comprising an input channel, an output channel, and a "black box" processing system. The input channel consists of subjects' states, traits, and training behavior variables, whose fluctuations—driven by auto-regulation—lead to variations in the output variables related to training behavior. States refer to conditions or characteristics of the subject that persist and may change within a one-week period, whereas traits are more stable and evolve in more than a week. Both states and traits are classified as subjective, objective, or psychophysical. Subjective states and traits are self-reported measures based on personal perceptions and sensations (e.g., rate of perceived exertion, self-assessed recovery, personality, motivation, etc.). Objective states and traits encom-

pass quantifiable variables independent of self-perception (e.g., performance metrics, body composition, training experience, etc.). Psychophysical variables link subjective and objective measures or subjective measures and training behavior. Training behavior inputs include all variables associated with training (e.g., intensity, volume, duration, etc.). The output channel reflects modifications in training behavior as a result of the subjects' performance during training governed by auto-regulation rules and algorithms. The "black box" represents a system of rules and algorithms that processes input variables to generate outputs (e.g., "Increase the number of repetitions by one in the next set if the subject reaches eight repetitions"). Additionally, all variables are recorded both at the time of their measurement and upon any changes in time. (e.g., pre-training, intra-session, weekly, etc.).

CONCLUSION: This theoretical framework will guide future literature in the training auto-regulation area.

WINNER FOR LIFE: AN INNOVATIVE PROGRAMME TO PROMOTE LIFE SKILLS DEVELOPMENT AND TRANSFER

TROTTIER, C., PÉPIN, M.A., DRAPEAU, V., GOULET, C., BILLAUT, F., VEILLETTE, R., TRUDEL, P.

LAVAL UNIVERSITY

INTRODUCTION: According to School Sport Canada, over 750,000 student-athletes attend schools where they can practice their sport in a sport-study programme. Their mission is to promote positive development and life skills in student-athletes. Despite this noble aim and the benefits associated with sport practice, there may be undesirable outcomes, such as performance anxiety and injuries. Therefore, life skills programs should be based on scientific advances and respond to stakeholders' expressed needs.

METHODS: In this perspective, our research team launched the Winner For Life programme. The aim was to introduce improvements over a previously implemented programme and to take into consideration a need assessment evaluation in 10 high schools offering sport-study programmes in Québec, Canada. The objective of the improved programme is to equip school sport stakeholders and parents to teach student-athletes four general life skills: (a) optimal mental skills, (b) healthy eating habits, (c) safety behaviours, and (d) physical and mental recovery skills. Stakeholders and parents are invited to collaborate to impart the life skills across different settings (e.g., classroom, training, family). A hybrid format was chosen: distance (Internet platform) and face-to-face components combined with individual intervention and follow-up to make the program accessible and adaptable to the realities of school sport stakeholders and parents. The programme's educational activities and tools are designed following Trudel et al.'s constructivist learning model. Accordingly, for each life skill, the program included: (a) practical workshops, videos, and tools (mediated learning situations), (b) online forums for stakeholders and parents to exchange ideas (unmediated learning situations), and (c) reflective cards to help stakeholders and parents reflect on how they could facilitate life skills development and transfer (internal learning situations). Based on the complementarity of the three learning situations, innovative interventions are created.

RESULTS: The programme design will be presented along with specific examples of the tools and strategies used to help student-athletes apply life skills in school sports and other life settings.

CONCLUSION: This innovative, interdisciplinary program is designed to enable school and sports stakeholders, as well as parents, to work together to teach life skills to student-athletes and ensure their use in different contexts such as sport, school and home.

UTILIZING MHEALTH TO PROMOTE HEALTHY LIFESTYLES AMONG ADOLESCENTS WITH INTELLECTUAL DISABILITIES

FERIA, A., SAÑUDO, B., SCHWARZ, D., ANGOSTO, S., GARCÍA, J., CARRASCO, L., SÁNCHEZ-OLIVER, A., SCIVOLA, G., RESTREPO, M., LANGBEIN, E., MILOS, A., SKULLIC, G., RODRÍGUEZ, A.

UNIVERSITY OF SEVILLE

INTRODUCTION: Despite the critical role of physical activity and nutrition in improving public health, individuals with intellectual and developmental disabilities (IDD) exhibit alarmingly low engagement levels in these domains. Addressing these disparities, the IDHEApp project developed a gamified mobile intervention tailored to the unique needs of this population, aiming to enhance physical activity and dietary habits through personalized, engaging challenges.

METHODS: Our intervention leverages gamification principles to foster adherence and behavior change. Intensity levels were calibrated using a systematic review of sedentary and physical activity guidelines and iterative feedback from stakeholders, including adolescents with IDD, caregivers, and educators. Pilot studies validated the app's usability, while a living-lab randomized controlled trial (RCT) across multiple EU countries tested its effectiveness. Personalized challenges were designed based on baseline data and focused on step counts, sedentary interruptions, and dietary balance, incorporating competitive and cooperative elements to motivate participation.

RESULTS: Preliminary findings from pilot tests indicated high engagement, with participants demonstrating a 20% increase in daily step counts and a 15% reduction in sedentary time within four weeks. Dietary challenges led to improved intake of fruits and vegetables by 12%, with adherence to recommendations verified via app-reported data. Feedback revealed that personalized and team-based challenges were key drivers of sustained participation.

CONCLUSION: The gamified approach proved effective in tailoring interventions to individual capabilities and fostering sustained healthy behaviors among adolescents with IDD. Collaborative and competitive elements, combined with progressive intensity adjustments, were instrumental in achieving outcomes. These insights underscore the potential of gami-

fication as a scalable solution for promoting health equity in underserved populations. Future directions include broader application of the intervention and refinement of engagement metrics to further optimize results.

THE ASSOCIATION BETWEEN THE PHYSICAL FITNESS AND MOTOR COORDINATION IN THE DIFFERENTIATION OF THE METABOLOME FINGER PRINT IN INDIVIDUALS WITH DOWN SYNDROME

CAVAGLIERI, C., AMARAL, M.A.B., MELO, N., OLIVEIRA, A., NEVES, L., AGIOVLASITIS, S., SILVA, A.A.C.

STATE UNIVERSITY OF CAMPINAS

INTRODUCTION: Down syndrome (DS) is characterized by intellectual disability and endocrinological and metabolic comorbidities leading to alterations in clinical markers compared to peers without DS. However, the most important metabolic pathways associated with these differences are still unclear. Thus, the objective of the study is to characterize the plasma metabolomic profile and its correlation with physical fitness and functional capacity in adults with DS.

METHODS: Twenty-two individuals with DS (11 men; age 24 ± 4.37 years) and 15 without DS (8 men; age 24 ± 4.08 years) underwent electrical bioimpedance, anthropometrics assessments, Vo₂max, handgrip, KTK for motor coordination test, timed-up-and-go (TUG), sit to stand (STS). Blood samples were analyzed by nuclear magnetic resonance at 600 MHz. All participants underwent a medical evaluation prior to the study. Data acquired were checked for normality, homoscedasticity, and sphericity with the Kolmogorov-Smirnov, Levene and Mauchly test. The data were transformed with Box-Cox and z-score. Then a partial least squares discriminant analysis (PLS-DA) was applied and metabolites with Vip Score >1 in both components were retained for pathway enrichment analysis. The Kruskal-Wallis test with Dunn's post hoc test and Eta square (η^2) was utilized to compare the main metabolites between groups and all other variables were compared utilizing ANOVA and a Tukey post-hoc. Afterwards, a persons correlation was realized.

RESULTS: Individuals with DS had significantly lower body mass, stature, and leg circumference ($\eta^2 > 0.189$, $p < 0.05$), and a worse motor coordination, VO₂max, TUG, STS, and hand grip scores ($\eta^2 > 0.417$, $p < 0.05$) than individuals without DS. 62 metabolites were acquired and 8 were retained after the PLS-DA and enrichment pathway analysis: 1,3-diaminopropane, ascorbate, asparagine, glutamate, glutamine, lysine, methionine, and phenylalanine. The most enriched pathways were ammonia recycling, aspartate metabolism, carnitine synthesis, phenylalanine and tyrosine metabolism, urea cycle, lysine degradation, amino sugar metabolism, beta-alanine metabolism, nicotinate and nicotinamide metabolism, biotin metabolism. The retained metabolites were significantly different ($p < 0.05$) between individuals with and without DS, with moderate effect sizes ($\eta^2 > 0.068$), except for glutamate which had a large effect size ($\eta^2 = 2.971$). Ascorbate was significantly associated with TUG ($r = 0.32$, $p = 0.047$).

CONCLUSION: The alterations found in the DS group indicate associations with synapse function and formation, intellectual disability, especially glutamate and phenylalanine. Additionally, lower ascorbate levels, may be associated with higher oxidative stress levels in DS, which is associated with lower muscle development, leading to a lower performance in TUG. Therefore, interventions targeting these metabolic pathways, such as regular exercise and pharmacological treatments, may mitigate the effects of DS.

ASSOCIATION BETWEEN PHYSICAL ACTIVITY, PSYCHOLOGICAL WELL-BEING AND SLEEP QUALITY IN ATHLETES PRACTICING ADAPTED SPORTS

BIASIOLO, C., CAVEDON, V., MILANESE, C., ZANCANARO, C.

UNIVERSITY OF VERONA

INTRODUCTION: Physical activity is widely recognized as a key factor for health and well-being, particularly for individuals with disabilities. The development of adapted sports (AS) has increased opportunities for this population to engage in regular physical activity. Despite the growing popularity of AS, the impact of sports participation on quality of life and related factors remains poorly investigated. The study aimed to investigate the relationship between physical activity levels (PAL), sedentary behaviours (SB), psychological well-being (PWB) and sleep quality (SQ) in athletes practicing AS.

METHODS: Seventy-four questionnaires were completed by athletes (36.1 ± 9.42 years; females=24; males=50) with physical or sensory disabilities (PSD) who regularly engage in AS, and were analysed. The survey included questions related to PAL and SB using the short form of the International Physical Activity Questionnaire (IPAQ-sf); weekly training volume (VOL_ALL); PWB using the World Health Organization-Five Well-Being Index (WHO-5); SQ using the Pittsburgh Sleep Quality Index (PSQI); enjoyment of physical activity (EPA) using the Physical Activity Enjoyment Scale (PACES). The distribution of the data was checked using the Shapiro-Wilk test. The partial association between variables was estimated by Spearman's Rho correlation coefficient (r) accounting for the effects of age, gender and disability type. The level of significance was set at $p < 0.05$. The statistical analysis was conducted using the Jamovi software (v.2.6.17).

RESULTS: A negative and statistically significant association ($r = -0.428$, $p < 0.001$) was found between WHO-5 and PSQI. In contrast, a positive and statistically significant association ($r = 0.267$, $p = 0.03$) was found between WHO-5 and IPAQ-sf. A positive and statistically significant association ($r = 0.268$, $p = 0.032$) was observed between PACES and IPAQ-sf, as well as PACES and VOL_ALL ($r = 0.299$, $p = 0.017$). PACES also showed a positive and statistically significant association with WHO-5 ($r = 0.266$, $p = 0.034$). PSQI was negatively associated with VOL_ALL, IPAQ-sf and PACES; however, these associations were not statistically significant ($r = -0.082$, $p = 0.511$; $r = -0.098$, $p = 0.435$; $r = -0.026$, $p = 0.838$, respectively). SB showed a negative and statistically significant associations with VOL_ALL ($r = -0.268$, $p = 0.032$), WHO-5 ($r = -0.266$, $p = 0.034$) and IPAQ-sf ($r = -0.253$, $p = 0.044$).

CONCLUSION: Higher PWB is associated with better SQ and PAL. Greater EPA is associated with higher PWB, higher training volume, higher PAL. SQ, although it impacts the quality of life, does not directly affect PAL or EPA. Higher SB are linked to lower PAL and poorer PWB. These findings underscore the importance of participation in AS for individuals with PSD. Coaches and strength and conditioning specialists should focus on developing inclusive, enjoyable and tailored training programs that enhance PWB and athletic performance. Customized interventions to improve SQ and reduce SB could enhance athletes performance and overall well-being.

ASSOCIATIONS BETWEEN SCHOOL-BASED ENVIRONMENTAL FACTORS AND PHYSICAL ACTIVITY IN ADOLESCENTS: A SYSTEMATIC REVIEW AND META-ANALYSIS

SUN, T., HOU, X., DONG, X., WANG, H., HONG, P., SHI, Y.

BEIJING SPORT UNIVERSITY

INTRODUCTION: This study aimed to explore the effectiveness of different school environmental factors on improving adolescents' PA levels.

METHODS: A comprehensive search of five databases (PubMed, Embase, Web of Science, EBSCO, and Cochrane Library) was conducted from the earliest available records to September 2023. When two or more studies explored the same school environmental factor, a meta-analysis was performed. The involved school environmental factors encompassed seven school social environmental factors and six school physical environmental factors.

RESULTS: Eighteen studies with a total of 340,749 participants were included in the meta-analysis. The result revealed a significant positive correlation between the school environment and adolescents' PA (OR = 1.09; 95% CI = 1.06 to 1.12; $P < 0.001$; $I^2 = 85.9\%$). Specifically, the school social environment was significantly positive-associated with adolescents' PA level (OR = 1.18; 95% CI = 1.04 to 1.33; $P = 0.011$; $I^2 = 83.5\%$). Among the school social environmental factors, the school-offered daily PE (OR = 1.20; 95% CI = 1.04 to 1.38; $P = 0.012$; $I^2 = 89.5\%$), school-organized extracurricular PA (OR = 1.16; 95% CI = 1.05 to 1.28; $P = 0.003$; $I^2 = 87.6\%$), the encouragement of using sport equipment or facilities (OR = 3.25; 95% CI = 1.87 to 5.64; $P < 0.001$; $I^2 = 64.1\%$), and outdoor obstacle course (OR = 1.58; 95% CI = 1.25 to 1.98; $P < 0.001$; $I^2 = 36.2\%$) were significantly positive-correlated with adolescents' PA level, respectively. Additionally, the school physical environment did not show a significant association with adolescents' PA. However, among the school physical environmental factors, the number of school PA facilities (OR = 1.07; 95% CI = 1.03 to 1.11; $P = 0.001$; $I^2 = 78.1\%$) was significantly positive-associated with adolescents' PA level.

CONCLUSION: This meta-analysis demonstrates that the school environment is helpful for increasing adolescents' PA level. Among the various school social environmental factors, the school-offered daily PE, school-organized extracurricular PA, the encouragement of using sport equipment or facilities, and outdoor obstacle courses are found to be particularly beneficial for promoting adolescents PA. Furthermore, regarding the school physical environment, the number of school PA facilities is found to be a key factor in enhancing PA among adolescents.

TIME ABOVE VENTILATORY THRESHOLD AS A DETERMINANT OF POST-EXERCISE HYPOTENSION: SEX-SPECIFIC FINDINGS FROM HIKING

PAPALE, O., FESTINO, E., DI ROCCO, F., BARBEAU, A., FOSTER, C., PRESTANTI, I., SERAFINI, S., IZZICUPO, P., CORTIS, C., FUSCO, A.

UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE

INTRODUCTION: The temporary reduction in blood pressure (BP), particularly in systolic BP (sBP), following exercise is known as Post-Exercise Hypotension (PEH). Although PEH is influenced by several internal (i.e., age) and external (i.e., caffeine) factors, no studies have yet specifically investigated the influence of the time spent above the ventilatory threshold ($\text{MIN} \geq \text{VT}$) on sBP reduction. Therefore, this study aimed to investigate the sex-specific PEH responses following hiking and their relationship with the $\text{MIN} \geq \text{VT}$.

METHODS: 7 females (F) (age: 24.7 ± 0.7 years; BMI: 23.8 ± 2.7 kg/m²) and 7 males (M) (age: 24.1 ± 0.8 years; BMI: 20.2 ± 1.5 kg/m²) participated in a laboratory treadmill walking incremental test and an outdoor hiking session (~3800m length). Participants self-selected a comfortable walking speed for the initial 2-min stage at 0% grade during the incremental test. The grade then increased by 2% every 2 minutes stage until volitional exhaustion. VT was determined using the deflection point method. After 24 hours of rest, participants completed the hiking session. sBP was measured 15 minutes before (PRE) and 30 minutes after (POST) the hike. PEH was calculated as the difference between sBP at PRE and POST. T-tests were used to compare the hike time of completion, $\text{MIN} \geq \text{VT}$ and PEH between sexes. A linear regression analysis was performed with PEH as dependent variable, while $\text{MIN} \geq \text{VT}$, sex and their interaction were included as independent variables. Statistical significance was set at $p < 0.05$.

RESULTS: The hike was completed in 41.4 ± 3.7 min and 42.4 ± 3.5 min by M and F, respectively, and no significant differences were found. Significant differences between sexes were found for $\text{MIN} \geq \text{VT}$ ($F = 8.0 \pm 2.6$ min; $M = 1.7 \pm 2.3$ min; $p = 0.0005$) and PEH ($F = 12.3 \pm 7.8$ mmHg; $M = 4.0 \pm 5.5$ mmHg; $p = 0.04$). The regression model explained 74% of the variance in PEH ($R^2 = 0.74$, $p = 0.003$). In F, increasing $\text{MIN} \geq \text{VT}$ was associated with a significant reduction in PEH ($p = 0.011$). M had significantly lower PEH than F at $\text{MIN} \geq \text{VT}$ @0-min ($p = 0.001$), indicating a weaker PEH response with intensities $\leq \text{VT}$. The

significant positive interaction term ($p=0.002$) indicates that the effect of $\text{MIN} \geq \text{VT}$ on PEH differs by sex. In M, PEH varied widely at lower $\text{MIN} \geq \text{VT}$ but increased to 15mmHg at 6 min, suggesting that longer $\text{MIN} \geq \text{VT}$ is required for a stronger PEH. In contrast, F exhibited a more stable PEH response with consistently positive values above 9-min.

CONCLUSION: Despite sex-related variations in sBP levels, PEH was observed in both sexes. The findings highlight a sex-specific difference in PEH regulation, potentially influenced by autonomic and vascular adaptations. While F experience a PEH reduction with increasing $\text{MIN} \geq \text{VT}$, M exhibit an opposite trend, where more $\text{MIN} \geq \text{VT}$ was associated with a rise in PEH. This suggests that M require prolonged high-intensity exercise $\text{MIN} \geq \text{VT}$ for significant PEH, while F benefit from a more immediate response (<3 -min). These results emphasize the importance of adapting higher-intensity training to maximize PEH.

THE IMPACT OF TAEKWONDO TRAINING ON FUNCTIONAL FITNESS IN THE ELDERLY: A 12-WEEK INTERVENTION STUDY

DI ROCCO, F., FESTINO, E., PAPALE, O., CAPRANICA, L., CIACCIONI, S., DEL DUCA, V., CHIODO, S., FUSCO, A., CORTIS, C.
UNIVERSITY OF CASSINO AND LAZIO MERIDIONALE

INTRODUCTION: Aging is generally associated with osteopenia (loss of bone mass), sarcopenia (loss of muscle mass), and structural and functional brain declines. Regular physical activity positively impacts older adults by enhancing functional autonomy, quality of life, and the ability to perform activities of daily living. Among combat sports, Taekwondo (TKD) offers a diverse range of movements varying in frequency, intensity, duration, and application, which may benefit fitness components in older individuals. This study aimed to evaluate the effects of a 12-week TKD program on functional fitness assessment in older individuals, considering sex-related differences.

METHODS: 16 older subjects (5 male (M), 11 female (F); age: 73.8 ± 5.9 year) were administered the American Alliance for Health, Physical Education, Recreation & Dance (AAHPERD) functional fitness tests before (PRE) and after (POST) the TKD program. According to the AAHPERD protocol (1), subjects performed Chair Sit and Reach test (CSRT) to assess flexibility, Arm Curl test (ACT) for strength, 2 Minute Step test (2MST) for endurance, Agility Dynamic Balance test (ADBT) for agility/dynamic balance, and Coordination "Soda Pop" test (SPT) for coordination. The reached distance (cm) from the toes in CSRT, the total number (AU) of fully-ranged repetitions in ACT, the total number (AU) of correct steps in 2MST, and the best score in ADBT and SPT (s) were recorded and used for the analysis. Repeated Measure ANOVA was used to examine the effects ($p < 0.05$) of TKD program on the functional fitness assessments, in relation to sex.

RESULTS: No sex differences emerged for all tests in PRE vs POST evaluations. There were no differences in CSRT (F = PRE: 3.7 ± 6.8 cm, POST: 4.1 ± 7.2 cm; M = PRE: 8.8 ± 10.2 cm, POST: 8.0 ± 10.2 cm) and ADBT (F = PRE: 44.2 ± 8.7 s, POST: 45.5 ± 11.5 s; M = PRE: 39.8 ± 5.3 s, POST: 39.5 ± 7.2 s). ACT performance decreased in both sexes, with statistically significant decrease only in F (PRE: 11.9 ± 2.6 reps, POST: 9.1 ± 4.9 reps, $p=0.044$). The 2MST performance significantly improved in both M (PRE: 52.6 ± 21.7 steps; POST: 74.6 ± 12.6 AU, $p=0.011$) and F (PRE: 51.4 ± 13.9 AU; POST: 64.0 ± 16.2 AU, $p=0.034$). The SPT performance significantly ($p < 0.001$) improved in both M (PRE: 21.2 ± 3.9 s, POST: 11.4 ± 1.3 s) and F (PRE: 22.3 ± 6.8 s, POST: 12.6 ± 2.4 s).

CONCLUSION: Findings suggest the 12-week TKD program significantly improved endurance and coordination, while flexibility and agility/dynamic balance remained unchanged. The practice of regular TKD can be an efficient intervention strategy to minimize the deleterious effects of aging, contributing to improved well-being in the elderly. As a good alternative to conventional interventions, TKD could be integrated into public health programs for older individuals, as it is a safe, accessible intervention with good adherence.

THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITY AND LUMBOPELVIC PAIN DURING PREGNANCY: A LONGITUDINAL STUDY OF HOUSEWORK, OCCUPATIONAL ACTIVITIES, AND SPORTS AND EXERCISE

KAWABE, R.1, KATAYAMA, A.2, OKIMURA, H.2, MORI, T.2, AOYAMA, T.1
1. KYOTO UNIVERSITY 2. KYOTO PREFECTURAL UNIVERSITY OF MEDICINE

INTRODUCTION: Over half of pregnant women experience daily lumbopelvic pain (LPP), including pubic symphysis pain (PSP), low back pain (LBP), and sacroiliac joint pain (SIJP). Physical activity (PA) is thought to influence the severity of LPP, but the effects of different categories of PA, such as housework, childcare, occupational activities, and leisure-time sports/exercise, remain unclear. This study investigates the relationship between the amount and type of PA (housework/childcare, occupational activities, and sports/exercise) and LPP during pregnancy and postpartum.

METHODS: In total, 23 Japanese pregnant women who visited obstetric and gynecological hospitals were included. The severity of LPP was assessed using the Numerical Rating Scale (NRS), and PA was classified using the Pregnancy Physical Activity Questionnaire. A longitudinal study was conducted to assess PA at 12, 20, 30, and 36 weeks of pregnancy, and its association with pain at these time points, as well as one month postpartum. Statistical analysis was performed using t-tests and Spearman's rank correlation coefficient.

RESULTS: At 12 weeks, women without pain exhibited significantly higher occupational PA than those with pain ($p = 0.01$). At 36 weeks, women with pain showed significantly higher housework/caregiving activity levels at both 20 weeks ($p = 0.05$) and 36 weeks ($p = 0.03$). One month postpartum, women without pain showed higher levels of occupational activity at 12 weeks ($p = 0.03$) and sports/exercise activity at 20 weeks ($p = 0.02$). Regarding specific pain types, PSP was negatively correlated with housework/caregiving activity at 12 and 20 weeks (12 weeks: $p = -0.43$, $p = 0.04$; 20 weeks: $p = -0.43$, $p = 0.04$), and with sports/exercise activity at 20 and 30 weeks (20 weeks: $p = -0.44$, $p = 0.04$; 30 weeks: $p = -0.47$, $p = 0.03$). At 30 weeks, PSP was also negatively correlated with sports/exercise activity at 20 weeks ($p = -0.44$, $p = 0.04$).

At 36 weeks, PSP was positively correlated with housework/caregiving activity at 20 weeks ($p = 0.43$, $p = 0.04$). LBP showed a negative correlation with occupational PA at 12 and 20 weeks (12 weeks: $p = -0.55$, $p = 0.01$; 20 weeks: $p = -0.44$, $p = 0.04$). At 36 weeks, LBP was negatively correlated with occupational PA at 36 weeks ($p = -0.47$, $p = 0.03$). No significant correlations were observed between SIJP and PA.

CONCLUSION: This study suggests that occupational PA during early pregnancy may be associated with LBP, while housework/caregiving PA in late pregnancy is related to pelvic pain, including PSP. Furthermore, sports and exercise activities, particularly during mid-pregnancy, may help alleviate postpartum pain and may be associated with specific pelvic pain conditions, such as PSP. Therefore, adjusting PA in different categories during pregnancy may help reduce LPP and support postpartum recovery. Further research is needed to clarify the mechanisms by which PA alleviates LPP and to examine the role of sports and exercise interventions.

EVIDENCE FOR PEDIATRIC DYNAPENIA AND POTENTIAL EFFECTS OF THE COVID-19 PANDEMIC

PINTO, R., CRUZ-MONTECINOS, C., FREITAS, S.R., RUAS, C.V., NOSAKA, K., PINTO, M.D., RATEL, S.
FEDERAL UNIVERSITY OF RIO GRANDE DO SUL

INTRODUCTION: Muscular strength in children and adolescents has progressively declined over recent decades (1, 2), and this decline of muscle strength is referred to as “pediatric dynapenia” (3). Despite “dynapenia” being fundamentally defined as loss of muscle strength, pediatric dynapenia assessment has largely relied on physical fitness tests such as standing long and vertical jumps, pull-ups and sit-ups, rather than muscle strength measurements. Moreover, pediatric dynapenia has not been systematically tracked over time, nor has the potential impact of the COVID-19 pandemic been examined. This study examined changes in knee extension strength of adolescents between 2010 and 2021, and investigated the potential effect of the COVID-19 pandemic on the changes.

METHODS: Maximal voluntary isometric contraction (MVIC) torque of the knee extensors (KE) relative to body mass (BM) in 226 male adolescents aged between 13–15 years with the same maturity status and body mass was examined in this retrospective analyses. Data were collected from studies conducted between 2010 and 2021, including the post-COVID-19 period, across two laboratories in Brazil (UFRGS) and France (UCA).

RESULTS: Analyses revealed a significant decline (~31%) in KE MVIC torque relative to body mass over 12 years ($P < 0.01$) and a significant ($P < 0.01$) effect of the COVID-19 pandemic on the strength, reducing from before (~4 Nm/kgBM) to after the pandemic (2.7 Nm/kgBM).

CONCLUSION: Adolescent force-generating capacity has declined over the last decade, with the COVID-19 pandemic exacerbating this trend. These findings suggest that modern lifestyles characterized by increased sedentary behaviour reduced the muscular strength in adolescents. While no formal cut-off criterion exists for “pediatric dynapenia,” the observed declines indicate a potential rise in its prevalence over the past decade, with the pandemic accelerating this trend. More efforts focusing on interventions to mitigate this decline and increase muscular strength in youth are necessary.

AEROBIC EXERCISE PRECONDITIONING SUPPRESSES SUBCUTANEOUS TUMOR GROWTH AND GLYCOLYSIS VIA PI3K/AKT PATHWAY IN TUMOR-BEARING MICE

XUE, Z., YIXUE, X., LINGBING, Z., ZHENG TANG, Q., SHUZHE, D.
CHENGDU SPORT UNIVERSITY

INTRODUCTION: Aerobic glycolysis is a typical metabolic characteristic of tumor, and exercise may regulate the metabolism of tumor cells and thus affect tumor growth. A large amount of epidemiological evidence shows the anticancer effect of exercise, but whether exercise preconditioning can inhibit tumor growth remains unclear. The aim of this study was to investigate the effect of aerobic exercise preconditioning on subcutaneous tumor in tumor-bearing mice and its mechanism.

METHODS: 6 weeks of age male C57BL/6 mice were selected and subjected to 12 weeks of treadmill pre-aerobic exercise intervention. Then, Hepa1-6 tumor-bearing mice were established and divided into a sedentary group and an exercise intervention group. After the intervention and the formation of tumors, the tumors were sampled and weighed. The glycolytic function of the tumors in the mice was observed by detecting the glucose content, the activity of PKM2 enzyme (pyruvate kinase 2), LA (lactic acid), and the content of ROS. RNA-Seq analysis and functional enrichment were carried out to explore the impact of pre-aerobic exercise on the glycolytic capacity of tumor tissues. The phosphorylation level of proteins in the PI3K/AKT signaling pathway was verified by Western Blot. Combining the public database of single-cell tumors TISCH2 and the results of RNA-Seq analysis in this study, the association between glycolysis and immune cell infiltration was explored, and macrophage infiltration was detected by immunofluorescence.

RESULTS: Compared with the control group, we found that aerobic preconditioning inhibited hepa1-6 tumor growth and down-regulated PKM2, GLUT1, LDHA and HK2 expression in tumor tissue. RNA-Seq showed that differentiated gene expression in aerobic exercise group was enriched in PI3K/AKT signaling pathway. Further western blot detection showed that P-PI3K and P-AKT proteins were significantly down-regulated in the tumor tissue of the exercise group. Meanwhile,

RNA-Seq showed that exercise down-regulated the expression of genes related to glucose metabolism. TISCH2 database single cell population gene cluster map (macrophage population) suggests that these genes are closely related to immune cell infiltration. Immunofluorescence assay also showed that exercise significantly reduced inflammatory infiltration of M1 macrophages.

CONCLUSION: This study suggests that aerobic exercise preconditioning can down-regulate tumor glycolysis activity and inflammatory infiltration of M1 macrophages through PI3K/AKT signaling pathway, thereby inhibiting subcutaneous tumor growth.

SPORT AND PHYSICAL ACTIVITY PARTICIPATION IN HUNGARIAN GIRLS AND BOYS

UVACSEK, M., WÁGNER, B.

HUNGARIAN UNIVERSITY OF SPORTS SCIENCE

INTRODUCTION: Physical activity is essential for health and wellbeing. According to the last HBSC data collection, less than 25% of students do enough physical activity in Hungary (Németh 2024). Monitoring the different activities of children is essential to understand the reasons. The aim of the study was to collect data about primary school children's physical activity and analyse the gender difference. The questionnaire was compiled by the Global Matrix 4.0 indicators. We asked parents about the children's overall physical activity, daily physical activity, sport participation, and active transport.

METHODS: In the online data collection, 677 parents (42.85±6.49 years old) provided information about 677 children (10.98±2.53 years old). Data were collected in 2023 spring using social media platforms and online correspondence. Our questionnaire was edited with the Qualtrics program; the data were analysed with TIBCO 14.0 Statistics; the gender differences were tested with t-tests and chi square tests.

RESULTS: We found a significant difference in overall PA where 73% of girls and 82% of boys achieved the 60 min. MVPA/day on average. However, the number of days spent physically active was similar: 4.54 days (girls) vs. 4.81 days (boys). Altogether, 46% of children participated in club sports (44% of girls and 48% of boys). Girls preferred sports were handball and basketball; meanwhile, boys chose mostly football and kayaking & canoeing. Active transport was present at the same level in both genders, 78% of girls and 81% of boys reported this type of activity.

CONCLUSION: We have found that daily physical activity and active transport were reported at a higher rate compared to the last representative data collection. We believe that parents can better predict their children's physical activity than children. Our data showed that in primary school children, the gender difference was not significant. The increased physical activity might be explained with the daily PE in schools and with the governmental support of sports and the higher rate of educated parents.

SCALING SUCCESS: PARENTAL PERCEPTIONS OF THE BENEFITS OF A 20-WEEK FOOTBALL LIVING-LAB APPROACH FOR CHILDREN LIVING WITH CEREBRAL PALSY

MARTINS, R., PATTISON, W., VELLA, L., POSTLETHWAITE, R., DUNCAN, M.

COVENTRY UNIVERSITY

INTRODUCTION: Living-lab approaches have been successful in bridging the gap between university research and communities. However, these have never been used to promote physical activity opportunities for children living with cerebral palsy (CP) and the effects on children's development are yet to be known. Therefore, we created a 20-week football program inspired by Football is Medicine and Physical Literacy for children between the ages of 5-10 living with CP and subsequently explored parents perceived benefits of the program for their children using a qualitative approach.

METHODS: Seven one-to-one semi-structured interviews were conducted with the parents of the children who participated in the programme to gauge the impact of engagement on the children's lives. Following this, deductive thematic analysis was performed and pen profile diagrams created to explore parents perceived benefits of the program for their children.

RESULTS: Parents reported that participation in the programme was beneficial for their children fostering physical literacy. They highlighted improvements in their children's competence and confidence (n=7), motivation and enjoyment (n=7), as well as increased social interaction (n=7). Furthermore, parents noted that the sessions were inclusive (n=6), fostering a sense of community, and were tailored to their needs (n=5). Some parents perceived their child's participation in the programme as a form of treatment, equating involvement in the football programme to additional physiotherapy and rehabilitation sessions commonly undertaken by children living with CP. Additionally, parents valued the opportunity to share and develop new strategies to support their child's well-being in daily life.

CONCLUSION: Parents reported improvements across multiple aspects of physical literacy, noting progress in social, psychological, and physical domains. Consequently, the football programme has fostered a welcoming environment that supports the holistic development of children living with CP.

EFFECTS OF EXERCISE ON DEPRESSION IN ADOLESCENT PATIENTS WITH OBESITY AND T2 DIABETE MELLITUS

YAFI, M., JHONSON, A.M., RIGGS, K., EISSA, M.

UNIVERSITY OF TEXAS JOHN P AND KATHERINE G MCGOVERN MEDICAL SCHOOL

INTRODUCTION: Exercise is recognized to reduce depression in adults. Although there is an increase in the prevalence of depression in adolescents, especially among those who have chronic diseases such as obesity and type 2 Diabetes Mellitus (T2DM), the effect of exercise on depression symptoms has not been adequately studied. This study aims to ex-

amine the relationship between exercise and depression symptoms in a clinic-based adolescent group who are seen for obesity and T2D management

METHODS: A retrospective chart review of patients with obesity who were consecutively seen at a university-based multi-disciplinary pediatric weight management clinic between July 1, 2018, and June 30, 2021, was performed. Demographic, anthropometric, clinical, physical activity and laboratory data, psychiatric history, and depression status using PHQ-9 score were abstracted. Selection criteria were age 12-18 years, BMI % > 95th%; and charts include data on: BMI; PHQ9 scores, physical activity in minutes/week; and T2D status (defined as HgA1c > 6.5, history of T2D diagnosis, and/or receiving metformin or/and insulin). R 4.1.2, packages: ggplot2, epitools, and ggpvr were used for Data analysis.

RESULTS: Charts of 178 subjects were identified. Female adolescents had a significantly higher PHQ9 score compared to males ($p < 0.05$). There was no significant difference in PHQ9 scores when patients were compared based on T2DM status. In a regression model that included T2DM status and psychiatric diagnoses, every minute added of exercise decreased the total PHQ9 score by 0.006 ($P < 0.05$). For a group that included only patients who have T2DM and reported physical activity at least 3 hrs/ week, there was a moderate negative correlation between PHQ9 scores and min/ week exercise with $r = -0.54$ ($p = 0.057$). In subjects who do not have T2DM, the correlation was not statistically significant ($r = -0.05$ with $P = 0.6$).

CONCLUSION: In adolescents who had both obesity and T2DM and exercised at least 3 hours/week, increased exercise was associated with lower total PHQ 9 scores. Though our finding was not statistically significant, likely because of the small sample size, promoting physical activity for a minimum of 3 hours/ week may improve the depression symptoms in this group of patients.

Further studies with larger samples are needed to confirm our results.

EXERCISE-ASSOCIATED ALTERATIONS OF CIRCULATING MICRORNA IN PATIENTS WITH HEART FAILURE

HSU, C., YUAN, S.S., HSU, P.H., FU, T.C., HSU, W.C., WANG, J.S.

KEELUNG CHANG GUNG MEMORIAL HOSPITAL

INTRODUCTION: Emerging evidence suggests that circulating microRNA (miRNA) profiles can be affected by physical activities. High-intensity interval training (HIIT) is known to be associated with anti-cardiac fibrosis by modulating DNA methylation. The study identified miRNA profile changes after high-intensity interval training (HIIT) in patients with heart failure (HF).

METHODS: Among 40 included HF patients under guideline-directed medical treatment (GDMT), 20 were randomized to have additional 36 sessions of HIIT and 20 without HIIT were considered GDMT participants. The HIIT participants underwent supervised HIIT at alternating 80% and 40% of VO₂peak for 30-min in each session. Baseline information, and cardiopulmonary exercise test and 2-D echocardiography for left ventricular (LV) geometry. Next generation sequencing for human serum to identify circulating miRNA profiles before and after interventions in both groups of patients.

RESULTS: Compared to GDMT participants, a significant increase of VO₂peak as well as heart rate reserve (HRR) and a significant decrease of VE-VCO₂ slope after completing HIIT. Significantly decreased LV mass was observed in HIIT participants in comparison with patients underwent GDMT. HIIT-associated significant improvement of VO₂peak, oxygen uptake efficiency slope, and HRR were observed, but a significant decrease of VE-VCO₂. Significant changes of LV geometry were observed in HF patients underwent GDMT and HIIT. However, HIIT rather than GDMT resulted in a significant decrease of LV mass. There were 9 (miR-93-3p, miR-361-3p, miR-181a-5p, let-7e-5p, miR-106b-3p, hsa-miR-6765-3p, miR-421, miR-425-5p, miR-29a-3p) among 244 identified miRNAs expressed significantly different between GDMT and HIIT participants. The above circulating miRNAs were significantly involved in the muscle cell differentiation and cell survival after ingenuine pathway analysis.

CONCLUSION: The HIIT-induced physiological adaptations may be associated with circulating miRNA expressions. This epigenetic modulation could further contribute to the improvement of cardiac functions as well as aerobic fitness in HF patients.

MISSING LINK IN THE EARLY DETECTION OF A CONDITION LEADING TO RELATIVE ENERGY DEFICIENCY IN SPORT (REDS): METABOLITE LOGISTIC ADAPTATION OF SPIROERGOMETRY

KURUCSAI, G., NÉMETH, H.T., TAKÁCS, P.

DR. KURUCSAI MEDICAL CARE CENTRE

INTRODUCTION: The International Olympic Committee (IOC) firmly states the importance of recognising REDs. 90% of adolescent athletes will suffer at least one injury requiring invasive treatment by the age of 18. How can this be prevented? The answer is sought by many non-standardized methods, involving wearable technologies, but mostly only physiological limits are measured and maximized.

The care of athletes is teamwork, from which pathophysiological factors are thus left out. The answer is the measurement of energy expenditure (EE) during exercise, which detects excessive training, but also growth reserves and, in addition, characterises the athletes lifestyle outside training time.

METHODS: Metabolically oriented adaptation of spiroergometry (CPET) measures muscle biochemistry, i.e. if EE happens from free fatty acids (FFA) or carbohydrates (CHO).

With addition of the dynamics of by-product elimination and hormonal characteristics, competitive conditions can be modelled, as opposed to e.g. Vitamax or similar protocols where we can usually observe only a short peak performance.

56 active adolescent athletes were measured with CPET (Group A), of which 15 (Group A-OB) were members of the EFL US soccer team with BMI 30+. As pathophysiological controls, 77 amateur athletes (Group OB) BMI 30+ were selected.

Their training was divided into 20 min warm-up, 30 min individual gymnastics, for A and A-OB an additional 15 min intense exercise (on the field by portable devices), and 20 min recovery. Metabolite logistics were measured in stages, muscle oxygen saturation, by-products, insulin and adiponectin were also assessed.

RESULTS: Metabolite logistics: complete training, rate of FFA utilization: A=36.7+/-7.49%, A-OB=20.54+/-4.9%, OB=35.1+/-9.4%,

Intense 15min: rate of FFA A=19.36+/-9.98%, A-OB=3.68+/-1.83%, $p < 0.001$, load (in METS): A=6.84+/-1.31, A-OB=7.433+/-1.06 (NS).

Individual gymnastics rate of FFA utilization: A=38.4+/-6.95%, A-OB=22.4+/-6.1%, OB=33.9+/-7.4%, intensity (in METS): S=4.72+/-0.72, S-OB=5.06+/-1.19 OB=2.9+/-0.84 ($p < 0.05$ in OB vs. A, and in OB and A-OB). During training, the mean CHO utilization was A=106+/-25.9g, A-OB 145+/-31.3 g. (cf.: muscle glycogen stores: 400g CHO)

Mean adiponectin A-OB=4.1+/-0.4, A=7.8+/-1.9, OB= 4.05+/-0.7 $\mu\text{g/ml}$. By-product elimination time correlates with aerobic/anaerobic switching and with CHO/FFA utilization ratio. Blood pH decrease and VO_2

CONCLUSION: Pathophysiology should be introduced into performance diagnostics, at least in cases of insufficient development of the athlete, underperformance, periodically with advancing age. EE must be optimised to ensure genetically determined anthropometric development.

Assessment of by-product elimination helps to determine recovery time and emphasizes the importance of stretching. Biochemical results interpret the background of pathophysiology of REDs.

EFFECTS OF ACUTE AEROBIC EXERCISE AND WHOLE-BODY VIBRATION INTERVENTIONS ON NEUROCOGNITIVE PERFORMANCE AND BIOCHEMICAL INDICES IN POSTMENOPAUSAL WOMEN

TSAI, C., WANG, C.T., PAN, C.Y, TSENG, Y.T., CHEN, F.C.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Engaging in acute aerobic exercise has been shown to significantly enhance neurotransmitter activity and neurotrophic factor levels, thereby improving neural function in late middle-aged and older adults [1]. Similarly, a single session of whole-body vibration (WBV) has been reported to elicit acute hormonal responses, promote the release of neuroprotective growth factors, and activate the brain cortex [2]. Postmenopausal women tend to perform worse on cognitive interference tasks compared to their premenopausal counterparts [3]. However, no studies to date have examined the combined effects of aerobic exercise and resistance exercise performed on a WBV platform on inhibitory control in this population. Furthermore, the neurophysiological and molecular mechanisms underlying acute exercise-induced neuropsychological changes, as well as the interconnections among these factors, remain unclear. Therefore, this study aimed to evaluate the effects of moderate-intensity aerobic exercise (MIAE) and a combination of MIAE with isometric resistance exercise on a WBV platform (MIAE+WBV), in comparison to no exercise (NEI), on neurocognitive performance and molecular biomarkers in postmenopausal women.

METHODS: Sixty-six participants were randomly allocated into three groups: MIAE (n = 22), MIAE+WBV (n = 22), and NEI (n = 22). Neurocognitive performance was assessed using measures such as accuracy rate (AR), reaction time (RT), and brain event-related potential (ERP; P3 component) during the Stroop task. Serum levels of insulin-like growth factor 1 (IGF-1), norepinephrine (NE), osteocalcin (OC), and uncarboxylated OC (ucOC) were also evaluated before and after the intervention (or resting period for the NEI group).

RESULTS: No significant changes in RTs, ERP P3 latency, or P3 amplitude for the compatible condition were observed in either exercise group. However, both MIAE and MIAE+WBV groups showed significant increases in AR ($ps < .007$) and P3 amplitude ($ps < .003$) during the incompatible condition. Notably, only the MIAE+WBV group demonstrated significant improvements in AR for the compatible condition ($p = .007$). Both exercise groups exhibited elevated post-exercise levels of IGF-1 ($ps < .003$), NE ($ps < .008$), OC ($ps = .001$), and ucOC ($ps < .024$). Additionally, significant correlations were identified between NE and P3 amplitude changes in both exercise groups ($ps < .028$) and between ucOC and AR changes in the MIAE+WBV group ($p = .041$), underscoring the link between molecular and neurocognitive outcomes.

CONCLUSION: These results indicate that both MIAE and MIAE+WBV effectively improve neurocognitive function in postmenopausal women, with MIAE+WBV demonstrating greater efficacy compared to MIAE alone.

SMART CIRCUIT AEROBIC EXERCISE IMPROVES PLATELET MITOCHONDRIAL BIOENERGETIC EFFICIENCY IN SEDENTARY MEN

WANG, J., LIM, A.

CHANG GUNG UNIVERSITY

INTRODUCTION: Physical exercise paradoxically imposes platelet function according to responses dependent on exercise type/intensity/volume. This study aimed to compare the effects of smart circuit- and single-based exercise regimens on platelet mitochondrial bioenergetics at the same exercise intensity/volume in sedentary men.

METHODS: Fifty healthy sedentary men were randomly assigned to participate in a circuit exercise group (CIR, n=17, circuit exercise on bicycle, rowing, and elliptical ergometers at 60% heart rate reserve, 10 minutes of each exercise followed by 1 minute of rest) or cycling exercise group (CYC, n=17, three sets of cycling at 60% heart rate reserve for 10 minutes followed by 1-minute rest), or to a control group (CON, n=16) that did not receive exercise intervention. The smart training programs on CIR and CYC were conducted using real-time heart rate and workload feedback. Systemic aerobic capacity and platelet mitochondrial oxidative phosphorylation (OXPHOS) and electron transport chain (ETC) were measured through automatic gas analysis and high-resolution respirometry, respectively.

RESULTS: Both CIR and CYC significantly improved VO₂max by 21% and 28%, respectively. Although both CIR and CYC significantly increased platelet OXPHOS and ETC capacities, CIR revealed higher platelet ETC–OXPHOS excess capacity than CYC. Moreover, training-induced ΔVO₂max was positively correlated with ΔETC ($r=0.34$, $P=0.028$).

CONCLUSION: Smart aerobic exercise improves cardiorespiratory fitness and platelet mitochondrial OXPHOS capacity. Moreover, CIR is superior to CYC in improving mitochondrial bioenergetics efficiency.

THE ROLE OF PHYSICAL EXERCISE ON HIPPOCAMPAL VOLUME IN DEPRESSIVE SYMPTOMS: A SYSTEMATIC REVIEW AND META-ANALYSIS

SUHRKAMP, J., JAVELLE, F., WÄHLEN, L., DONATH, L., BLOCH, W.

EXERCISE TRAINING AND SPORT INFORMATICS

INTRODUCTION: Hippocampal atrophy is a frequently observed structural impairment in depressive disorders [1]. The positive impact of physical exercise on hippocampal volume could be shown in both animal and human models. Still, heterogeneous results can be observed regarding exercise within the context of depressive disorders [2]. Accordingly, this systematic review and meta-analysis aim to evaluate whether exercise inhibits hippocampal decline in animal and human depression models or could even enhance hippocampal volume.

METHODS: We searched Web of Science, SportDiscus, PubMed (MEDLINE), PsycINFO, Google Scholar, and Cochrane until the 30th of March 2023, and conducted independent meta-analyses for animal and human studies (combining results on cellular composition and total volume). Both meta-analyses were based on a random-effect model. All data is on open access (osf.io/mdvqz). Inclusion decisions were based on the following PICOS criteria: Participants with depressive symptoms or any diagnosis of depression, intervention of any type, comparison of hippocampal volume pre- and post-intervention, outcome focusing on volume changes, study design peer-reviewed studies in English.

RESULTS: Out of 1275 identified, 789 were screened by title and abstract. Forty-nine studies in full-text screening were excluded based on the wrong publication type (1 animal), missing depression assessment (18 human/6 animal), missing intervention (11 human) or volume assessment (15 human/7 animals). The review included nine studies (four animal and five human). The meta-analysis for the animal model, which included male rodents ($k=5$, $n=87$ [45 intervention, 42 control]) showed a large but insignificant ($p=.081$) average effect for hippocampal growth (Hedges' $g=1.13$, 95% Confidence Interval (CI) = -0.22 to 2.48) and exhibited extreme heterogeneity (Predicted Interval (PI)=-2.53 to 4.78, $I^2=67\%$, $\tau^2=1.052$). The meta-analysis for the human model ($k=5$, $n=249$ [126 intervention, 123 control]) showed a very small and non-significant average effect ($g=0.08$, 95% CI -0.19 to 0.36, $p=.435$) with substantial heterogeneity (PI=-0.69 to 0.86, $I^2=0\%$, $\tau^2=0.043$). Participants did either aerobic, aerobic and resistance training or yoga for 20 to 60 min, 3-7 times a week with low to moderate intensity. No moderator analyses were conducted due to sample size and heterogeneity limitations. None of the studies met all risk of bias criteria, indicating potential bias.

CONCLUSION: Our systematic review and meta-analysis found no conclusive evidence that physical exercise affects hippocampal volume in animals and humans with depressive symptoms. Despite larger average effects in animal studies compared to human studies, heterogeneity was substantial in both. Further research is needed, including longer intervention durations and varied intensity settings.

UPPER LIMB FUNCTION IS THE IMPORTANT INDICATOR OF SARCOPENIA IN FEMALE OLDER ADULTS

LIN, L., TSAI, C.K., LO, Y.H., HUNG, C.Y.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: The physical activity of older people decreases with age, which is likely to cause the loss of muscle mass, muscle strength, and functional fitness. While prior research on sarcopenia has predominantly examined the relationship between grip strength and lower limb functional movements in older adults, relatively few studies have focused on the

physical function of the upper limbs. This study aimed to assess upper limb reaction and agility among older women with varying levels of sarcopenia risk.

METHODS: A total of 98 community-dwelling females aged 65 years and older (mean age: 74.38 ± 6.95 years; BMI: 23.28 ± 3.98 kg/m²) were categorized into four groups based on the risk of sarcopenia. This classification was determined according to the skeletal muscle index (SMI), handgrip strength, and gait speed cut-off points outlined by the Asian Working Group for Sarcopenia 2 (AWGS2). The groups were defined as follows: (1) no risk group (NR, n = 29), (2) low sarcopenia risk group (LR, n = 31), (3) medium sarcopenia risk group (MR, n = 22), and (4) high sarcopenia risk group (HR, n = 28). Upper extremity muscle mass and endurance (30-second arm curl test), upper extremity flexibility (back scratch), dynamic balance (8-foot up-and-go), static balance (Clinical Test of Sensory Integration of Balance; CTSIB), reaction time (whole-body reaction) were evaluated. One-way ANCOVA was conducted to analyze differences among the groups. Pearson's product-moment correlation was also employed to determine the correlation between muscle mass, functional fitness, and agility.

RESULTS: The skeletal muscle index (SMI) and upper extremity muscle mass demonstrated significant positive correlations with handgrip strength, 30-second arm curl performance, and closed eyes static balance ($p < .05$). The no-risk (NR) group exhibited significantly better handgrip strength compared to the low-risk (LR, 23.3% lower), medium-risk (MR, 45.7% lower), and high-risk (HR, 67.1% lower) groups ($p < .001$). Additionally, the LR group displayed stronger grip strength than the MR group (27.7% lower) and the HR group (46.5% lower) ($p < .001$). In static balance (closed-eye standing on a cushion), the NR group achieved a significantly higher stability index (3.31) compared to the MR group (2.67) and the HR group (2.39) ($p < .05$). Regarding whole-body reaction time, the NR (529.32 ms), LR (435.20 ms), and MR (465.14 ms) groups were significantly faster than the HR group (743.50 ms). In dynamic balance, the NR group (6.23 seconds), LR group (5.95 seconds), and MR group (5.93 seconds) were significantly faster than the HR group (9.07 seconds) ($p < .05$). The upper limb flexibility and muscular endurance showed no significant differences among the four groups. Moreover, SMI was influenced by 37.7% through variables including back scratch performance, 30-second arm curl, and handgrip strength.

CONCLUSION: Based on the results of this study, older adults with low muscle mass do not experience influenced functional fitness unless their grip strength is significantly low. Especially in older women, the risk of sarcopenia increases with a decline in upper limb strength, further driving the occurrence of multiple sarcopenia-related symptoms. This highlights the importance of maintaining or increasing upper limb strength, a key factor in maintaining good physical function with high-risk sarcopenia. It is recommended that future studies investigate the impact of sarcopenia on upper limb functional movements in older adults of different genders.

FACTORS ASSOCIATED WITH INSUFFICIENT OUTDOOR PLAY AND SPORTS PARTICIPATION AMONG CHINESE CHILDREN AGED 6-10 YEARS: EVIDENCE FROM A TWO-WAVE SURVEY

YE, S., WU, Y., FAN, Q., QIAN, H., CHEN, L.

JIAXING UNIVERSITY

INTRODUCTION: This study investigated the risk factors associated with insufficient engagement of Chinese early school-aged children in outdoor activities, including play and sports.

METHODS: Data were gathered from two-wave parent-proxy surveys. The analysis involved 1612 children (46.15% girls; mean age = 7.83 years) who had participated in outdoor activities. Responses were analyzed using Generalized Estimating Equations to identify relevant correlates impacting childrens outdoor play or outdoor sports. Children were assessed on their outdoor activities' levels, and variables were analyzed for their impact on these levels.

RESULTS: Maternal outdoor activity (<1 hour/day) and less clear requirements for outdoor play are correlated with children's outdoor activity time (<2 hour/day) ($p < 0.05$). The number of outdoor playfields also significantly associated with insufficient outdoor activity, particularly on weekends ($p < 0.05$). For outdoor sports (<1 hour/day), the male gender of the child was a protective factor (OR = 0.33, $p < 0.001$), while paternal outdoor activity time (<1 hour/day) and unclear outdoor activity requirements were risk factors ($p < 0.01$).

CONCLUSION: The risk factors of insufficient engagement of Chinese early school-aged children in outdoor pursuits were included the lack of time parents spend on outdoor activities, their unclear requirements, and the limited availability of outdoor playfields. Specifically, mothers outdoor activities time is linked to childrens outdoor play, while the male gender of the child and fathers' outdoor activities are associated with children's outdoor sports participation.

THE EFFECTS OF A SMARTPHONE-BASED SELF-CARE APPLICATION ON LOWER LIMB MUSCLE TIGHTNESS IN PHYSICALLY ACTIVE INDIVIDUALS

CHIU, Y., CHIU, C., CHOU, L., TSAI, Y.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Muscle tightness is a common yet often overlooked condition that can significantly affect sports performance and daily activities while increasing the risk of injury. Excessive muscle tension may lead to a diminished range of motion in joints, altering biomechanical function during physical activities and consequently increasing the risk of sports-

related injuries. For lower limb muscles, muscle tightness can impose additional stress on other joints within the kinetic chain, potentially leading to chronic pain conditions. Given the high prevalence of muscle tightness and its associated adverse effects, the development of effective preventive and therapeutic strategies is of growing importance.

With the rapid advancement of technology, smartphones have become increasingly integrated into healthcare, offering significant benefits. This technological evolution has supplemented traditional rehabilitation methods and facilitated personalized, continuous care and early intervention strategies, potentially improving long-term health outcomes. This study aims to evaluate the efficacy of a smartphone-based self-care application in relieving lower limb muscle tightness among physically active individuals.

METHODS: Fifteen physically active participants (11 males, 4 females; mean age = 21.5 ± 3.3 years) were recruited for this study. A self-care application was developed using Android Studio (Iguana | 2023.2.1) and included instructional modules on basic self-myofascial release techniques and stretching exercises targeting the lower limbs. Outcome measures were assessed before the initiation of the home program (pre-test) and after the four-week intervention period (post-test). Key measurements included changes in range of motion (ROM), performance on the agility T-test, and scores on a visual analog pain scale. Paired t-tests were conducted using SPSS 17.0, with statistical significance set at $\alpha = 0.05$.

RESULTS: Significant ROM improvements were observed in hip flexion (Right: pre-test $99.1 \pm 14.2^\circ$ vs. post-test $113.5 \pm 6.9^\circ$, $p = 0.001$; Left: pre-test $89.9 \pm 26.1^\circ$ vs. post-test $107.3 \pm 9.0^\circ$, $p = 0.016$) and ankle plantarflexion (Right: pre-test $56.4 \pm 11.9^\circ$ vs. post-test $63.7 \pm 7.9^\circ$, $p = 0.003$; Left: pre-test $58.9 \pm 10.5^\circ$ vs. post-test $63.7 \pm 8.9^\circ$, $p = 0.007$). Agility also improved significantly (T-test: pre-test 4.9 ± 2.4 sec vs. post-test 3.2 ± 2.7 sec, $p = 0.001$), as did pain scores (pre-test 3.2 ± 2.7 vs. post-test 2.1 ± 2.7 , $p = 0.007$). These findings suggest smartphone applications can effectively support home-based interventions for muscle tightness.

CONCLUSION: This study demonstrates that a smartphone-based self-care application can improve ROM, agility, and pain perception in physically active individuals. These findings highlight the potential clinical applications of smartphone-assisted interventions in addressing lower limb muscle tightness. Future research should explore long-term effects and broader applications in diverse populations.

DO FOAM ROLLERS COUNTERACT THE FATIGUE OF NORDIC HAMSTRING EXERCISE?

COSKUN, R., BURGER, C., FISCHER, J., SEGUEL, J.M., ARABACI, R., KONRAD, A.

EDUCATION SCIENCE

INTRODUCTION: The Nordic Hamstring Exercise (NHE) is an effective method for strengthening hamstring muscles and reducing the risk of injury [1]. The acute fatigue and delayed onset muscle soreness (DOMS) from NHE emphasize the need for effective recovery strategies. Foam rolling (FR) is a common and simple method used that might help speed up recovery [2]. Hence, this study aimed to evaluate the potential recovery effects of FR following NHE on muscle stiffness, pain pressure threshold (PPT), flexibility, countermovement jump (CMJ), and maximal voluntary isometric contraction (MVIC) immediately and 48 h after the FR application.

METHODS: Thirty-two physically active males (aged 18–30 years; mean $\pm$ SD: 23.2 ± 3.5 years, height: 179 ± 6 cm, weight: 75.3 ± 11.6 kg) were randomly assigned to either an FR group ($n = 16$) or a control group (CON, $n = 16$) group. Measurements were taken at three time points: pre-test, post-test_0h (immediately after exercise), and post-test_48h (48 hours after exercise). Participants completed 3 sets of 10 repetitions of the NHE before undergoing the recovery interventions. The intervention group performed 2 sets of 60 seconds of foam rolling on the hamstring muscles (both legs, totaling 240 seconds), whereas the CON group remained seated on a chair for the same duration. The evaluated variables included muscle stiffness, flexibility, pain pressure threshold, jump performance, and maximal isometric contraction peak power.

RESULTS: FR enhanced acute flexibility after NHE (12.7%, $p < 0.001$) and helped to maintain flexibility over 48 hours, compared with the CON group. However, no significant differences were observed between the FR and control groups for muscle stiffness, PPT, CMJ, or MVIC, both acutely and at 48 hours ($p > 0.05$).

CONCLUSION: Our hypotheses were partially supported in this study. FR can help to speed up recovery following NHE as well as can acutely increase flexibility [3]. However, its effects on muscle stiffness, pain tolerance, and performance indicators are limited immediately after and 48 hours following NHE. Future studies need to further investigate the acute benefits of FR and its effectiveness across diverse populations and different recovery conditions.

PREVALENCE OF CHRONIC NONCOMMUNICABLE DISEASES AND MODIFIABLE RISK FACTORS IN ELDERLY WOMEN

BRITO, L., CUNHA, T., BRUM, P.C.

UNIVERSIDADE DE SÃO PAULO

INTRODUCTION: Chronic non-communicable diseases (NCDs) are among the leading causes of global morbidity and mortality, exacerbated by modifiable risk factors such as physical inactivity, smoking, and inadequate nutrition. Regular physical activity is recognized for mitigating the effects of these conditions; however, its relationship with comorbidity management in specific populations, such as elderly women, remains underexplored. This study aimed to investigate the prevalence of NCDs and their association with modifiable risk factors, such as smoking and obesity, in elderly women engaged in supervised physical activities.

METHODS: A cross-sectional study was conducted with 23 elderly women from southern Brazil who had been regularly participating in physical activities, including functional gymnastics and walking, over the past seven years. Individual and

collective data were collected on smoking, medication use, and health-related physical fitness, including flexibility, muscle strength, body composition, and cardiorespiratory fitness. Additionally, cardiovascular disease (CVD) risk factors, such as hypertension, hypercholesterolemia, diabetes mellitus, and obesity, were assessed. The study outcomes included the presence of CVD risk factors and the number of risk factors per individual (0, 1, 2, or ≥ 3 risk factors). Logistic and multinomial regression analyses were performed, with a statistical significance level set at 5%.

RESULTS: The participants had a mean age of 66.5 ± 8.4 years. Among them, 21.7% exhibited values indicative of high cardiovascular risk. The presence of 1, 2, or ≥ 3 NCD risk factors was significantly associated with an increase in abdominal circumference (AC). Former smokers showed a higher prevalence of hypertensive blood pressure levels ($p < 0.05$), while obese women had a significant correlation with increased AC ($p < 0.05$). Findings also indicated that regular physical activity was associated with lower continuous medication use among overweight elderly women with NCDs.

CONCLUSION: The results reinforce the importance of weight control and smoking cessation in reducing cardiovascular risk among elderly women, particularly those engaged in physical activity. Furthermore, the significant association between abdominal circumference and cardiovascular risk factors underscores the need for early identification and intervention to prevent adverse health outcomes. The association between regular exercise and favorable clinical outcomes, such as reduced medication use and hospitalizations, highlights the protective role of physical activity in managing NCDs. These findings have implications for clinical practice and suggest the need for personalized prevention and rehabilitation strategies in this population.

THE INFLUENCE OF TRAINING AND COMPETITION ON SLEEP BEHAVIOUR OF SOCCER REFEREES

LASTELLA, M., MILLER, D.J., VINCENT, G.E., ELSWORTHY, N., SCANLAN, A.T., DUFFIELD, R.

CENTRAL QUEENSLAND UNIVERSITY

INTRODUCTION: The aims of the present study were to (1) quantify the in-season sleep behaviours of soccer referees and (2) compare sleep behaviours between nights before training, before matches and after matches.

METHODS: Fourteen professional soccer referees (mean $\pm$ SD; age 34 ± 4 years; sex: 11 males, 3 females) participated in this observational study. Referees' sleep behaviours were examined using self-report sleep diaries and wrist activity monitors for 31 nights during the 2018-2019 A-league season. Separate linear mixed models were conducted to assess the differences in sleep behaviours between nights before training, before matches and after matches.

RESULTS: Referees did not obtain the recommended 7–9 hours of sleep on 70% of all nights before training, 45% of all nights before matches and 72% of all nights following matches. Referees went to bed later, spent less time in bed, and slept significantly less post-matches compared to pre-training and pre-match nights ($p < 0.05$). No differences in sleep quality were apparent between nights as indicated by sleep efficiency, sleep onset latency, wake in sleep and movement fragmentation index.

CONCLUSION: The poor sleep behaviours of referees may negatively affect their physical and cognitive abilities, and thus performance during matches. The findings related to poor sleep behaviours highlight the importance of implementing monitoring systems to understand the sleep behaviours of referees, with further research encouraged to ascertain the efficacy of various sleep hygiene practices to optimise sleep in this population.

THE RELATIONSHIP BETWEEN CHANGES IN VARIOUS PHYSICAL FITNESS LEVELS AND CHANGES IN THE SPORT COMPETENCE AMONG JUNIOR HIGH SCHOOL STUDENTS AS THEY ADVANCE TO THE NEXT GRADE

TERADA, K., NAKAMURA, R., KANEKO, R., OBATA, O., NAKATANI, T., UTSUMI, M., MIYAI, N.

TENRI UNIVERSITY

INTRODUCTION: The sport competence is confidence in exercise and the ability to participate in sports independently (Inoue et al., 2016; Obata et al., 2015). There are reports that a relationship exists between some types of physical fitness and sport competence in junior high school students. In this study, we examined whether changes in physical fitness and sport competence over time are related.

METHODS: All first and second grade students (111 students) at a certain junior high school were measured for rebound jump (RJ) index, vertical jump, and grip strength (left and right) at the same time over a two-year period. RJ index was obtained from the ground contact times and jump heights. At the same time, the Sport Competence Scale (Okazawa et al., 1996) was used to score three items: "perceived of physical competence," "feeling of control," and "peer and teacher acceptance," and these were then summed to calculate a "sport competence" score. The changes in the subjects various physical fitness and sport competence over the two-year period were classified into "improvement" and "unchanged/decline," and cross-tabulated, and a chi-square test was used to examine whether there were differences in the proportions of the subjects.

RESULTS: As a result, no significant differences were found in the proportions of any items for the RJ index and sport competence. For vertical jump and grip strength (right), significant differences were only observed in the subcategory "perceived of physical competence." Similarly, for grip strength (left), differences were observed in all items, including "sport competence," except for "peer and teacher acceptance."

CONCLUSION: These results suggest that changes in vertical jump and grip strength, which primarily reflect muscle strength, are associated with changes in some items of sport competence, but that the RJ index, whose value is influenced not only by muscle strength but also by complex physical functions such as the stretch-shortening cycle, is not

associated with sport competence. Therefore, it can be inferred that improving muscle strength may be necessary for junior high school students to feel an increase in their sense of sport competence after one year.

CAN LONG-TERM PARTICIPATION IN COMMUNITY-BASED EXERCISE MAINTAIN OR IMPROVE COGNITIVE SCORES IN OLDER WOMEN?

NAKAGAICHI, M., UCHIDA, R., ANAN, Y.

HEALTH AND SPORTS SCIENCES

INTRODUCTION: The authors focused on the effectiveness of square stepping exercise (SSE) and fostered resident-led exercise salons for older adults practicing SSE. However, the longitudinal effect of long-term voluntary activities in exercise salons practicing SSE on cognitive function has not yet been examined. Therefore, in this study, we examined longitudinal changes in the cognitive function of older women living in the community who had continuously participated in an exercise salon for older adults practicing SSE for 3–5 years.

METHODS: This study included 228 older women living in the community who had continuously participated in an exercise salon for older adults for 3–5 years, where SSE was practiced once weekly. The Five Cognitive Functions test, a group cognitive test for older adults, was administered as a cognitive function test.

RESULTS: Both the young-old (aged ≥ 65 years; 83 participants) and old-old (aged ≥ 75 years; 145 participants) groups showed significant improvement in memory scores, verbal fluency scores, thinking scores, and overall scores after 3–5 years of salon participation. In addition, the rate of improvement in memory score and overall score was higher in the young-old group than in the old-old group. The high (41 participants) and low (36 participants) cognitive score groups at the start of salon participation also showed improvement in memory score, thinking score, and overall score. In addition, the low-score group had a higher rate of improvement in the attention segmentation function score, thinking score, and overall score.

CONCLUSION: SSE is an exercise program implemented in Japan to reduce the need for long-term care. Although the effect of SSE on cognitive function within a short period during salon development has been verified, the longitudinal effect of long-term voluntary activities in exercise salons practicing SSE on cognitive function has not yet been examined. Therefore, we examined longitudinal changes in the cognitive function of older women who had continuously participated in an exercise salon for older adults practicing SSE for 3–5 years. The results showed considerable improvement in memory scores, verbal fluency scores, thinking scores, and overall scores after 3–5 years of salon participation. Thus, older adults can prevent and improve age-related decline in cognitive function by voluntarily practicing SSE for 3–5 years.

EFFECTS OF DIFFERENT TYPES OF EXERCISE INTERVENTIONS ON INSULIN RESISTANCE IN PATIENTS WITH TYPE2 DIABETES MELLITUS: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

LIU, H., ZHAO, P.

KOREA UNIVERSITY

INTRODUCTION: The objective of this meta-analysis is to evaluate and compare the effectiveness of different types of exercise interventions in improving insulin resistance (IR) in patients with type 2 diabetes mellitus (T2DM).

METHODS: A comprehensive systematic search was conducted across multiple databases, including PubMed, CINAHL, Embase, the Cochrane Library, Web of Science, SPORTDiscus, and Scopus. Randomized controlled trials (RCTs) evaluating the effects of exercise interventions on IR in T2DM patients were included. The search period extended from the inception of each database through October 15, 2024. The methodological quality of the trials was assessed using the Cochrane risk of bias tool. A network meta-analysis (NMA) was performed to compare the effects of various exercise modalities, including aerobic exercise (AE), resistance training (RT), combined exercise (CE), mind-body exercise (MBE), and high-intensity interval training (HIIT).

RESULTS: The analysis included 19 randomized controlled trials (RCTs), involving a total of 1,327 subjects. The NMA revealed that HIIT, CE and AE led to significant improvements in IR. Specifically, HIIT demonstrated the most pronounced improvement in the homeostasis model assessment of insulin resistance (HOMA-IR) with a SUCRA of 92.3%, followed by CE (70.4%) and AE (60%) among patients with T2DM.

CONCLUSION: The results of this study indicate that HIIT is the most effective intervention for improving IR in patients with T2DM. CE and AE also demonstrated significant efficacy, while RT and MBE showed no significant effects. However, further research is needed to validate these findings as more high-quality studies emerge.

THE ASSOCIATION BETWEEN PHYSICAL ACTIVITY, SOCIAL JET LAG AND PREMENSTRUAL SYMPTOMS IN FEMALE ADULTS

CHEN, H., HATSUKARI, A., SAWAMURA, S., NISHIDA, M.

WASEDA UNIVERSITY

INTRODUCTION: Physical activity (PA) reduces sleep complaints and Premenstrual symptoms (PMS)-related discomfort while enhancing mood and sleep quality [1,2]. Social jet lag (SJL), or weekday-weekend sleep discrepancies, can cause fatigue [3]. This study examines the relationship between PA, SJL, and PMS in females, exploring how PA and SJL contribute to PMS to provide insights into improving female health.

METHODS: A total of 344 females aged 20–45 were included, excluding those with severe sleep disorders, drug use, smoking, or pregnancy. PA (MET-min/week), including intensity levels (vigorous, moderate, and walking), was assessed via International Physical Activity Questionnaire (IPAQ). SJL was measured using Munich ChronoType Questionnaire (MCTQ), which tracks primary sleep times, wake times, and discrepancies between work and free days. PMS was evaluated with Daily Record of Severity of Problems (DRSP), a validated tool assessing a wide range of physical, emotional, and behavioral symptoms. Pearson's correlation was used to examine the relationships among PA, SJL, and DRSP, with data analysis conducted in Excel. The statistical significance level was set at $\alpha = 0.05$.

RESULTS: Participants (mean age 37 ± 6 years) had an average total PA of 714 ± 1761 MET-min/week, including vigorous (8 METs), moderate (4 METs), and walking (3.3 METs). PA levels varied widely among individuals, with some engaging in high-intensity exercise while others reported lower levels of daily movement. The mean SJL, defined as the difference in mid-sleep time between workdays and free days, was 3 ± 7 hours, indicating substantial variability in sleep patterns across participants. PMS severity, measured using DRSP scores, had an average score of 20 ± 9 out of a possible 48, reflecting a range of mild to severe symptoms reported by participants. No significant associations were observed between SJL and PA ($r = -0.016$, $p = 0.763$), PA and DRSP ($r = -0.035$, $p = 0.515$), or SJL and DRSP ($r = 0.043$, $p = 0.430$).

CONCLUSION: This study did not find statistically significant associations between PA, SJL, and PMS severity. Although the results did not indicate clear relationships, maintaining regular sleep patterns and engaging in PA remain important for overall well-being. The variability in sleep behaviors, PA patterns, or the subjective nature of PMS symptoms may have influenced the findings. Future studies with larger sample sizes or different methodologies may help clarify these potential links.

EFFECTS OF HOME-BASED PROGRESSIVE ELASTIC BAND RESISTANCE EXERCISE ON PHYSICAL FITNESS FOR INDIVIDUALS WITH CHRONIC KIDNEY DISEASE

GUO, L., CHIANG, A., HSU, M.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Patients with chronic kidney disease (CKD) are often in a state of catabolism, oxidative stress, and protein loss for a long time, leading to reduced muscle synthesis, uremic toxin accumulation, and impaired physical function and activity levels, which may increase the risk of mortality [1]. Progressive resistance exercise training has been shown to improve cardiorespiratory function, quality of life, and physical performance. The study aimed to investigate the effects of progressive resistance exercise home-based intervention in patients with late-stage CKD.

METHODS: Thirty-seven patients with CKD stages IIIb to V were randomized to the intervention and control groups. The intervention group (IG) received 12 weeks of home-based progressive resistance exercise using elastic bands, with resistance adjustments made during the follow-up visit in the fourth and eighth weeks. The control group (CG) maintained regular nursing care and nutritional education. Data on demographics, physical fitness (body composition, muscle strength, functional performance), nutritional assessment, and physiological indicators were collected pre- and post-intervention. Statistical analyses of within-group and between-groups were conducted based on data normality. A statistical level of $p < 0.05$ was accepted.

RESULTS: 37 participants completed the study (IG: $n=20$; CG: $n=17$) with similar baseline characteristics. At baseline, approximately 50% of participants in both groups were classified as stage IIIb (IG: 55%; CG: 47%). Both groups classified the primary intensity level of activity as mild or lower. The three most prevalent chronic conditions observed in both groups were diabetes, hypertension, and urinary system diseases. The sit-to-stand 30-second test (STS) and the six-minute walk test (6WMT) exhibited significant differences within the intervention group (STS pre/post: 14.1 ± 7.2 / 16.6 ± 7.4 times; 6WMT pre/post: 372.3 ± 107.0 / 438.9 ± 77.5 m), while the control group showed no change. The intervention group experienced a noteworthy decline in serum total triglycerides after home-based exercise (median (IQR): pre/post: 207.0 (106.0~275.2) / 160.5 (102.2~164.4) mg/dL), whereas the control group exhibited an increase (pre/post: 177.8 (84.0~235.8) / 318.1 (94.4~256.0) mg/dL). The two groups had no significant differences in blood glucose, glycated hemoglobin, renal indicators, or body composition.

CONCLUSION: CKD patients undertaking home-based progressive resistance exercises help improve body weight and triglycerides while maintaining or enhancing physical performance, such as the speed of sitting to standing. This home-based exercise method is low-cost, easy to carry, and space-efficient, making it a feasible option for CKD patients to initiate exercise in home situations.

THE EFFECT OF RESPIRATORY MUSCLE ENDURANCE TRAINING ON EXERCISE TOLERANCE IN PATIENTS WITH SPINAL CORD OR BRAIN INJURY: A PILOT STUDY

ANGOLANO, A., VILLA, D., GARGIULO, L., MARCORA, S.M.

UNIVERSITY OF BOLOGNA

INTRODUCTION: The aim of this pilot study was to investigate the effects of respiratory muscle endurance training (RMET) using SpiroTiger® on stabilized spinal cord or brain-injured patients. The hypotheses were that RMET would improve exercise tolerance, lung function, and quality of life in these patients when used as an adjunct to a standard physiotherapy program.

METHODS: Four adult male patients with spinal cord or brain injuries were recruited for this pilot study. In addition to their regular physiotherapy sessions, participants performed twelve RMET sessions over a period of 3 to 5 weeks. These additional training sessions were administered by a kinesiologist using the SpiroTiger® equipment.

A time-to-exhaustion (TTE) test on the arm cycle ergometer was performed before and after the RMET. During this test, heart rate (HR) was measured with an HR monitor, and dyspnea and arm effort were rated using specific instructions and the category-ratio 10 rating of perceived exertion (RPE) scales. These responses during the TTE test were analyzed using the Group Isotime method described by Nicolò et al. (2019) and correspond to the values recorded at the third minute.

Additionally, health-related quality of life (SF-36) and respiratory function (spirometry) were assessed before and after RMET. Due to the small sample size, data are presented as median (range), and pre-test to post-test differences were tested using a one-tailed Wilcoxon test for paired samples. Given the pilot nature of this study and its small sample size, trends were considered significant at $p < 0.10$.

RESULTS: All four patients completed the study. There was a trend ($p = 0.063$) toward a significant improvement in TTE, which increased from 363 (395) to 580 (820) seconds. This improvement in TTE was accompanied by reductions in HR [pre-test 135 (28) post-test 127 (11) beats/min, $p = 0.063$], RPE-Dyspnea [pre-test 6 (2) post test 4.5 (4) a.u., $p = 0.087$], and RPE-Arm Effort [pre-test 7 (1) post-test 4.5 (6) a.u. post-test, $p = 0.091$]. Additionally, there was a trend for a significant increase in forced vital capacity [pre-test 4.41 (0.710) post-test 4.5 (0.9) liters, $p = 0.091$]. No significant trends were observed for SF-36 scales or other spirometric variables.

CONCLUSION: This brief RMET program was well tolerated by this small group of patients. The improvements in exercise tolerance, as observed using both objective (HR, TTE) and subjective (RPE-Dyspnea and RPE-Arm Effort) metrics, suggest that this type of respiratory training may be a beneficial adjunct to standard physiotherapy in patients with stabilized spinal cord or brain injury. Future randomized controlled studies with a larger group of patients are required to confirm the findings of this pilot study.

EFFECTS OF HIGH-INTENSITY FUNCTIONAL TRAINING ON BODY COMPOSITION AND GREATER RESPONSIVENESS IN REDUCING DIASTOLIC BLOOD PRESSURE AND RESTING HEART RATE IN SEDENTARY BOYS

LEITE, N., MORAES-JUNIOR, F.B., TADIOTTO, M.C., BRAND, C., MOTA, J., PEREIRA, B., ROSÁRIO, R.

FEDERAL UNIVERSITY OF PARANÁ AND UNIVERSITY OF PORTO

INTRODUCTION: Anthropometric indicators, body composition (BC), cardiorespiratory fitness (CRF), and blood pressure (BP) are clinical and non-invasive health parameters in the pediatric population. These parameters are used to diagnose children and adolescents at cardiometabolic risk and to monitor therapeutic responses, especially early changes in BP in boys. The aim of this study was to analyze the effects and responsiveness of BC, CRF, and BP in sedentary boys after 12 weeks of high-intensity functional training (HIFT).

METHODS: 26 boys participated in the study, aged 12 to 16 years, distributed into the HIFT group ($n=13$) and the control group (CG, $n=13$). Body mass (BM), height, waist circumference (WC), waist-to-height ratio (WHtR), fat mass (FM), fat-free mass (FFM), muscle-to-fat ratio (MFR), maximal oxygen uptake relative ($VO_{2ml/kg/min}$), absolute ($VO_{2l/min}$), and resting heart rate (HR_{rest}) were assessed. The HIFT was performed without equipment, using body weight as an overload, for approximately 35 minutes per session, three times per week, for 12 weeks of intervention. The CG participants maintained their usual physical activity during the study period. ANOVA was used for comparisons at baseline and at 12 weeks ($p<0.05$), and the effect size (ES) was calculated to compare the magnitude of the effect of the intervention and the prevalence of responders.

RESULTS: No significant differences were found between the groups at baseline, except for higher FFM in the CG ($p=0.006$). After 12 weeks, the HIFT showed a trivial reduction in FM ($p=0.033$, $ES=-0.16$) and possibly beneficial reductions in %FM ($p=0.011$, $ES=-0.24$), DBP ($p=0.367$, $ES=-0.31$), and HR_{rest} ($p=0.405$, $ES=-0.34$). In addition to trivial increases in height ($p=0.022$, $ES=0.05$), FFM ($p=0.001$, $ES=0.16$) and possibly beneficial increases in MFR ($p=0.002$, $ES=0.23$) and VO_{2peak}

relative ($p=0.313$, $ES=0.21$) were observed. The CG increased only in height ($p=0.005$, $ES=0.05$) and MFR ($p=0.023$, $ES=0.21$). The prevalence of responders indicated that adolescents participating in HIFT were more responsive in reducing DBP (responders=69.2 vs. 30.8%, $\beta=0.385$, $p=0.034$) and HRrest (responders=61.5 vs. 23.1%, $\beta=0.385$, $p=0.031$) than those in the CG.

CONCLUSION: Regular physical activity provided health benefits in sedentary boys, but HIFT did not result in a significant increase in CRF, probably due to the type of muscle overload. We conclude that adolescents who participated in the HIFT presented a significant improvement in body composition and greater responsiveness in reducing diastolic blood pressure. It should be noted that both health problems have increased in adolescents and can be controlled by changes in daily life such as regular physical exercise.

THE EFFECTS OF RESISTANCE TRAINING ON METABOLIC PARAMETERS, MUSCLE STRENGTH, AND PHYSICAL FUNCTION AMONG INDIVIDUALS WITH TYPE-2 DIABETES MELLITUS

SOOKAN, T., MTSHALI, N.

UNIVERSITY OF KWAZULU NATAL

INTRODUCTION: Type-2 diabetes mellitus (T2DM) is a global epidemic that is on the rise due to lifestyle changes. Resistance training has the potential to improve health outcomes for individuals with T2DM. There are a limited number of studies that have been done on individuals with T2DM in developing countries, like South Africa, to evaluate the effects of resistance training among individuals with T2DM. The study aimed to determine the effect of a 12-week resistance training programme on metabolic parameters, muscle strength, and physical function among individuals with T2DM.

METHODS: A total of forty-five ($n=45$) untrained participants with T2DM aged 67.09 (SD ± 10.58) participated in the study. Participants were randomly assigned to either the control group ($n=23$) or the experimental group ($n=22$). The experimental group participated in a 12-week resistance training and nutrition education programme, whilst the control group participated in a nutrition education programme. Pre- and post-measurements included glycosylated haemoglobin (HbA1c); fasting blood glucose; lipid profile; muscle strength measured using 1 RM on the pressure air biofeedback (PAB®); and physical function measured using the timed up-and-go test (TUG).

RESULTS: The intervention group demonstrated a significant decrease in HbA1c (8.58%-7.84%; $p<0.01$) mmol/L, fasting glucose 8.83 (SD ± 4.07) mmol/L to 7.84 (SD ± 3.22); $p<0.05$) mmol/L and triglycerides (333.50 mg/L to 258.64 mg/L; $p<0.05$) levels post-intervention compared to the control group. Both upper and lower body grip strength increased from 35.11 (SD ± 4.75) kg pre-intervention to 42.88 (SD ± 174.95) kg post-intervention. The TUG test was significantly (13.56s-12.55s; $p<0.05$) reduced by 5% in the intervention group.

CONCLUSION: This study's findings indicated that a twelve-week resistance training programme effectively reduced metabolic parameters such as blood glucose levels, HbA1c, triglycerides, and total cholesterol in the experimental group, when compared to the control group. Additionally, it improved muscle strength and physical function in individuals with T2DM. Resistance training consistently yields significant improvements in functional tasks and enhances health-related quality of life. Integrating a structured nutrition education programme with resistance training can greatly improve the management of T2DM.

EFFECTS OF A 36-WEEK CIRCUIT AND BODYWEIGHT TRAINING PROGRAM ON BODY COMPOSITION IN OLDER ADULTS: A PRE- AND POST-TEST ANALYSIS

HO, C.

LOTUNG POH-AI HOSPITAL

INTRODUCTION: According to existing literature, exercise training has a significant impact on increasing muscle mass, reducing body fat, and managing body weight. This study is based on the 111-year Silver Fitness Club body composition data to explore the effects of 36-week circuit and bodyweight training on body weight, body fat, and skeletal muscle mass, and to evaluate the impact of different training phases on individual physical fitness.

METHODS: Study Design : This study is a pre- and post-test comparison. Participants underwent a 36-week exercise program, with body weight, body fat, and skeletal muscle mass data collected before, during, and after training for analysis.

Participants : Participants were recruited from the local Silver Fitness Club, age from 65 to 82, excluding those with severe cardiovascular diseases or musculoskeletal disorders.

Training Program: Weeks 1-18: Circuit training using six machines, performed three times per week, each session lasting 40-60 minutes, including chest press, leg press, and rowing machine exercises.

Weeks 19-36: Bodyweight training (TRX, kettlebell, resistance bands), performed three times per week, each session lasting 40-60 minutes, with gradually increasing intensity.

Data Collection: Body weight (kg): Measured using an electronic scale.

Body fat (%): Measured using bioelectrical impedance analysis (BIA).

Skeletal muscle mass (kg): Measured through BIA.

Data Analysis :

Paired sample t-tests were used to analyze pre- and post-training differences.

ANOVA was used to assess trends across different training phases.

RESULTS: Body Weight Changes: Average weight decreased by 0.39% (range: -2.3% to +1.1%), indicating that exercise training contributes to weight management.

Body Fat Changes: Average body fat percentage decreased by 4.52% (range: -13.0% to 0%), demonstrating the effectiveness of training in fat reduction.

Skeletal Muscle Mass Changes: Average skeletal muscle mass increased by 2.68% (range: 0% to 5.55%), confirming the positive impact of training on muscle growth.

CONCLUSION: The results of this study show that the 36-week circuit and bodyweight training significantly influenced weight management, fat reduction, and skeletal muscle growth. The bodyweight training phase, in particular, exhibited greater muscle growth, suggesting that such training effectively stimulates muscle development. Furthermore, the findings support the integration of circuit and bodyweight training as an effective strategy for improving physical fitness and overall health.

CONCLUSION: A well-structured exercise training program can effectively promote weight management, reduce body fat, and increase skeletal muscle mass. This study recommends incorporating both machine-based circuit training and bodyweight training in exercise prescriptions to achieve optimal training

WALKING FOOTBALL FOR PERSONS WITH DEMENTIA: TEAMING UP FOR HEALTH AND WELLBEING AMONG PLAYERS AND VOLUNTEER COACHES.

STØA, E., SCHÖKEL, F., BREIEVNE, G., BRATLAND-SANDA, S.
UNIVERSITY OF SOUTH-EASTERN NORWAY

INTRODUCTION: The public health issues of loneliness and mental health challenges can, according to the ABC-model, be met with volunteering in social, cultural and/or physical activities (Santini et al., 2018). Together with another public health issue, i.e., the decline in physical activity, health and wellbeing and need for health services in persons with dementia, this pilot study aimed to explore how walking football for persons with dementia can counteract both these public health issues.

METHODS: A total of four persons with mild to moderate dementia wore triaxial accelerometers for eight walking football sessions over a period of eight weeks, the same sessions were observed using structured and unstructured observations. Each player had one or two volunteer coaches closely following them and their moves on every session. Focus group interviews were conducted with 10 volunteer coaches. We framed the analyses in the Self-Determination Theory (Ryan & Deci, 2017) with special emphasis on the satisfaction of the basic psychological needs of autonomy, competence and relatedness.

RESULTS: The 60-minute walking football sessions were organized using sport specific training principles to promote motor learning, particularly balance and coordination, with progression of types and complexities of exercises. Each session was characterized by bodily movements, and with little or no sedentary time among the players. Observations suggested improved physical and social competence among the players, and improved competence among the volunteer coaches on how to interact with persons with dementia. Observations together with interviews of the volunteer coaches gave impressions of mutual enjoyment and social connectedness. The volunteer coaches reported an experience of volunteering in walking football for persons with dementia as very meaningful, social and enjoyable.

CONCLUSION: Walking football for persons with dementia is a promising activity that is suitable for improving health and wellbeing among both players and volunteer coaches. A satisfaction of especially the basic psychological needs of relatedness and competence was identified. For volunteer coaches with little or no knowledge about dementia, this can also serve as a way to increase understanding and knowledge about the illness, and thus reduce stigma and barriers for interacting with persons with dementia.

ACTIVE PREGNANCY - PROMOTING AN ACTIVE AND HEALTHY LIFESTYLE DURING PREGNANCY TO IMPACT MATERNAL HEALTH AND FITNESS. EXERCISE TRIAL PROTOCOL

SANTOS-ROCHA, R., SZUMILEWICZ, A.

1. SANTARÉM POLYTECHNIC UNIVERSITY & SPRINT SPORT PHYSICAL ACTIVITY AND HEALTH RESEARCH & INNOVATION CENTER, PORTUGAL; 2. GDANSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT, POLAND

INTRODUCTION: Maintaining light to moderate physical activity (PA) and a healthy lifestyle during pregnancy has several benefits for the health of the woman and the fetus. Physical fitness is considered a powerful marker of health since it is associated with a lower risk of cardiovascular events, cancer, and all-cause mortality in all ages. A few studies with pregnant women highlighted the potential impact of higher physical fitness levels on better maternal and fetal health.

It is pertinent to implement comprehensive prenatal exercise programs and to contribute to evidence-based knowledge about their impact on PA, fitness, functionality, and health parameters (weight gain, common pregnancy complaints and diseases, quality of life, pregnancy outcomes, new-born health, and postpartum recovery), regardless of maternal age, healthy lifestyle compliance, and context of intervention.

This communication will describe the exercise trial protocol regarding the primary objectives of the Active Pregnancy project (1), which aims to implement an exercise-based multi-center control trial and assess its effects on women's PA, fitness, and health parameters depending on the context of intervention (virtual vs presential); PA and healthy lifestyle compliance with guidelines; and maternal age (< or >35 years).

METHODS: The ACTIVE PREGNANCY exercise trial protocol follows the SPIRIT guidelines (2). The exercise program, supervised by qualified exercise professionals, was previously developed and tested (3) in collaboration with multidisciplinary researchers. Ethical approval was obtained. Pilots were conducted in 2023/2024. Functional field tests and questionnaires will be the main tools to collect baseline and post-intervention variables. We expect to reach more than 300 pregnant women by the end of the project.

RESULTS: The main expected results are the development and implementation of effective exercise programs and strategies aimed at improving maternal health and fitness parameters, updating evidence-based educational resources, raising individual awareness, and empowering women to participate in the management of their health and their babies' health; and boosting research and knowledge in this field.

CONCLUSION: Considering the increasing risk of non-communicable diseases resulting from a sedentary lifestyle and low levels of PA during pregnancy in many countries, conducting multidisciplinary and multifaceted experimental studies in this area is necessary. New data can support evidence-based recommendations and strategies to promote physical activity during pregnancy and enhance the health of the mothers and their children.

THE RELATION OF BODY MASS INDEX WITH PERIOSTIN AND RESPIRATORY PARAMETERS IN COLLEGIATE FOOTBALL ATHLETES

IMAI, T., KOICHI, W.

AICHI INSTITUTE OF TECHNOLOGY 2. UNIVERSITY OF TSUKUBA

INTRODUCTION: Athletes have the right physical characteristics for performance, with training appropriate to their athletic characteristics and position. Some competitive sports have heavyweight positions and is overweight athletes. Although overweight in athletes is different from obesity resulting from general inactivity, it has been reported to have health risks such as sleep apnea and cardiovascular disease. On the other hand, while it is known that many athletes have respiratory diseases, there are few studies on the effects of being overweight on respiratory parameters.

Recently, periostin, a matricellular protein, is a known biomarker for type 2 and has been reported to be inversely correlated with BMI in asthma. It has also been reported that respiratory function is low to obesity, but it is not clear whether the same trend is observed in overweight athletes.

Objective: To determine whether periostin and respiratory parameters differ by BMI category in college football athletes.

METHODS: A total of thirty-seven collegiate football athletes participated in this study (age 20.8 ± 1.9). All participants were non-smokers and were not taking medications. Participants were categorized into three groups based on body mass index (BMI): BMI < 25 (normal weight, NW, n=11), $25 \leq \text{BMI} < 29.9$ (overweight, OW, n=17), and BMI ≥ 30 (obesity, OB, n=9).

Participants' body weights were measured by health meters (UC411PBT-C, A&D, Japan). The respiratory function was used the HI-801 spirometry (Chest, Japan), and respiratory impedance was performed using the FOT using the Most Graph-01 (Chest M.I., Tokyo, Japan). The parameters used were resistance at 5 Hz (R5), resistance at 20 Hz (R20), reactance at 5 Hz (X5), and resonant frequency (Fres), where the reactance crossed zero and the elastic and inertial forces were equal in magnitude and opposite in direction. Blood samples were collected on the same day. The periostin levels were measured using an ELISA kit from Shino Test Co., Ltd. (Tokyo, Japan). Two samples were below the detection threshold and were excluded from further analysis. All data were expressed as mean $\pm$ SD.

RESULTS: The BMI of NW, OW, and OB were 23.1 ± 1.4 , 26.7 ± 1.3 and 33.1 ± 2.6 . BMI was significantly negatively correlated with periostin ($p < 0.05$) and X5 ($p < 0.05$), positively correlated with R5 ($p < 0.01$) and R5-R20 ($p < 0.01$). Periostin was significantly higher in the NW (37.6 ± 6.9 ng/ml) than in the OB (32.0 ± 4.6 ng/ml) but not in the OW (33.9 ± 3.3 ng/ml). R5 was significantly higher in the OB (3.0 ± 1.0 cmH₂O/L/s) than in the NW (1.8 ± 0.4 cmH₂O/L/s) but not in the OW (2.3 ± 0.6 cmH₂O/L/s). R5-R20 was higher in the OW and OB (0.0 ± 0.3 , and 0.3 ± 0.2 (cmH₂O/L/s)) than in the NW (-0.4 ± 0.4 cmH₂O/L/s). Fres was significantly higher in the OB (7.7 ± 2.6 Hz) than NW (5.1 ± 1.1 Hz). Respiratory function was not significant between groups.

CONCLUSION: BMI is associated with decreased periostin and increased respiratory impedance in collegiate football athletes.

CHANGES IN PLASMA AMINO ACID PROFILE FOLLOWED BY 3-MONTHS COGNITIVE TRAINING

KUMAGAI, K., KAGEYAMA, Y., ISAKA, T., NAKAGAICHI, M.
KYUSHU SANGYO UNIVERSITY

INTRODUCTION: Age-related cognitive decline, which triggers dementia, has become one of the major health problems. The number of dementia patients in Japan is estimated to reach 5.23 million by 2030, and if the number of patients with mild cognitive impairment is added, the number of dementia patients may exceed 11 million. To maintain the quality of life of the elderly and control medical costs, early detection of dementia, as well as primary prevention, will be important issues. AminolIndex®, which can assess the risk of various diseases based on plasma amino acid profiles from a single blood sample, is considered to be an effective test in terms of early detection. As for primary prevention of dementia, cognitive training, which improves cognitive functions such as thinking, attention and judgement, has been reported to be useful. Square stepping exercise (SSE) and CogEvo, are known as such trainings and have been reported to improve cognitive function. The aim of this study was to investigate changes in plasma amino acid profiles followed by a 3-months cognitive training comprising SSE and CogEvo.

METHODS: Sixteen community-dwelling elderly Japanese females (70.8±1.0 yrs) participated in cognitive training after providing written informed consent. The training took place twice a week for a total of 24 sessions over a period of 3 months. Each session consisted of CogEvo and SSE, which was implemented for about 15 and 45 minutes respectively. For CogEvo, five basic tasks were performed each time using touch panel monitor screens. For SSE, 5 to 12 step patterns were performed per day, starting at the beginner level and gradually increasing in difficulty throughout the 3 months. Before and after the 3-month training sessions, venous blood samples were collected from the participants and the plasma free amino acid (PFAA) levels were assessed. The risk of cognitive decline in AminolIndex® was calculated using the plasma free amino acid levels. Body composition and physical function (Functional Reach test and Timed Up & Go test) were also measured before and after training. Paired t-tests were applied for comparison between pre- and post-training measurements and a 5% threshold for significance was set.

RESULTS: Three months of training significantly improved cognitive function as assessed by CogEvo ($p < 0.01$). In contrast, body composition and physical function remained unchanged. In addition, there was a decreasing trend in the risk of cognitive decline as assessed by the AminolIndex® ($p < 0.1$), with a significant difference when low-risk individuals in AminolIndex® (5 subjects) before the training were excluded ($p < 0.05$).

CONCLUSION: Twice-weekly, 3-month cognitive training combining CogEvo and SSE may improve cognitive function in community-dwelling elderly females, and may reduce the risk of subjects at high risk of cognitive decline. On the other hand, to improve body composition and physical function, it may be necessary to perform additional activities.

EFFECTS OF MOLECULAR HYDROGEN SUPPLEMENTATION ON GLYCOLIPID METABOLIC DISEASES: A SYSTEMATIC REVIEW AND META-ANALYSIS

ZHANG, L., ZHENG, T., BAO, D.
BEIJING SPORT UNIVERSITY

INTRODUCTION: Glycolipid metabolic disease (GMD) is a complex chronic metabolic disease with a rapidly growing number of patients due to obesity and sedentary lifestyles, and it has become one of the major chronic diseases causing public and clinical problems worldwide. Studies indicate that molecular hydrogen (H₂), with antioxidant and anti-inflammatory properties, may be a promising strategy to alleviate GMD and decline cardiovascular risks. This study aimed to systematically review and meta-analyze the impact of H₂ supplementation on GMD.

METHODS: This study systematically evaluated the impact of H₂ intake on glycolipid metabolic diseases, following PRISMA guidelines and registered with PROSPERO (CRD42023476671).

RESULTS: Eleven publications (11 studies) consisting of 425 participants were included. The pooled effect sizes of H₂ on TC (SMD_{pooled} = -0.23, 95%CI -0.42 to 0.04, $p = 0.02$, $I^2 = 0\%$, $p = 0.81$) and TG (SMD_{pooled} = -0.40, 95% CI -0.64 to 0.15, $p = 0.001$, $I^2 = 0\%$, $p = 0.52$) were significant with low heterogeneity. The pooled effect sizes of H₂ on HDL (SMD_{pooled} = 0.05, 95% CI -0.18 to 0.28, $p = 0.67$, $I^2 = 32\%$, $p = 0.15$) and CRP (SMD_{pooled} = -0.10, 95% CI -0.41 to 0.21, $p = 0.54$, $I^2 = 0\%$, $p = 0.67$) were not significant and trivial without heterogeneity. Subgroup analysis revealed that the effects of H₂ on Glycolipid metabolic were impacted significantly by the intervention time of H₂ implementation, and intervention types (i.e., water or gas).

CONCLUSION: This review suggests hydrogen supplementation may improve total cholesterol (TC) and triglyceride (TG) levels in glycometabolic disorder (GMD) patients, with no effect on blood glucose, hormones, enzymes, or inflammation. The duration and method of hydrogen intake may influence its effects, requiring further study.

Hydrogens molecular mechanisms are complex, primarily involving anti-oxidative, anti-inflammatory, and cytoprotective properties. The study found a significant reduction in TC, but no significant change in LDL levels, possibly due to targeting modified LDL or measurement limitations. Hydrogen inhalation might enhance LDL therapeutic effects, needing more research. Hydrogen may also improve HDL function without changing its levels, suggesting effects on composition and enzymatic activities.

Longer hydrogen treatment durations (over six weeks) may yield better glucose-lowering results, aligning with previous studies, but more data is needed. The liver, crucial for sugar and lipid metabolism, accumulates hydrogen well, especially after ingestion, significant for conditions like nonalcoholic fatty liver disease (NAFLD). Hydrogen intervention in NAFLD reduces liver fat and inflammation, potentially by alleviating oxidative stress.

Hydrogen supplementation significantly reduces certain cardiovascular risk factors (TC, TG) in GMD patients but does not affect body weight or other factors. More rigorous studies are needed to confirm these findings and optimize hydrogen's therapeutic potential.

THE EFFECT OF 12 WEEKS OF CONCURRENT TRAINING ON BLOOD SAMPLES AND FUNCTIONAL FITNESS PERFORMANCE IN SUB-HEALTHY OLDER ADULTS

LEE, C., CHANG, N.J., LU, Y.Y.

NATIONAL SUN YAT-SEN UNIVERSITY

INTRODUCTION: Evidence suggests moderate-intensity aerobic exercise training improves CVD risk factors, and resistance training improves skeletal muscular fitness. However, whether health benefits can be achieved through other exercise modalities, such as concurrent training, is unclear. This study explores which modality of 12 weeks of aerobic and resistance concurrent training has the best health benefits for older adults.

METHODS: Forty-four sub-healthy older adults (age 65 years) were randomized to perform resistance before high-intensity aerobic interval training (RE+AE), AE before RE, or a walking group. Subjects show at least one symptom of metabolic syndrome, such as hyperlipidemia, hyperglycemia, hypertension, or others. The training program of AE consisted of jogging in place, burpees, rope skipping, mountain climbers, air squats, jumping lunges, push-ups, and squat jumps. The program of RE consisted of a loading barbell or two dumbbells with a back squat, single-step squat, bench press, standing rowing, deadlift, and shoulder press. Body composition, functional fitness tests, and blood measurements were taken before and after 12 weeks of training.

RESULTS: There were significant improvements from pre-training to post-training in the 8-foot up-and-go test (AE+RE: 20%; RE+AE: 19%; Walk: 15%), arm curl test (16%, 16%, 10%), and 6-minute walk test (19%, 20%, 7%) ($p < .05$). Comparing the changes between the experimental groups, body fat percentage were significantly lower in the AE+RE (-8.8%) and RE+AE (-5.7%) than Walk, muscle mass was significantly higher in the AE+RE (+5.3%) and RE+AE (5.6%) than Walk ($p < .05$). High-density lipoprotein (HDL) increased dramatically in three groups (AE+RE: 8%; RE+AE: 7%; Walk: 9%) when compared with pre-training ($p < .05$), but only the blood glucose (-5.6%), HbA1c (-1.7%), and total cholesterol (-8.8%) levels were significantly decreased after training in the AE+RE group.

CONCLUSION: Twelve weeks of aerobic exercise followed by resistance training, resistance training followed by aerobic exercise, or walking exercises lead to specific improvements in functional fitness performance for older adults. However, choosing aerobic exercise before resistance training in concurrent training yields more significant benefits for body fat, muscle mass, functional physical performance, and blood metabolism improvement.

SLEEP DURATION DOES NOT AFFECT PULSE WAVE VELOCITY IN NOVICE-RESISTANCE-TRAINED YOUNG ADULTS: A PILOT STUDY

ALIAS, T., SEUNATH, D., RIDDELL, S., CANOY, L., ANDERSEN, J.C., DE SOUZA, E.O., TAMULEVICIUS, N.

THE UNIVERSITY OF TAMPA

INTRODUCTION: Short sleep duration (≤ 6 hours) is a risk factor for cardiovascular disease (CVD) and mortality (1). Arterial stiffness (AS) is an endothelial function marker considered to be a risk factor of CVD (2). It is unclear if short sleep duration affects AS in young, physically active individuals. The purpose of this pilot study was to compare sleep duration and AS in novice-resistance-trained (RT) young adults.

METHODS: Thirteen participants (3 men, 10 females; 19.5 ± 1.1 y.o.; height 167.9 ± 8.5 cm; weight 65 ± 15.6 kg) were included in the study. Sleep duration was monitored using Actigraph (model wGT3X-BT) for 24 hours over 7 days. AS was assessed using the SphygmoCor XCEL device, that measured the pulse wave velocity (PWV) and augmentation index (Alx). Participants who slept less than six hours per day were defined as short sleepers, and those who slept more than seven hours per day were defined as long sleepers. An independent samples t-test was performed to compare PWV and Alx among both groups. All data was analyzed using MS Excel and Jamovi (version 2.3.28).

RESULTS: No significant difference was found in PWV between short sleepers (5.22 ± 0.76 m/s, CI [4.68, 6.44]) and long sleepers (5.2 ± 0.76 m/s, CI: [4.59, 5.86]); $p = 0.45$). Also, there was no significant difference in Alx between short sleepers (6.20 ± 3.70 , CI: [1.60, 10.80]) and long sleepers (5.88 ± 4.58 , CI: [2.05, 9.70]); $p = 0.9$).

CONCLUSION: Sleep duration does not affect AS among novice RT young adults. Contrarily, previous research in older population has shown that sleeping less than 6 hours per night was associated with increased AS (1,2). However, since our population was young adults and the sleep data was collected within seven consecutive days, the quantity of sleep may not influence AS measures of PWV and Alx. Further investigation should examine larger sample sizes of young, physically active adults.

AGE-RELATED DIFFERENCES IN BONE STRAIN MAGNITUDE AND RATE UNDER MECHANICAL LOADING IN RATS

OGA, R., FURUMI, T.1, CHEN, Y.C.1, TAMAKI, H.2

1 GRADUATE SCHOOL OF PHYSICAL EDUCATION, NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA, 2 DEPARTMENT OF SPORTS AND LIFE SCIENCE, NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Mechanical stress regulates bone metabolism, with both strain magnitude and strain rate serving as key modulators of mechanotransduction. Age-related changes in bone microstructure and mineralization can alter how bone responds to mechanical loading, potentially modifying strain magnitude and strain rate. Thus, elucidating how aging influences in vivo bone strain magnitude and strain rate under mechanical loading is essential for understanding age-related changes in bone adaptation. We measured in vivo bone strain magnitude and strain rate under mechanical loading and investigated the effects of aging on these parameters.

METHODS: Male Fischer 344 rats were assigned to young or middle-aged groups. In vivo bone strain was measured by attaching thin-film strain gauges to the medial surface of the tibia under anesthesia. Loads were applied to the bone using a mechanical testing device or a vertical vibration device at various magnitudes (2.5–30N, 6–590 $\mu\epsilon$) and rates. Time-series data of load (N) and strain ($\mu\epsilon$) were analyzed to determine peak load magnitude (N), load rate (N/s), peak strain magnitude ($\mu\epsilon$), and strain rate ($\mu\epsilon$ /s).

RESULTS: Both young and middle-aged rats exhibited a positive correlation between load and bone strain magnitude. However, middle-aged rats showed reduced bone strain magnitude responsiveness to load compared to young rats. Bone strain magnitude and strain rate also showed a positive correlation in both groups. Middle-aged rats showed a greater strain rate per unit of strain magnitude compared to young rats.

CONCLUSION: These data demonstrated age-related differences in bone strain magnitude and strain rate. Age-related structural changes, coupled with promoted bone mineralization, may have influenced the mechanical properties of bone, resulting in alterations in strain magnitude and strain rate. Given the critical role of strain magnitude and strain rate in bone formation, consideration of age-related changes in these parameters may be essential for optimizing exercise interventions aimed at maintaining bone health across different age groups.

COMPLIANCE WITH THE 24-H MOVEMENT GUIDELINES AND THE RELATIONSHIP WITH BODY MASS INDEX IN JAPANESE TODDLERS

YANAOKA, T., TAKEDA, S.

HIROSHIMA UNIVERSITY

INTRODUCTION: Although recent 24-h movement guidelines for toddlers established recommendations for physical activity (PA), screen time (ST) and sleep [1,2], little evidence is available regarding the compliance with meeting the guidelines and their associations with body mass index (BMI) in Japanese toddlers. Thus, we aimed to investigate compliance with the 24-h movement guidelines for toddlers and associations between compliance and BMI in Japanese toddlers.

METHODS: Five pre-schools were selected. All toddlers (42 boys and 42 girls) aged 3–4 years attending these pre-schools were participated in this study. Pre-school teachers reported participants' PA, ST and sleep at pre-schools. Parents reported participants' PA, ST and sleep when participants were not at pre-schools. Parents also reported their own PA, ST and sleep and the height and weight of themselves and participants. Participants were classified as meeting the guidelines if they averaged ≥ 180 min/day of PA, which consisted of ≥ 60 min of moderate-to-vigorous intensity; ≤ 60 min/day of ST; and 10–13 h/day of sleep. The compliance with meeting the 24-h movement guidelines was calculated for each behaviour separately and in combinations. Unpaired t-test was performed to test differences in BMI z-scores between participants complying with (i) none or any individual guideline, (ii) any combination of meeting two guidelines, and (iii) those who met all three guidelines. The correlation coefficient between the BMI z-score of the parents and the participants was calculated using the Pearson's product-moment correlation test. The chi-square test was performed to compare the frequency of the PA guideline compliance between parents and participants in weekend days.
